Sixty-three consecutive patients aged 2 months to 27 years with simple ventricular septal defect (VSD) or the syndrome of Fallot's tetralogy were prospectively investigated with 2-dimensional (2-D) echocardiography to assess the accuracy of the method in defining the anatomic site of the VSD. Twenty-two patients were referred for surgery without invasive investigation. The anatomy was confirmed in all patients at operation. Two-dimensional echocardiography was reliable in identifying subaortic, inlet, small, moderate, and large subtricuspid, large subpulmonary, and most large central and apical muscular VSDs. Mistakes were made initially in distinguishing doubly committed subarterial defects from subaortic VSD because of difficulty in imaging the right ventricular outflow in short axis at the aortic root level, small subpulmonary defects obscured by prolapsed aortic cusp tissue, and small apical or outlet muscular VSDs because of difficulty in distinguishing true "dropout" from trabeculations. Other VSDs particularly muscular, were sometimes overlooked after another large VSD had been identified. Thus, identification of the anatomic site of VSDs by 2-D echocardiography is a reliable method that can replace invasive investigation in assessing the uncomplicated VSD before operation. Ventricular septal defects are classified as muscular or subvalvular and subdivided according to the valve to which the defect is related.

Two-dimensional (2-D) echocardiography is a useful noninvasive method of recognizing ventricular septal defect (VSD).[1–4] Because the site of a VSD is as important as its size in determining the natural history of the patient,[5] both must be known for proper management. The clinical and hemodynamic effects on the cardiovascular system are a good indication of the size of the defect, depending in part on the influence of associated lesions. However, the anatomic site of the VSD cannot be determined by clinical examination but can be identified by angiography[6,7] and now by 2-D echocardiography.[1–4] In the hope of replacing invasive investigation and defining possible sources of error of interpretation, a prospective study was undertaken to examine the accuracy of the anatomic information provided by 2-D echocardiography in patients with VSD who had subsequent surgical treatment.

Nomenclature of congenital heart disease, particularly VSD, has received much attention. The chosen taxonomy depends in part on the basic discipline of the investigator. Surgeons, anatomists, embryologists, pathologists, radiologists, and cardiologists see the same thing from different viewpoints.

An ideal classification must be simple, easily communicated, involve what is visible and not developmental postulants, and be useful for all disciplines. Thus is introduced another classification of VSD, intentionally pragmatic, simple, precise, and comprehensive. It is also applicable, without adaptation, to more complex anomalies in which VSD is one part of the anatomic disturbance.

Methods

Between November 1980 and February 1982, 63 consecutive patients aged 2 months to 27 years with VSD were prospectively examined by 2-D echocardiography in the National Heart Hospital. The age range of these patients was as follows: <1 year, 11 patients; 1 to 5 years, 14; 6 to 10 years, 12; 11 to 15 years, 10; 16 to 20 years, 9; >20 years, 7 patients. Criteria for inclusion in this study were (1) atrioventricular (AV) concordance, ventriculoarterial concordance, and situs solitus (patients with AV defects [common AV canal and intermediate forms], double outflow right or left ventricle, and any

ticulous description at open-heart surgery; (3) technically satisfactory 2-D echocardiography with full visualization of the ventricular septum was mandatory and observed by each investigator. The site of the VSD was defined and recorded before operation.

Thirty-eight patients had either single or multiple VSD; 25 had Fallot's tetralogy with various degrees of obstruction of the right ventricular outflow tract. The VSD was complicated by Ebstein's anomaly in 1, aortic regurgitation in 6, coarctation of the aorta in 2, interrupted aortic arch with parachute mitral valve in 1, persistent ductus arteriosus in 2, and straddling tricuspid valve in 3.

Open-heart surgery was performed in all patients, 22 of whom had no preoperative invasive investigation.

Two-dimensional echocardiograms were taken initially with a phased-array electronically focused 3.5-MHz probe (Toshiba) and subsequently, in most, with a mechanical sector scanner inline 3-MHz probe (Advanced Technology Laboratories). Patients were studied in the supine or left lateral 30° decubitus position. The transducer was so placed as to show the ventricular septum in different planes using selected tomographic views of the heart, obtaining long- and short-axis parasternal views, apical 4-chamber views, and subcostal short-axis and 4-chamber views[8] (Fig. 1).

Two-dimensional echocardiograms were interpreted before angiography and surgery. All were reviewed after receiving detailed anatomic information from the surgeon.

Nomenclature of VSD

Ventricular septal defects occurred in 1 of 2 parts of the ventricular septum, either subvalvular or muscular. Subvalvular VSDs were directly related to AV or semilunar valves, or both, without any interposed muscle tissue between the hole and the valve cusps which formed a border or limiting boundary. Muscular defects were those bordered by muscle and not immediately related to AV or semilunar valves, or both.

Ventricular septal defects in the subvalvular group were subdivided according to the contiguous valve or valves (Fig. 2), as follows:

Inlet: This VSD lies beneath the septal leaflets of both AV valves and extends posteriorly beneath the tricuspid leaflet close to the crux or posterior ridge. Both AV valves are attached at a common level to the base of the atrial septum (central fibrous body). Associated straddling or overriding of the AV valves, or both, was frequent. This defect has been referred to elsewhere as AV canal type,[9] VSD in the posterior septum,[10] and perimembranous inlet.[4]

Subtricuspid: This common VSD is under the septal cusp of the tricuspid valve which frequently has chordal attachments to its borders and an abnormality or acquired deformity of the contiguous cusp. This defect does not extend as far posteriorly as inlet VSD, and the mitral valve is separated from the tricuspid valve by the AV septum so that the AV valves are not at the same level as in inlet defects. Subtricuspid VSDs have previously been termed inlet muscular,[11] VSD posterior to the medial papillary muscle,[12] infracristal, and perimembranous inlet defects.[4]

Subaortic: This type of VSD is usually large and immediately beneath the aortic valve cusps which form the cephalad border and which can be seen, particularly the right and noncoronary cusps, pouting through the defect when viewed from the right ventricle. The defect may extend posteriorly to the tricuspid anulus, may be associated with various degrees of malalignment of the ventricular septum, and is separated from the pulmonary valve and right outflow by infundibular septum. It is the VSD in classic Fallot's tetralogy. Previously, this subaortic VSD[5] was termed VSD anterior to the medial papillary muscle,[12] perimembranous (subaortic) outlet,[11] infracristal, or high.

Subpulmonary: This type of VSD is located in the outflow tract of the right ventricle. The superior border is formed by the pulmonary cusps and pulmonary anulus. It is separated from the aortic valve by a remnant

TABLE I Echocardiographic Identification of VSD and Surgical Correlation in 63 Patients

Type of VSD	Patients (n)	Surgery and Previous Angiography		2-D Echocardiography	
		+	0	Visualized	Position Identified
Inlet	8	4	4	8	8
Subtricuspid	7	5	2	5	4
Subaortic	30	16	14	30	30
Subpulmonary	2	2	. . .	1	1

Outlet	3	3	. . .	. . .	. . .
Total	63	41	22	55	53

2-D = 2-dimensional; VSD = ventricular septal defect.

part of the deficient infundibular ventricular septum. These defects are often small and associated with prolapse of the right coronary cusp in older patients, which is unusual in children <4 years of age. Large subpulmonary VSDs were uncommon in this group. Subpulmonary defects, small and large, have been called supracristal,[12–15] anterior infundibular,[16] infundibular septal, high, and perimembranous outlet/subpulmonary.[10]

Doubly committed subarterial: This type of VSD is also located in the outflow tract of the right ventricle immediately below the pulmonary valve but also extending beneath the aortic valve. There is fibrous continuity of the aortic and pulmonary anuli, and the infundibular septum is completely or partly absent. This defect may be isolated or coexist with pulmonary valvular stenosis presenting clinically as Fallot's tetralogy. Prolapse of both right and noncoronary cusps sometimes occurs. The doubly committed subarterial VSD lies either mainly beneath the aortic valve extending to beneath the pulmonary valve "ring," as in atypical Fallot's tetralogy, or more beneath the pulmonary "ring" and extending posteriorly to below part of the aortic valve. The latter type is often associated with pulmonary vascular disease and sometimes coarctation of the aorta. Hence, there is a need to understand the importance of these apparently minor differences in position as clearly there is a difference in blood flow during fetal life with different consequences in postnatal life. These defects have been named supracristal,[12,13,15] subpulmonary,[17] and complete infundibular septal,[16] and are separately distinguished from muscular and perimembranous as doubly committed subarterial defects.[10]

Muscular defects also were subdivided according to their position in the muscular ventricular septum (Fig. 2):

Apical: The VSD is situated near the apex of the heart caudal to the trabecular septomarginalis. Defects are single or multiple; when large, they resemble lattice work. Apical defects have been described as low[18] and, when multiple, as Swiss cheese.[16]

Central: This type of VSD occurs in the midportion apex and the plane of the AV valves. These defects are single or associated with subvalvular defects, small or large. This defect has been referred to as low, infracristal, and trabecular muscular VSD.[11]

Outlet: Outlet muscular VSD is found in the outflow tract of the right ventricle above or in a limb of the trabecular septomarginalis. The superior border of this defect extends up to or is located within the infundibular septum. This VSD is separated from the pulmonary valve by muscle of the infundibular ventricular septum. Such defects have been called high, anterior muscular,[16] and supracristal.[12,15]

Defects in the "posterior" [10] part of the septum were not recognized in this series.

Results

Ventricular septal defect was clearly identified by 2-D echocardiography in 55 patients (88%) (Table I). In 8 in whom it was not "seen" by 2-D echocardiography it was subsequently found to be subtricuspid in 2, small muscular outlet in 3, muscular apical in 1, subpulmonary in 1, and shallow, doubly committed subarterial in 1 in whom cusp tissue almost closed it. The position of the VSD was wrongly diagnosed in 2 patients, in 1 with a subtricuspid defect where it was thought to be subaortic because of false "dropout." In the other patient with clinical signs of Fallot's tetralogy, the VSD was defined as subaortic when it was doubly committed subarterial. This error occurred early in our experience and was not made in the last 30 patients.

The diameter of the VSD detected by 2-D echocardiography, as measured at surgery, ranged from 4 to 18 mm and that of the undetected VSD 2 to 6 mm. Echocardiography was reliable in detecting large VSDs.

Subvalvular Defects

Inlet: Eight patients aged 5 months to 8 years had this type of VSD; 3 of the 8 had a straddling tricuspid valve. All had surgical closure, without previous catheterization in 4, and clinical features suggested a large defect measuring 12 to 18 mm at operation.

Two-dimensional echocardiography: The defect was correctly sited in all and easily seen when the ventricular

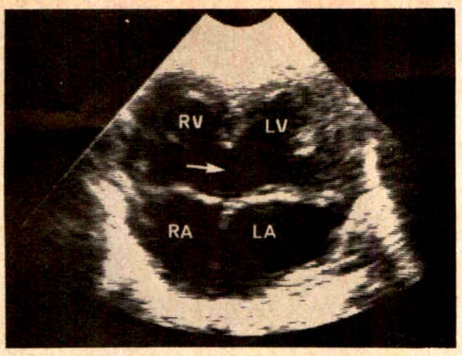

FIGURE 3. Apical 4-chamber view in an 8-year-old patient with inlet VSD. The dropout (**arrow**) appears beneath both septal leaflets. The AV valves are attached at the same level to the base of the interatrial septum. The atrioventricular septum is deficient. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

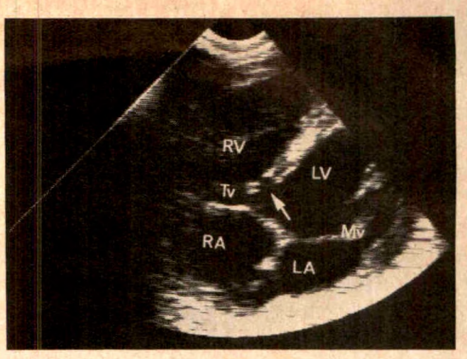

FIGURE 4. Apical 4-chamber view in an 18-month-old patient with subtricuspid defect. The VSD (**arrow**) lies beneath the septal cusp of the tricuspid valve. Both AV valves are attached at different levels of the interventricular septum, separated by the atrioventricular septum. Note also marked malalignment of the ventricular and atrial septa. LA = left atrium; LV = left ventricle; Mv = mitral valve; RA = right atrium; RV = right ventricle; Tv = tricuspid valve.

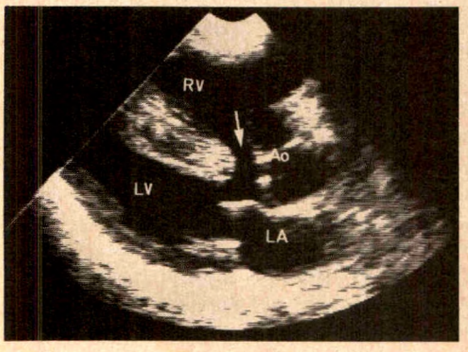

FIGURE 5. Parasternal long-axis view in a 16-year-old patient with Fallot's tetralogy and aortic regurgitation. The **arrow** shows the subaortic VSD between the aortic cusps and the crest of the malaligned interventricular septum. The aortic valve is thickened and there is no coaptation of the aortic cusps in diastole. Ao = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle.

position. The VSD appeared as an obvious large lack of ventricular septal tissue beneath both septal leaflets of the AV valves which were attached at the same level to the central fibrous body at the base of the atrial septum (Fig. 3). From apical and subcostal views, the tensor apparatus of the AV valves was carefully studied; abnormal insertion of the tricuspid valve into the left side of the ventricular septum was seen in 2 of the 3 patients in whom a straddling tricuspid valve was found at operation. In the parasternal long-axis view of the left ventricle the ventricular septum appeared to be intact in 6 of 8 patients with inlet VSD. In the other 2 with the largest defects, "dropout" was seen 0.5 cm beneath the aortic valve and subaortic extension was found at surgery. One patient had an additional large apical muscular VSD which was missed on 2-D echocardiography and at operation. It was confirmed at reoperation after catheterization.

To exclude a true common AV canal the atrial septum and the morphology of the AV valves were specifically studied.

Subtricuspid: This type of VSD was present in 7 patients aged 5 months to 25 years; coarctation of the aorta coexisted in 2 and Ebstein's anomaly in 1. Surgical closure of the VSD was performed without previous catheterization in 2. The size of the VSD at operation was 10 to 15 mm.

Two-dimensional echocardiography: This VSD was seen in 5 of 7 patients. In the 2 patients in whom a subtricuspid defect was overlooked, there was another large central muscular VSD. The position of the VSD was correctly identified in 4 of the 5 patients in whom the VSD was seen; in 1 the defect was erroneously considered to be subaortic. The VSD was best seen in apical and subcostal 4-chamber views in which the VSD appeared just beneath the septal cusp of the tricupid valve; the hole appeared to be sealed during diastole and open in systole (Fig. 4). The septal attachments of the AV valves were obviously separated by the line of AV septum. In the parasternal long-axis view of the left ventricle the VSD sometimes could be seen as "dropout" beneath the aortic valve in the subaortic area but separated from the anterior wall of the aorta by a bar of muscle <1 cm beneath the aortic valve. This part o subaortic septum was not seen in the 1 patient in whon the VSD was wrongly identified as being subaortic.

Subaortic: This type of VSD was present in 30 pa tients aged 6 months to 27 years, 20 of whom had Fal lot's tetralogy. The defect was complicated by paten ductus arteriosus in 2 and an interrupted aortic arc with parachute mitral valve in 1. Associated aorti regurgitation was found in 2, aged 16 and 27 years, wit Fallot's tetralogy. The position of the VSD was con firmed at surgery in all. Fourteen of the 30 patients wer referred for surgery without previous cardiac cathe terization. The size of the VSD ranged between 14 an 18 mm.

Two-dimensional echocardiography: The VSD wa always correctly identified. It was obvious in th parasternal long-axis view of the left ventricle as a lon discontinuity (hole) between the anterior wall of th aorta and the right aortic cusp and the crest of th ventricular septum (Fig. 5). No septal muscle or tissu was present between the VSD and the aortic cusps, an

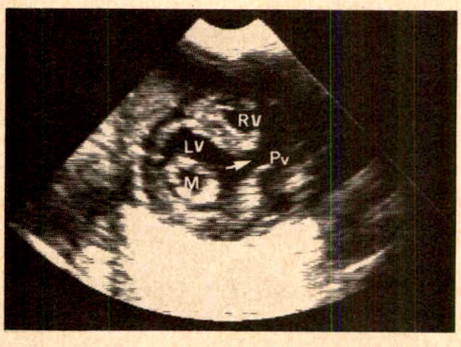
here was malalignment of the ventricular septum which n diastole was directed to the point of aortic valve closure. In the short-axis view of the aorta, the defect was seen beneath the right coronary cusp and that part of he noncoronary cusp extending usually to the tricuspid ring (Fig. 6). It was separated from the pulmonary valve by the solid muscle formed by the infundibular septum which in patients with Fallot's tetralogy was thickened rom hypertrophy with dense endocardial echoes. In the 2 patients with Fallot's tetralogy and aortic regurgitation the right coronary cusp was large, thickened, and prolapsed into the defect. In 1 of them there was fluttering of the crest of the ventricular septum from the egurgitant jet, and the aortic cusps did not coapt in liastole (Fig. 5).

Subpulmonary: Two patients aged 2 and 12 years had subpulmonary defects proved by surgery. The defect was small (8 mm) in 1 with aortic regurgitation from prolapse of the right coronary cusp into the defect. In he other, the VSD was 12 mm in diameter.

Two-dimensional echocardiography: The position f the VSD was correctly identified in 1 of the 2 patients. n a 12-year-old boy with aortic regurgitation in whom he VSD was not seen, cusp tissue was present in the mall defect and was visible on angiography, and a pansystolic murmur suggested its presence. In this patient t had been difficult to assess the right ventricular outlow tract from the subcostal position, and thus the lefect was not seen. The subpulmonary VSD in the patient in whom it was correctly sited appeared as dropout" under the pulmonary valve without interposed muscle when the right ventricular outflow tract vas scanned from the subcostal position (Fig. 7).

Doubly committed subarterial: This defect was present in 8 patients aged 4 months to 27 years. Five atients aged 14 to 27 years had the clinical features of allot's tetralogy, with associated aortic regurgitation rom prolapse of the right coronary cusp in 3. All had peration, 2 without previous cardiac catheterization. he size of the defect was 12 to 18 mm.

Two-dimensional echocardiography: Seven of 8 oubly committed subarterial defects were identified y 2-D echocardiography. In 1 with Fallot's tetralogy,



IGURE 7. Subcostal scanning of the right ventricular outflow tract in 2-year-old patient with subpulmonary VSD. The **arrow** shows the efect. There is no septal muscle between the hole and the pulmonary alve. LV = left ventricle; MV = mitral valve; PV = pulmonary valve; V = right ventricle.

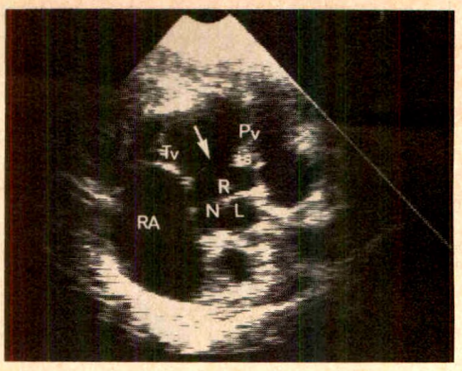


FIGURE 6. Parasternal short-axis view of the aorta in a 12-year-old patient with isolated subaortic VSD. The defect (**arrow**) lies beneath the right coronary cusp extending to the tricuspid ring. The infundibular septum separates the VSD from the pulmonary valve (Pv). IS = infundibular septum; L = left coronary cusp; N = noncoronary cusp; R = right coronary cusp; RA = right atrium; Tv = tricuspid valve.

the VSD was wrongly thought to be confined to the subaortic area as in classic tetralogy of Fallot. In the parasternal long-axis view of the left ventricle the defect appeared to be only subaortic with the superior edge formed by the aortic cusps. In the short-axis view at aortic root level the VSD was beneath the right coronary cusp and that part of the left coronary cusp extending up below the pulmonary valve (Fig. 8). No infundibular septum was detected and the defect was clearly separated from the tricuspid valve ring.

Muscular Defects

Apical: A large VSD at the apex occurred in 2 patients aged 2 months and 4 years. All had cardiac catheterization and angiography before operation, with the defect measuring 12 to 13 mm.

Two-dimensional echocardiography: Apical defects were identified in 1 of the 2 patients. One with a large single apical VSD had large areas of "dropout" at the

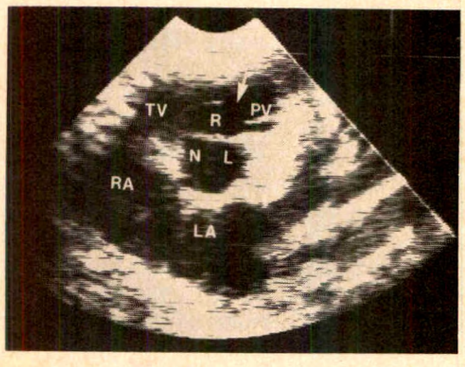

FIGURE 8. Parasternal short-axis view of the aorta in a 27-year-old patient with Fallot's tetralogy and doubly committed subarterial VSD. The defect (**arrow**) lies beneath the right coronary cusp extending up below the pulmonary valve. The infundibular septum is absent. The VSD does not reach the tricuspid ring. L = left coronary cusp; LA = left atrium; N = noncoronary cusp; PV = pulmonary valve; R = right coronary cusp; RA = right atrium; Tv = tricuspid valve.

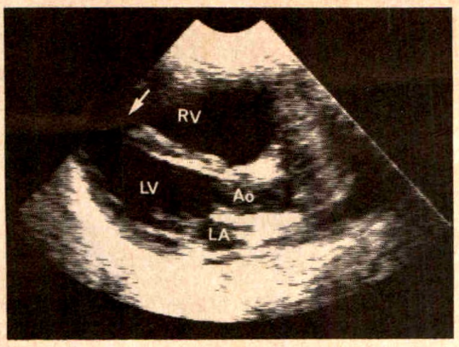

FIGURE 9. Parasternal long-axis view of the left ventricle in a 4-year-old patient with an apical muscular VSD. The dropout (**arrow**) appears near the junction of the interventricular septum with the free wall of the left ventricle. Ao = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle.

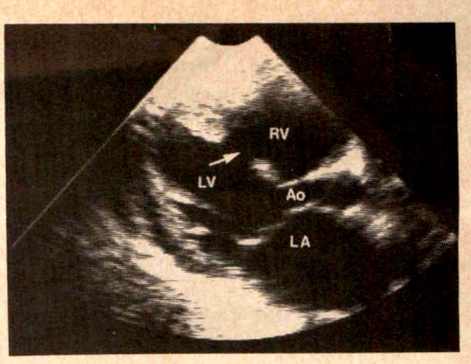

FIGURE 10. Parasternal long-axis view of the left ventricle in a 4-year-old patient with a central muscular VSD. The **arrow** shows the position of the defect which lies almost at the same distance between the apex and the aortic root. No valves are related to the defect. Ao = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle.

junction of the ventricular septum with the free wall of the left ventricle in 4-chamber and long-axis views of the left ventricle (Fig. 9). Scanning the left ventricle in short axis at the level of the papillary muscles, the ventricular septum appeared to be intact. Nevertheless, from this position and by tilting the transducer laterally to profile the apex, a defect was easily seen. The other patient with multiple small apical defects (Swiss cheese septum), no VSD was seen in any projection, but small defects between the trabeculae were found at operation.

Central: This muscular VSD occurred in 3 patients aged 2 to 4 years. All were catheterized before surgery. The size of the defects was 10 to 15 mm. In 2 patients there was an additional subtricuspid defect of 7 and 8 mm.

Two-dimensional echocardiography: The central muscular VSD was identified in all, but the associated subtricuspid defect in 2 was not seen, as just described. In parasternal long-axis view of the left ventricle the defect appeared as a lack of fusion of the ventricular septum, its center almost at the same distance from the apex and the aortic root (Fig. 10). In both apical and subcostal 4-chamber views the hole appeared equidistant from the apex, and the plane of the AV valves was adjacent to the trabecular septum marginalis.

Outlet: Three patients aged 14 to 19 years had a single outlet muscular defect 10 to 12 mm in diameter. All were catheterized before surgical closure.

Two-dimensional echocardiography: The VSD was not correctly recognized by 2-D echocardiography in any. The patients were well-built adolescents in whom it was difficult to profile the ventricular septum from the subcostal position, and no "dropout" in the ventricular septum was seen from any view scanned from precordial and apical areas. In 2 of the 3 patients the echocardiogram was repeated after operation in order to see the patch; this appeared only when imaging the long axis of the left ventricle and scanning anteriorly with 30° clockwise rotation of the transducer to see the right ventricular outflow tract (Fig. 11). The patch was not seen beneath the pulmonary valve in standard short-axis views or from the base of the heart.

Discussion

The anatomy of the ventricular septum has been precisely described, but confusion exists on the meaning and limits of various terms particularly when definitions involving embryologic postulants are used. Such commonly used terms as crista and infundibular septum mean different things to different workers.[19] Therefore, it is not surprising that the nomenclature of VSDs has been debated, confused, defined didactically, and redefined and has not resulted in a satisfactory simple classification acceptable to all the different disciplines involved in the management of patients or the heart with this common anomaly. Before VSD can be discussed, a useful terminology which can be communicated with ease and clarity is required. The now popular term *perimembranous*, although theoretically accurate and meaningful to some, includes several types of VSD[11] with very different natural histories, making inclusion under 1 heading unattractive to clinicians. In living patients, the exact site and limits of the membranous portion of the ventricular septum between the inlet and trabecular portion of the ventricular septum are diffi-

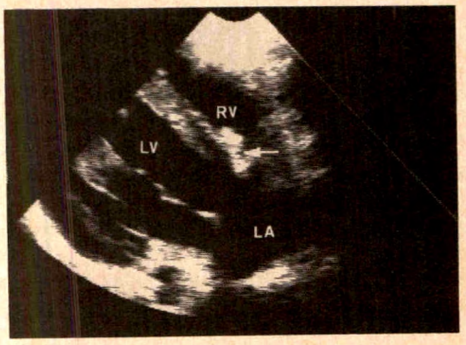

FIGURE 11. Postoperative echocardiogram in a 14-year-old patient who had an outlet muscular VSD. Parasternal long-axis view of the left ventricle with 30° clockwise rotation and scanning anteriorly to profile the right ventricular outflow tract. The **arrow** shows the position of the patch. The pulmonary valve does not appear in this plane. LA = left atrium; LV = left ventricle; RV = right ventricle.

cult to define because both appear trabeculated on echocardiography. Thus, imagination may be needed to define what surrounds something that may not be seen, particularly in hearts with more complex malformations. Furthermore, to distinguish among the various types of perimembranous VSDs, which is necessary, further wordy subdivision is needed. Therefore, it is preferable to describe holes in the ventricular septum in relation to structures, constantly present and universally recognized, that is, the aortic, pulmonary, and AV valves which can be sited without difficulty on angiography, 2-D echocardiography, anatomic inspection, and open-heart surgery. It is simple to name the VSD in relation to the valve directly beneath which it lies. When the VSD is separated from the valves by a bar of tissue, it lies in a part of the muscular septum that is divisible into regions in which defects may occur at the apex, center, or outflow. When the VSD is not confined to 1 area, a simple term *extending* can be added to describe it.

This classification is easy to use and readily applicable in more complex lesions associated with VSD, such as corrected transposition, double outflow, corrected malposition, and transposition of the great arteries.

In the current study, 2-D echocardiography was completely reliable in the diagnosis of subaortic and inlet VSD. Initially, occasional mistakes were made in distinguishing doubly committed subarterial VSD from subaortic VSD. Errors decreased after special care was taken in observing the short-axis view of the right ventricular outflow tract at the aortic root level to see the extent of the VS relation to the aortic cusps.[20] Other small subpulmonary and outlet muscular VSDs were also difficult to recognize in adolescents and adults. This part of the ventricular septum is well profiled from the subcostal position in infants and small children, but the view has limited application in older, larger patients. No difficulty was found in identifying these defects in infants and young children, unless there was associated prolapse of the right coronary cusp into the defect, and then the "dropout" of the VSD could be masked by the prolapsing cusp tissue into the defect.

The most significant errors were made in recognizing a second apical or central muscular VSD when 1 large VSD had already been found elsewhere. We suspect this might have been related to careless observation and complacency in finding 1 adequate explanation for the physical signs. This error is serious as the improperly briefed surgeon may overlook another muscular defect having already closed 1 in another part of the ventricular septum. Now, the muscular septum is more carefully scrutinized even when 1 VSD has been clearly located elsewhere. Recognizing multiple muscular (apical) small VSD was difficult because of the problem of distinguishing true holes from intertrabecular spaces.

This series by choice is concerned with moderate and large VSD in which it was possible to obtain surgical confirmation. However, the technique is equally applicable to small VSDs, particularly in the subtricuspid area in which they can be seen frequently surrounded by bright echoes due to fibrosis or attachment of tricuspid tissue, or both. Therefore, serial 2-D echocardiography is useful in identifying and following up those VSDs that will or are spontaneously closing. We now believe that 2-D echocardiography provides a reliable method for confirming the diagnosis and anatomic site of a VSD before surgery.

During the period of this study, many presurgical patients were investigated echocardiographically and sent for operation without previous catheterization. The wrong diagnosis of VSD was not made.

The present policy is not to carry out invasive investigation before surgery for uncomplicated VSD provided information is not required about pulmonary vascular resistance, the clinical features match the echocardiographic findings, and the anatomy of the right and left ventricular outflow tract is known. There is a risk of overlooking small or moderate muscular VSDs by not performing left ventricular angiography.

Acknowledgment: We are grateful to Marc de Leval, MD, Donald Ross, MD, and Magdi Yacoub, MD, who operated on these patients and carefully explained the anatomy to us.

Results After Repair of Coarctation of the Aorta Beyond Infancy: A 10 to 28 Year Follow-Up With Particular Reference to Late Systemic Hypertension

PATRICIA M. CLARKSON, MB, MICHAEL R. NICHOLSON, MB, BRIAN G. BARRATT-BOYES, MB, ChM, JOHN M. NEUTZE, MD, and RALPH M. WHITLOCK, MB

The late outcome in 160 patients aged 1 to 54 years who had surgical repair of coarctation of the aorta was examined 10 to 28 years postoperatively. Twenty years postoperatively the probability of survival of patients discharged from the hospital aged 1 to 19 years at operation was a little less than that of the general population (95% versus 97%). The discrepancy between patients and the general population was more marked in those aged 20 to 39 years and was grossly different when surgical repair was undertaken beyond age 40. There were 19 late deaths (12%), 79% due to cardiovascular disease. Thirteen patients had a poor result because of recoarctation (11 patients) or the development of complications at the site of repair (2 patients).

Most patients were hypertensive before operation. The frequency of hypertension decreased markedly in the first few postoperative years. Blood pressure was normal in most patients 5 to 10 years after operation, but when followed up for longer periods the proportion of patients with hypertension increased. Hypertension was more common in patients operated on after 20 years of age than in those aged 5 to 19 years at operation ($p = 0.007$). The likelihood of being alive without complications and with a normal blood pressure was 69% at 10 years, 55% at 15 years, and 20% at 25 years postoperatively.

Despite the fact that surgical repair of coarctation of the aorta (C of A) was first undertaken in 1944,[1] little information is available on the long-term results of this treatment.[2–5] This report describes the outcome in 160 patients followed up ≥10 years postoperatively, with particular emphasis on the frequency of elevated systemic blood pressure (BP).

Methods

Of 160 patients aged 1 to 54 years operated on for C of A from May 1949 until December 1968, all but 1 of the late survivors were traced from 1979 to 1980, although 4 patients known to be alive were not available for review. Of the 155 patients, 54% were examined by us, 21% by cardiologists elsewhere, and 22% by other physicians. At the time of review their ages ranged from 13 to 72 years. The minimum follow-up in survivors was 10 years and the average, 17.5 years. Duration of follow-up was 20 to 24 years in 38 patients and 25 to 28 years in 8.

Repair of C of A was judged clinically to be *good* if the femoral pulses were normal on palpation or the systolic BP in the legs was the same as or greater than that in the arms, or both; *satisfactory* if there was only minor impairment of the femoral pulses or the BP in the legs was ≤20 mm Hg below that in the arm; and *poor* if there was marked reduction or delay of the femoral pulses, the BP in the legs was more than 20 mm Hg below that in the arm, or there were complications at the site of repair.

Cardiac catheterization studies were undertaken in 47 patients 1 to 20 years after operation (median 5 years), but few had adequate aortograms for review, and in most patients the study was performed >10 years before the present review.

Blood pressure was considered elevated if the systolic pressure was ≥160 mm Hg or the diastolic pressure was ≥95 mm Hg, or if, in patients <19 years of age, pressures were beyond the 95th percentile.[6] Patients receiving antihypertensive therapy also were considered hypertensive.

50 +	5	3	2	0	0
Total	160	99 (62%)	45 (28%)	4 (3%)	11 (7%)

* One patient included in this column did not have blood pressure measurement.

Preoperative and serial postoperative casual BP records were available. Those recorded at hospital discharge (usually 7 to 10 days after operation), 1 to 2, 5 (±1), 10 (±1), 15 (±1), and 20 (±1) years postoperatively were selected for analysis. In a few cases BP measurements were not available 20 years after operation but were available a few years later, and this measurement was then used in Figure 2. Because measurements were not available for all time intervals in each patient, certain assumptions were made. If the BP was known and fell into the same category 5 and 15 years postoperatively, it was assumed to be in this category 10 years postoperatively. It could not be assumed that patients who were hypertensive 1 to 2 years and 10 to 15 years postoperatively were necessarily hypertensive 5 years after operation, so that such patients were categorized as having no data at that time.

TABLE III Associated Lesions

† Not classified as associated lesion.
As more than 1 defect was encountered in some patients, the figures are not cumulative.

Graded exercise testing was undertaken in 24 patients (21 with resection and end-to-end anastomosis and 3 with aortoplasties). None was receiving antihypertensive medication or had a poor result from repair. The method used was that of Bruce et al[7] modified to exclude the first stage, exercise commencing with a treadmill gradient of 12% and a speed of 4 kph and continuing until maximum voluntary exercise capacity was reached. Blood pressure was measured in the right arm during exercise using a Bonn sphygmomanometer which incorporated a cuff automatically inflated to suprasystolic pressure and had a maximal reading of 300 mm Hg. On slow deflation the systolic and diastolic BP was recognized by recording the onset and cessation of sound with a microphone. The apparatus was checked regularly for accuracy using a standard mercury sphygmomanometer and remained stable. BP and heart rate were measured each minute during exercise and immediately afterwards (within 30 to 60 seconds of cessation of exercise) with the patient still standing on the treadmill.

Actuarial curves were constructed to illustrate late results.[8] Comparisons between curves were made.[9] Cumulative actuarial curves were constructed after the method of Grunkemeier et al.[10] Comparisons between groups were made using the 2-tailed unpaired t test. Differences were considered significant at $p < 0.05$.

Clinical profile of patients: Of the 160 patients, 108 (67%) were male and 52 female. Only 40 (25%) were <10 years and only 8 of these <5 years of age at operation (Table I). Hypertension was common (Table II). Thirteen of the 45 patients

with systolic hypertension had aortic regurgitation (AR), but in only 3 was this thought to be hemodynamically important. Four patients had a previous subarachnoid hemorrhage. Myocardial infarction had occurred in 1 patient and angina pectoris in another, and 4 had bacterial endocarditis before operation. Eight patients had previously been treated for heart failure.

Associated lesions: Associated lesions present either before or after C of A repair are listed in Table III. Aortic regurgitation was found in 27 of the 36 patients with valve lesions. Fifteen had mild AR at the time of the C of A repair. It remained mild in 13 patients aged 20 to 62 years (average 40 years) when last seen and had become moderate in 1 and severe in another who had late postoperative endocarditis and subsequent aortic valve replacement. Five patients had important AR at the time of C of A repair and aortic valve replacement was later undertaken in the 4 hospital survivors. In 7, AR (mild in 6, moderate in 1) was first noted during the postoperative follow-up. Aortic stenosis of at least moderate severity was noted in 7 patients; 4 have had aortic valve surgery. In 1 early case the patient died with severe stenosis without operative treatment. Congenital mitral stenosis was seen in 1 adult who underwent valvotomy. Mitral regurgitation was noted in 4 patients, 2 of whom also had AR, but in none was it severe enough to warrant valve surgery.

Type of operation: The most commonly used technique was resection of the C of A and end-to-end anastomosis (Table IV). The ductus, when patent, was divided. Aneurysms were present in 12 patients (Table IV) and were either excised along with the C of A (except for 1 involving the right subclavian artery), or when they involved the upper intercostals, the vessels were divided and oversewn.

Postoperative complications: Important postoperative hemorrhage occurred in 10 patients, and reoperation was undertaken in 7. Mesenteric arteritis was diagnosed in 9 patients (6 male, 3 female). Two underwent laparotomy but neither required bowel resection, and both recovered. Another 12 patients (10 male, 2 female) complained of postoperative abdominal pain.

Paraplegia occurred in 2 patients. One had an associated saccular aneurysm which was resected along with the area of mild C of A and replaced by a Dacron® tube graft. The other had large patent ductus arteriosus opening directly into the aorta distal to the C of A which was resected, the aorta being intermittently cross-clamped for 30 minutes after the ductus had been divided. Both patients had minimal collateral development.

Chylothorax occurred in 4 patients and temporary hoarseness was noted in 2 (in 1 of whom Horner's syndrome also developed). There were single instances of damage to the left phrenic nerve, septicemia, cerebral symptoms, jaundice, and pleural effusion.

Results of operative treatment: The late outcome in 159 of the 160 patients is known (Table I). There were 3 hospital deaths (2%). Two occurred in 1949 (1 in association with important AR), and only 1 hospital death (associated with ven-

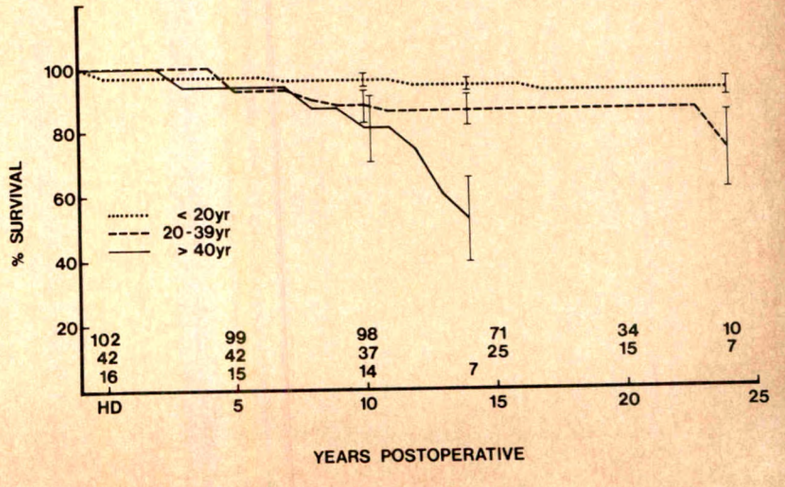

FIGURE 1. Actuarial curves relating chance of long-term survival to age at operation. Hospital deaths are included. * Figures in parentheses refer to general male population.
† Patients actually only followed up to 14 years postoperatively.

tricular septal defect, patent ductus arteriosus, and an elevated pulmonary vascular rersistance) in the last 157 patients (0.6%).

There have been 19 late deaths 2 to 23 years after operation. Autopsy was performed in 14. Fifteen deaths were due to cardiovascular disease. In 3 death was related to C of A; in 1 a dissecting aneurysm proximal to a tube graft developed 16 years after operation, 1 patient died 23 years after operation with detachment of a Dacron patch graft which had been used to revise the original repair 8 years previously, and the third died 11 years postoperatively from hemoptysis which appeared to arise from intercostal arteries. Six late deaths were due to coronary heart disease, 4 to aortic valve disease, 1 to associated congenital heart disease and pulmonary vascular obstruction, and another to poor left ventricular function present before operation. Two patients died after motor vehicle accidents, and the cause of death in 2 patients is unknown. Age at operation was significantly greater ($p < 0.001$) in patients who died late (33 ± 16 years) than in those who were long-term survivors (18 ± 11 years). The average age at death was 41 years.

Actuarial survival was 81 ± 6% (standard error) 24 years postoperatively. There was no significant difference in late survival between individual decades up to the fourth. In patients operated on at 1 to 19 years of age, 96, 94, and 92% were alive 10, 15, and 24, years postoperatively (Fig. 1), and of those aged 20 to 39 years, 88, 86, and 73% ($p = 0.09$). In patients >40 years at operation, the chance of survival was 81% 10 years after operation and only 52% 14 years postoperatively ($p = 0.007$ when compared with those aged 20 to 39).

The probability of survival in those discharged from the hospital was compared with that of a general male population[11] (Table V). The probability of survival 20 years postoperatively in patients aged 1 to 19 years at operation was a little less than that of the general population. The discrepancy between patients and the general population was more marked in those aged 20 to 39 years at operation and grossly different when surgical repair was undertaken after the age of 40 years.

Results of repair of C of A were known in 149 patients. Eighty-nine (57%) were judged clinically to have a good result and 47 (30%) a satisfactory result. Thirteen (8%) had a poor result because of either the development of an aneurysm (2 patients) or residual or recoarctation (11 patients). The latter was noted in 3.3% of patients after resection and end-to-end anastomosis (Table IV) and in 17.5% of those with other types of repair, reflecting more complex anatomy unsuited to simple resection. Revision of the repair was undertaken in 7 of the 11 patients without any hospital mortality and with relief of the obstruction in all.

Seventeen patients without recoarctation who were followed up beyond the 20th postoperative year had catheterization studies 1 to 20 (median 6) years after operation, all being over 16 years of age at the time. Only 1 of the 6 patients without a gradient across the anastomosis and 6 of the 11 patients with a small gradient were normotensive when last reviewed. Two patients had aortograms which showed that the anastomotic diameter was at least as wide as the lower thoracic aorta. One patient was normotensive, the other hypertensive. In 3 patients the anastomotic diameter was 72 to 82% of the lower aorta. Two of these patients were normotensive and 1 hypertensive.

Incidence of systemic hypertension: The frequency of hypertension before and after operation in 138 hospital survivors who were >5 years of age at operation and who did not have evidence of residual or recoarctation is summarized in Figure 2. There was no significant difference in the incidence of hypertension when those who had a good result after repair were compared with those who had a satisfactory result ($p = 0.18$).

Most patients were hypertensive before operation. Some became normotensive before hospital discharge whereas others became normotensive within 1 to 2 years. A few patients with elevated BP at this time were subsequently normotensive. A normal BP was present in most patients 5 to 10 years postoperatively, but with longer periods of follow-up the proportion with hypertension increased. The pattern was similar in all age groups.

The same data have been analyzed actuarially (Fig. 3). When each age group is compared with the next highest age

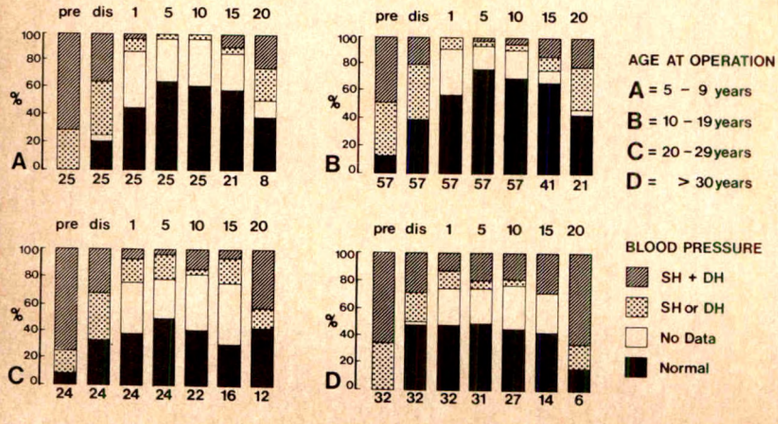

FIGURE 2. Blood pressures in 138 hospital survivors >5 years of age who did not have recoarctation are grouped according to age at operation. The numbers above the bars refer to years after operation. The numbers below the bars refer to the number of patients at risk in each time period. DH = diastolic hypertension; dis = hospital discharge; pre = preoperative; SH = systolic hypertension.

group, there is no significant difference between each pair of curves. However, hypertension was more common in patients operated on after 20 years of age than in those aged 5 to 19 years ($p = 0.007$). Both the 5 to 9 year age group and those aged 10 to 19 years at operation have a significantly lower incidence of hypertension than do patients >30 years of age at operation ($p = 0.02$ and 0.001).

The effect of important AR on the development of systolic hypertension was examined. In only 1 patient in whom moderate AR developed 19 years postoperatively was this a likely contributory factor, as other patients with severe AR were normotensive according to the definition used, or the timing of aortic valve replacement was such that there was no effect on BP at the time of analysis.

Forty-five patients aged 5 to 39 years at the time of repair were followed up beyond the twentieth postoperative year. Eight of the 13 who were normotensive at hospital discharge were normotensive when last seen. In contrast, only 7 of the 32 patients who were hypertensive at hospital discharge had a normal BP when last reviewed, that is, patients who were normotensive at discharge are more likely to have a normal BP very late postoperatively ($p = 0.03$).

Of the 125 late survivors with a good or satisfactory result from repair, 121 were <60 years of age when last reviewed. Of the 84 who were <40 years of age, 36% at review were hypertensive as were 78% of the 37 patients aged 49 to 59 years. These figures are contrasted with the prevalence of hypertension in patients in these age groups in the general population (using the same criteria as used in this study), where it was 4 and 17%, respectively.[12] Although 47% of 129 late survivors without recoarctation were hypertensive when last reviewed, only 28% of the 60 hypertensive patients had a BP ≥180 mm Hg systolic or ≥110 mm Hg diastolic.

Exercise testing: Results of graded exercise testing 11 to 25 years after operation in 24 patients who attained a heart rate of at least 85% of maximum for age[13] after 6 to 15 minutes (average 11) were examined. Age at operation was 7 to 40 years (average 17), and at testing 21 to 59 years (average 34). Eight patients were normotensive, 16 were hypertensive but on no treatment, and none had a poor result. A decrease in BP occurred within 30 to 60 seconds of stopping exercise in many patients (Fig. 4). No major differences were found when maximum systolic pressure with exercise was examined in relation to age at operation, age at testing, a good or satisfactory result of the C of A repair, or the achievement of maximal or submaximal heart rate with exercise. Average systolic BP with exercise was not significantly higher in patients who were hypertensive at rest than in those who were normotensive (285 ± 23 versus 266 ± 26 mm Hg; $p = 0.08$).

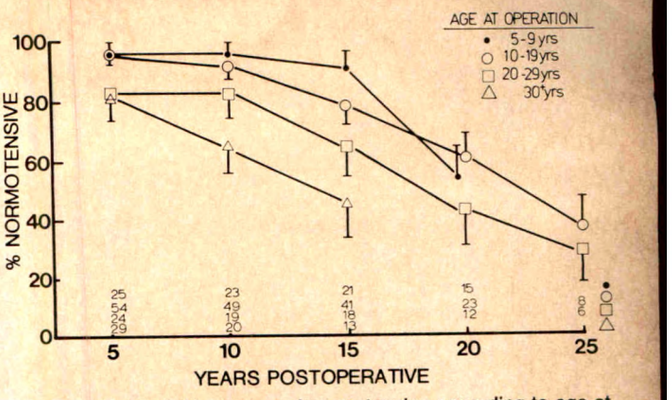

FIGURE 3. Actuarial incidence of normotension according to age at operation and the time of postoperative follow-up.

Two patients aged 9 and 23 years at operation were shown 2 to 7 years postoperatively to have no gradient across the anastomotic site which was at least as wide as the lower thoracic aorta on aortography. Both were hypertensive on review at 31 and 48 years, but had relatively low systolic pressures with exercise (160 → 250 mm Hg and 170 → 235 mm Hg).

Other postoperative morbidity in late survivors: At the time of review, 138 patients were alive, and recent medical assessment was available in all but 4. Exercise tolerance was normal in 114 of the 134 assessed patients (85%), mildly impaired in 19 (14%), and significantly reduced in 1.

Myocardial infarction occurred in 1 patient who experienced angina before operation, and an additional 5 patients developed angina. Cerebrovascular disease was noted late postoperatively in 4 patients. One hypertensive patient had a subarachnoid hemorrhage associated with a Berry aneurysm 17 years postoperatively, and in another a Berry aneurysm was found 8 years after operation when cerebral arteriography was performed because of episodic vertigo and headache. One

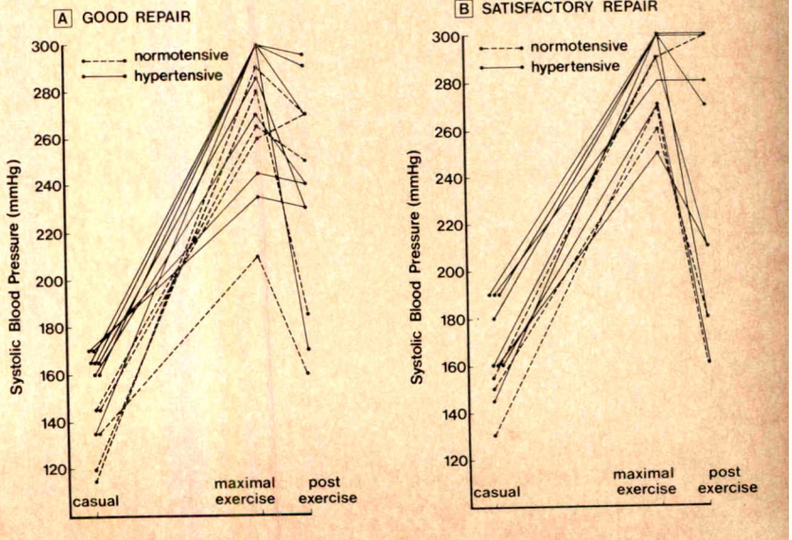

FIGURE 4. Response of arm systolic blood pressure to exercise. Blood pressure within a minute of stopping exercise is also shown. **Left,** patients with good repair; **right,** patients with satisfactory repair.

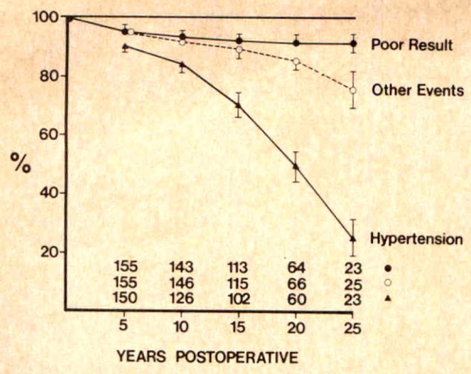

FIGURE 5. Individual actuarial curves showing the percent chance of freedom from postoperative complications.

patient with cerebral symptoms had left vertebral artery stenosis and 1 patient with a Braunwald-Cutter aortic prosthesis had a cerebral embolus. The 4 patients who had a subarachnoid hemorrhage preoperatively had no recognized recurrence 12 to 19 years after operation. Neurosurgical treatment had been undertaken in 1 of the 2 in whom Berry aneurysms were demonstrated. Evidence of degenerative hip disease[2] was not specifically sought, but overt problems were noted in 2 patients.

Summary of late results: The long-term course of hospital survivors is summarized in individual actuarial curves (Fig. 5). By 25 years postoperatively, 8% had a poor result. Important associated disorders, usually valve lesions requiring surgical treatment or symptomatic coronary or cerebrovascular disease, have been grouped together, are shown as "events," and were seen in 25%. Hypertension was noted in 75%.

The late postoperative course is also summarized in cumulative actuarial curves (Fig. 6), with complications arranged in an hierarchical manner. When more than 1 complication occurred in an individual patient, it was placed in the uppermost category.

The incidence of late deaths increased with increasing duration of follow-up as did the proportion of patients with events and hypertension. The percentage of patients who were alive without complications and with a normal BP was 69% at 10 years, 55% at 15 years, and 20% at 25 years postoperatively.

Discussion

We elected to confine this analysis to the results of C of A repair in patients >1 year of age, because problems in patients operated on during the first year of life, especially in relation to associated congenital cardiac anomalies and recoarctation, make this group best analyzed separately.

The hospital mortality and morbidity of C of A repair beyond infancy have been low.[14–16] The incidence of late mortality and morbidity can be expected to vary depending on the proportion of hospital survivors reviewed and the duration of follow-up. We were able to ascertain the late outcome in all but 1 patient. There was no significant difference in late actuarial survival in patients operated on in individual decades up to the fourth, but late survival more closely approximated that of a general male population when operation was performed before age 20 (Table V) and differed significantly from the general population when operation was performed after age 40.

Late death from cardiovascular disease is well recognized in patients after repair of C of A, and when follow-up extends at least 10 years postoperatively, its incidence is about 10%.[2–4] Eighty to 90% of these deaths are due to cardiovascular disease, the approximate distributions being 30% from aortic valve disease, 30% from coronary artery disease (based on the presumption that patients who die suddenly probably die from this cause although an alternative would be unrecognized aortic rupture), 15% from complications related to the operative site or proximal aortic dissection, and 15% from other cardiovascular disease including intracranial hemorrhage. Like Maron et al[3] we found that the mean age at operation of those who died late was significantly higher than that of long-term survivors. Because the divergence of death rate from normal was increasingly more marked with increasing age at operation beyond 20 years, this is likely due to the prolonged effects of C of A.

Hypertension has been recognized in the absence of recoarctation in late survivors.[2,3,17] Its incidence will vary according to the criteria used. We elected to use the World Health Organization criteria (≥160 mm Hg systolic, ≥95 mm Hg diastolic), because these criteria are unlikely to overestimate the incidence of hypertension in the age groups studied, are widely used in population studies, and in patients <19 years the Task Force Standards[6] to categorize those with pressures >95th percentile as hypertensive rather than >90th percentile as others have done.[18,19]

Our data indicate that the incidence of hypertension varies with the duration of follow-up. Blood pressure tends to decrease in the first few postoperative years, with most patients being normotensive 5 to 10 years after operation, but to increase in later years, and this pattern is similar regardless of age at operation. Not surprisingly, the incidence of late hypertension varies widely in series in which follow-up varies from 1 to many years postoperatively.[5,18] When follow-up was relatively long, the reported incidence was high (24 to 33%).[2,3] Late hypertension was more common in our patients when operation was delayed until after age 20 and this was also found by Menasche et al,[4] but it does occur in patients operated on in their first decade as shown by our study and those of others.[17–19] Whether the incidence of hypertension will be reduced by earlier operation remains unproved. We have followed up 18 patients (not all of whom are in this study) aged 0 to 4 years at operation and without residual coarctation for at least 10 years, 6 remaining at risk 20 years postoperatively. Two became hypertensive at 13 and 18 years. Actuarially, this group is no different from the 5 to 9-year-old group, but no firm conclusions can be drawn from such small numbers.

Coarctation may recur, but some cases are more properly termed *residual coarctation* when they are noted early postoperatively. The incidence varies, depending partly on the method used to evaluate the re-

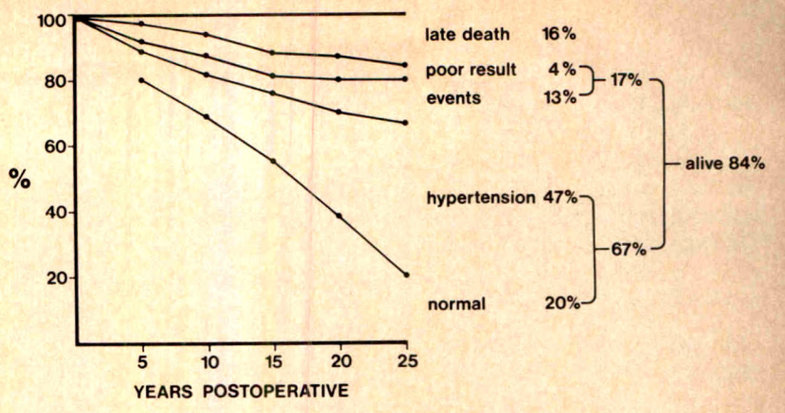

FIGURE 6. Cumulative actuarial curves summarizing overall results.

pair and the pressure gradient chosen.[3,17,20] Using a gradient >20 mm Hg, "recoarctation" was noted in only 4 (3.3%) of the 120 patients who had resection and end-to-end anastomosis and was more frequent when the lesion could not be dealt with in this manner (17.5%).

The relation between BP, especially with exercise, and the adequacy of the surgical repair is complex and not well understood. Different types of exercise testing have been used in patients after C of A repair, most examining the effect of maximal or submaximal exertion.[21–24] Blood pressure has been measured in the arm[21–26] and also in the leg in some cases.[22–26] In general postcoarctectomy subjects tend to have higher arm BP at rest than do control subjects, and the difference is more marked with exercise. It has been suggested that the response of the blood pressure to exercise may indicate an unsatisfactory surgical repair and highlight abnormal gradients between arm and leg pressures not apparent in the resting state.[22,24–26] The need to measure limb BP simultaneously using the same technique has been emphasized.[26] It is also important to note whether BP is measured during or after exercise. When exercise is discontinued, arm BP may decrease promptly (within 10 to 30 seconds),[19,27,28] the decrease tending to be more marked after higher levels of activity.[27] If we had only measured arm BP after the cessation of exercise, values lower than those during maximal exertion would have been recorded in a number of patients (Fig. 4). The response to exercise is also altered by antihypertensive agents.[28,29]

It is difficult to adequately assess the significance of blood pressure measurements in the absence of information concerning the anatomy of the anastomotic area, and like others we have not routinely undertaken aortography in our patients. In acute experiments, reduction of the cross-sectional area of the aortic lumen to 45 to 55% of normal produced a gradient across the constricted area.[30] In postoperative patients Frederickson and Jagt[31] and Frederickson[32] noted that a resting peak systolic gradient across the anastomosis was absent or <10 mm Hg when the anastomotic area was ≥40% of the descending aorta. There is not a consistent relation between central aortic pressures[31,32] or anastomotic width[23] and upper and lower limb pressures at rest or during maximal exercise.

This study gives an overall picture of the long-term outcome after coarctation repair as judged by usual clinical methods. The reason for the recrudescence of hypertension late postoperatively is not clear. In some patients the anastomotic area may be less than ideal, even though BP at rest is normal and a gradient between arm and leg pressures absent. In others the presence of a small gradient probably reflects some restriction at the site of the anastomosis. Our data do not allow firm conclusions about the contribution of anastomotic narrowing to late hypertension, which, however, was not more common in patients with only a satisfactory as compared with a good repair, or when there was a small (versus absent) resting gradient at cardiac catheterization. The effect of the type of repair on pulse wave dynamics and late hypertension cannot be determined at this time. Hansen et al[23] in cineangiographic studies after resection and end-to-end anastomosis noted the aortic wall near the anastomosis appeared stiff in most patients, but in some it was smooth with clearly visible pulsations. Thus, it is possible that narrowing or poor function of the anastomotic area may result in resting hypertension or an exaggerated response of upper limb systolic pressure to exercise. The similar postoperative pattern of BP behavior in patients of differing ages at operation (Fig. 2) does suggest that other factors may be involved. Animal studies indicate that the effects of transient hypertension are not totally reversible,[33,34] and it may be that late hypertension in patients is at least in part due to changes in the arterial wall related to high preoperative pressures which do not completely resolve despite adequate relief of the obstruction. Our data show that it is advantageous for C of A to be repaired before 20 years of age when both late survival and late hypertension are considered. Although it is likely that repair is better undertaken in the first rather than in the second decade of life, clear-cut differences were not demonstrated in this small group of patients.

The optimal age for elective C of A repair is not known.[18] Residual and recurrent C of A is more common when operation is undertaken in the first year of life.[17]

In this series, which does not include patients <1 year of age, the incidence of recoarctation was similar through each decade. Elective operation may be undertaken at 6 to 12 months of age, but long-term data to support this view are not yet available.[35]

The methods described in this study provide an approach to analysis of late results of repair in different age groups at similar times postoperatively and to assessing changes that occur with time. They are applicable in younger age groups not encompassed by this investigation.

Acknowledgment: We thank the many physicians who provided postoperative data on patients and without whose help the study could not have been completed.

The Valve of the Foramen Ovale in Interatrial Right-to-Left Shunt: Echocardiographic Cineangiocardiographic and Hemodynamic Observations

CHRISTOPH KUPFERSCHMID, MD and DIETER LANG, MD

In postpartum persistent right-to-left shunt at the atrial level, the valve of the foramen ovale fails to close. As a thin valve-flap the septum primum is pushed to the left during the phases of right atrial pressure predominance and closes to the septum secundum, when left atrial pressure exceeds right atrial pressure. Thus, it performs a marked movement during the cardiac cycle, reflecting the interatrial pressure-flow dynamics. With use of M-mode echocardiography, this movement pattern was studied in 24 patients: 13 with cyanotic heart disease (age 2 days to 21 years) and 11 newborns with persistent transatrial right-to-left shunt due to noncardiac disease. Cardiac defects were confirmed by cardiac catheterization and cineangiocardiography. Interatrial right-to-left shunts were proved by M-mode and 2-dimensional contrast echocardiography. The comparison of the M-mode echocardiographic findings in our patient groups with normal atrial septal movement studied in 20 healthy infants and children revealed considerable differences. The characteristic movement of the valve of the foramen ovale also was compared with results obtained by cineangiography and 2-dimensional echocardiography. Analysis of interatrial blood pressure difference provided a pathophysiologic explanation of the septum primum movement in transatrial right-to-left shunt.

Recently we detected a peculiar structure within the left atrium in the M-mode echocardiogram of a newborn with tricuspid atresia. We suspected that the origin of these echoes could have been the valve of the foramen ovale. This valve is formed by a part of the atrial septum, the septum primum. In the late fetal life, blood entering the right atrium by the inferior vena cava pushes the thin septum primum to the left and passes below the thick margin of the septum secundum into the left atrium. The movement pattern of the valve of the foramen ovale recorded by M-mode echocardiography reflects interatrial pressure-flow dynamics. In cases of postpartum persistent interatrial right-to-left shunt, a persistent fetal movement pattern of the valve of the foramen ovale can be a diagnostic help in the analysis of interatrial hemodynamics.

Methods

Patients: Because we identified the valve of the foramen ovale by M-mode echocardiography for the first time in 1979, we subsequently investigated all our patients with known interatrial right-to-left shunts due to different congenital heart diseases (Group 1, n = 13). Included in this group is the retrospective analysis of the M-mode tracings of 2 patients with total anomalous pulmonary venous connection. In addition, we looked at all newborns with suspected interatrial right-to-left shunts, as discriminated by inhaling 100% oxygen after ruling out structural heart diseases by 2-dimensional (2-D) echocardiography (Group 2, n = 11). This group was labeled as having persistent fetal circulation at the atrial level. Interatrial septal motion as recorded by M-mode and 2-D echocardiography was compared with the findings in 20 normal infants and children (Group 3) and with that in a 38-week fetus intrauterine with atrial tachycardia.

Among the 13 patients in Group 1, 7 had tricuspid atresia of various types, 2 had pulmonic atresia and intact ventricular septum, 3 had total anomalous pulmonary venous connection of the cardiac type without obstruction, and 1 newborn had transient tricuspid regurgitation. Three patients with tricuspid atresia (type B) underwent an aortopulmonary anastomosis, and 1 with tricuspid atresia (type A) had a pulmonary trunk banding. The remaining 7 patients had no previous palliative procedures. Among the 11 newborns in Group 2, 1 had a hepatic arteriovenous fistula, and 10 had such primary lung diseases as pneumonia, respiratory distress syndrome, and aspiration of amniotic fluid; 2 had undergone ligation of a persistent ductus arteriosus, whereas 4 had a significant ductal left-to-right shunt at the time of investigation as confirmed by aortography.

Methods: Table I summarizes the diagnostic methods used in the patients in the 3 groups, not including the 38-week fetus investigated by M-mode and 2-D echocardiography. M-mode echocardiography was done using an Echo IV Electronics for

TABLE I Diagnostic Methods Used in the 3 Groups

	Group I: Congenital Heart Disease (n = 13)	Group 2: Persistent Fetal Circulation (n = 11)	Group 3: Control (n = 20)
Age			
Range	1–21 days	2–10 days	2 days–8 years
Median	10 days	5 days	4 months
M-mode echocardiography	13	11	20
M-mode + contrast	5	11	3
Two-D echocardiography	11	11	20
Two-D + contrast	6	11	3
Interatrial blood pressure difference (mm Hg)	2	0	0

Medicine instrument with transducer frequencies of 2.5, 3.5, and 5 MHz depending on the patient's weight. On the basis of our experience with 2-D echocardiography and the anatomy of normal hearts, we usually chose the subcostal approach for the detection of the atrial septum in M-mode echocardiography. Only in cases of hypoplastic right ventricle and right atrial enlargement was recording done with a left or right parasternal transducer position. A sweep from the atrial septum to mitral valve was obtained in all patients studied by M-mode echocardiography with either subcostal or parasternal transducer position. Using stop-frame technique in 2-D echocardiography, we reevaluated our M-mode echocardiograms.

Two-D echocardiograms were performed with a mechanical sector scanner (Advanced Technical Laboratories) with 90° wide angle transducers of 3.5 and 5 MHz. Investigations were recorded on a video tape for later evaluation. For contrast echocardiography, 1 to 5 ml of 0.9% sodium chloride was injected into a peripheral vein draining to the superior vena cava. All cardiac defects were confirmed by cardiac catheterization and cineangiocardiography.

Lateral cineangiocardiography was used to analyze atrial septal motion in a patient with tricuspid atresia, type 2B. The frame-rate was 50/s after the injection of contrast medium into the right atrium. Individual pulses of the cineangiographic frames were recorded with the electrocardiogram. This protocol allowed later identification of the single frames. In 1 newborn with pulmonic atresia and intact ventricular septum and in a second with tricuspid atresia, type 2B, we superimposed graphically left and right atrial pressure diagrams, which were recorded during catheter withdrawal from the left to the right atrium. Care was taken in this correlation to ensure that the heart rate remained constant by measurement of the R-R intervals and that pressure tracings were analyzed during identical phases of the respiratory cycle. The resulting pressure-difference diagrams were compared with the atrial-septum movement of the patients as recorded by M-mode echocardiography using the electrocardiogram as the common time base.

Results

Detection and movement of the valve of the foramen ovale in M-mode echocardiography: The atrial septum could be recorded with sufficient quality in all patients entered in the study. In normal hearts the atrial septum performs a smooth sine-wave movement.[1] Its maximal motion is toward the left atrium in early systole and to the right atrium in end-diastole. This pattern was recorded in all our patients in the control group (Group 3) (Fig. 1). In all but 1 patient in Groups 1 and 2 we observed a different and characteristic movement of the atrial septum which will be confirmed later to reflect the movement of the valve of the foramen

ovale (Fig. 2). With the onset of ventricular systole (R wave in the electrocardiogram), the valve of the foramen ovale has its maximal elongation toward the left atrial posterior wall (point 1). This is followed by a rapid anterior movement during early ventricular systole. From this position (point 2), the valve turns back toward the left atrium in end-systole (point 3). A second anterior movement to point 4 follows. This point appears before the P wave on the electrocardiogram. The cycle ends with a mid- to end-diastolic backward movement, again reaching the starting point 1. This point occurs clearly before closure of the mitral valve (Fig. 3). This movement pattern was recorded with little variation in all the patients in Groups 1 and 2 except 1 newborn infant. In this patient with total anomalous pulmonary venous connection, we failed to detect the valve of the foramen ovale. Operation and autopsy revealed a large atrial septal defect with the size of septum primum and septum secundum markedly reduced.

The intrauterine M-mode echocardiogram of the 38-week fetus also showed the valve of the foramen ovale in a similar pattern as described previously. In this fetus with atrial tachycardia and 2:1 atrioventricular conduction, the elongation of the valve of the foramen ovale altered every second atrial contraction, presumably with respect to ventricular filling (Fig. 4).

The valve of the foramen ovale in 2-D echocardiography: No patient studied was omitted because of poor recording of the atrial septum. In patients in the control group (Group 3) we could not recognize any specific movement patterns of the atrial septum during the cardiac cycle. It was either straight or bulged slightly toward the left or to the right atrium. Even a rhythmic motion of the septum primum away from the septum secundum depending on the respiratory cycle as described by Biermann and Williams[2] could not be observed. However, in the patients in Groups 1 and 2 we recorded a vigorous motion of the septum primum within the cardiac cycle (Fig. 5). As confirmed by slow-motion and frame-to-frame analysis, it consisted of a biphasic opening and closure of the flap. With respect to the electrocardiogram, the opening positions

Abbreviations as before.

corresponded to points 1 and 3 and the closure positions to points 2 and 4 of the aforementioned M-mode echocardiographic findings (Fig. 2).

Contrast echocardiography: In all 17 patients in Groups 1 and 2 studied with 2-D contrast echocardiography, an interatrial right-to-left shunt could be observed in the subcostal 4-chamber view (Fig. 6), whereas in the control group (Group 3) no shunt was present.

In M-mode contrast echocardiography, the right atrial contrast filling phase could be observed with the transducer in a subcostal position. With respect to the electrocardiogram, the contrast material subsequently appeared within the left atrium at the very same moment, when the valve of the foramen ovale opens (Fig. 7).

The valve of the foramen ovale in cineangiocardiography: In 1 of the patients in Group 1 with tricuspid atresia type 2B, we were able to demonstrate the valve of the foramen ovale by cineangiocardiography in the lateral view. After right atrial contrast injection a vigorous movement of the septum primum was seen. This led to a rhythmic opening and closure of the foramen ovale, allowing contrast medium to pass into the left atrium. With respect to the electrocardiogram, opening and closure of the foramen ovale had the same timing as seen in the M-mode echocardiogram.

Interatrial blood pressure differences: The interatrial pressure difference diagram obtained in 2 newborns in Group 1 showed a striking similarity to the movement of the valve of the foramen ovale recorded in M-mode echocardiography. In the patient with tricuspid atresia a mean interatrial pressure difference of 4 mm Hg indicated a restrictive foramen ovale; in the second patient, the mean interatrial pressure difference was 1.5 to 2 mm Hg. The opening of the valve of the foramen ovale occurred when right atrial pressure exceeded the left side in early diastole. The moment clearly occurs before the P wave on the electrocardiogram and the apex of the right atrial A wave. The following closure of the flap in early systole and its slighter reopening and final closure can also be correlated to the instantaneous pressure predominances favoring either the left or the right side (Fig. 8).

Discussion

The valve of the foramen ovale is identical to the ventrocephalic free margin of the septum primum. In all cases of interatrial right-to-left shunt through a patent foramen ovale (whether intrauterine or postpartal), the blood flow pushes the thin septum primum to the left and passes below the thick dorsocaudal margin of the septum secundum into the left atrium. It does not make any difference whether the interatrial right-to-left shunt is dependent on a defect or functional. Postpartum there are many hemodynamic situations that can lead to a persistent interatrial right-to-left shunt. Usually there are anatomic or functional right heart obstructions, mainly accompanied by a more or less reduced right ventricular compliance or right atrial volume overload.

Our study in 24 patients demonstrates that the movement of the valve of the foramen ovale in cases of interatrial right-to-left shunt can be visualized by M-mode echocardiography. The tracing is markedly dif-

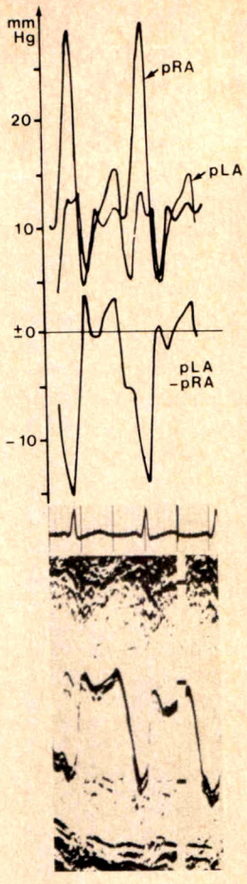

FIGURE 8. Comparison of the interatrial pressure difference with the movement of the valve of the foramen ovale in the subcostal M-mode echocardiogram of an infant with tricuspid atresia, type 2B. The single traces were synchronized to the electrocardiogram. pLA = left atrial pressure; pLA-pRA = interatrial pressure difference; pRA = right atrial pressure.

ferent from the atrial septum movement recorded in normal patients and similar to the findings in an intrauterine fetus.

There are few reports describing the movement of the valve of the foramen ovale by M-mode echocardiography. Schmaltz and Apitz[3] described an unusual left atrial echo in a newborn with hypoplastic right heart. They could not relate the echo to any structure of the heart. The reported tracings, however, were identical to those we found when studying the valve of the foramen ovale. Silvermann et al[4] reported a similar echo in a newborn with tricuspid atresia. They could exclude its origin from any right ventricular or right atrial structure. A corresponding report was given by Bini et al[5] in a case of tricuspid atresia. These investigators suggested that the only intracardiac structure capable of simulating a tricuspid valve movement was the valve of the foramen ovale. This hypothesis has not yet been proved sufficiently. Former observations by Biermann and Williams[2] described a rhythmic removal of the septum primum from the septum secundum depending on the respiratory phase using 2-D echocardiography. Their studies were not aimed at studying the typical movement of the valve of the foramen ovale in interatrial right-to-left shunt. Tei et al[6] described the atrial septum position and estimated thickness of the septum in 29 patients with right or left atrial overload using M-mode echocardiography. In this study there was also no description of the atrial septum movement. The M-mode echocardiographic tracing of an atrial septal aneurysm in an infant with hypoplastic right heart syndrome reported by Sahn et al[7] was identical to the movement of the valve of the foramen ovale in our patients, and a recent report of Reder et al[8] on this feature confirmed these findings. However, in our patients there was no evidence of atrial septal aneurysm as shown by 2-D echocardiography, cineangiography, or later operation.

Marked movement of the valve of the foramen ovale is a newly described tracing in M-mode echocardiography. By comparing this tracing with different diagnostic methods such as 2-D echocardiography and cineangiocardiography, we could be certain that the M-mode echoes described in fact originate from a vigorously active valve of the foramen ovale. It could be confirmed that the elongations toward the left atrium (points 1 and 3, Fig. 1) represent an opening of the flap, whereas the elongations toward the right atrium (points 2 and 4) are closure positions. This movement is passive and caused by the interatrial pressure-flow dynamics, as shown by comparison with atrial pressure tracings in 2 patients (1 with absent right atrioventricular connection and the other with a low-compliance right ventricle). Right atrial pressure dominance and subsequent interatrial right-to-left shunting occurs twice within the cardiac cycle: first, in early diastole probably because of absent or reduced right ventricular filling; and second, in systole because of a slightly more rapid pressure increase in the right atrial V wave than in the left. The 2 points of left atrial pressure predominance (points 2 and 4, Fig. 2) can be attributed to somewhat higher pressures of left atrial X and V waves. The closure of the mitral valve coincides in time with the decrease of the right atrial pressure dominance (Fig. 3 and 8), thus indicating the dependence of interatrial right-to-left shunting on the left ventricular filling.

As similar movement patterns of the valve of the foramen ovale were recorded by M-mode echocardiography in all patients in Groups 1 and 2, one can presume that the shunting dynamics were also similar in all, even though the individual hemodynamic situation differed considerably. Reduced or absent right ventricular compliance can only provide an explanation for the shunt dynamics in cases of tricuspid atresia and pulmonic atresia with intact ventricular septum. In the patient with tricuspid regurgitation and in those with total anomalous pulmonary venous connection, right atrial volume overload must be considered to effect interatrial right-to-left shunts. A similar condition can be assumed in the newborn with a systemic left-to-right shunt through a hepatic arteriovenous fistula. In these patients right ventricular compliance is probably normal, but not high enough to allow the increased right atrial volume to pass completely through the tricuspid valve.

In the 38-week fetus the commonly accepted explanation that the flow predominance of blood entering the right atrium through the inferior vena cava leads to the fetal right-to-left shunt at atrial level cannot be accepted entirely. This fetus had atrial tachycardia with 2:1 atrioventricular conduction. Biphasic opening of the valve of the foramen ovale indicates that a major interatrial right-to-left shunt occurs every second atrial contraction. One can therefore assume that the interatrial shunt depends more on the ventricular filling than on the venous blood flow dynamics.

In the newborns in Group 2 with primary lung disease and atrial right-to-left shunt, the interatrial hemodynamic features are poorly understood. The similarity of their foramen ovale valve movement in M-mode echocardiography leads to the assumption that the interatrial pressure-flow dynamic features are similar to those in the patients with cyanotic heart defects studied in Group 1. This is difficult to accept, because at least in the 4 patients with proven significant ductal left-to-right shunt, a left atrial volume overload should have been present. A markedly different ventricular compliance favoring the left side may provide a hypothetical explanation, which needs support by further hemodynamic studies.

Conclusion: The valve of the foramen ovale can be recorded by M-mode echocardiography in patients with interatrial right-to-left shunt. The sensitivity of this pattern was high in our patients as controlled by contrast echocardiography or cineangiocardiography. Specificity could not be tested accurately, as we did not investigate patients with right atrial pressure or volume overload having a foramen ovale that was not patent. In 1 patient with total anomalous pulmonary venous connection and a large atrial septal defect, we failed to record the expected movement of the septum primum.

Being a thin membrane, the foramen ovale flap easily follows interatrial pressure-flow changes. Thus its movement reflects very accurately the interatrial pressure-flow dynamics. Despite the different hemodynamic situations in all patients with atrial right-to-left shunt, the striking similarity of their foramen ovale flap movements indicates a similarity in atrial right-to-left shunt timing within the cardiac cycle. Interatrial shunt dynamics, however, may mainly depend on the ventricular filling capacities, irrespective of whether the shunt is dependent on a cardiac or a functional defect.

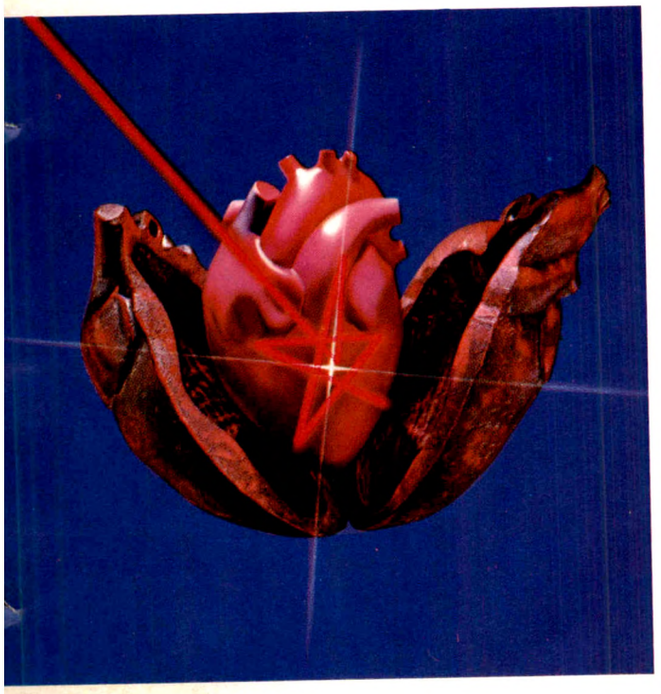
Heart failure makes
life more difficult

CAPOTEN®
(captopril tablets)
makes living
easier

SQUIBB

With the availability of CAPOTEN, heart failure† patients can enjoy an enhanced quality of life. Because, in patients who require more than digitalis and diuretics, CAPOTEN can improve their hemodynamic profile[1] and provide an opportunity to feel better.

- Eases principal heart failure symptoms[1]
- Restores patients' sense of well-being[1]
- Increases patients' capacity for exercise,[1] allowing them to participate more fully in the physical activities of everyday life



ACE* INHIBITOR

CAPOTEN®
(captopril tablets)

Can make the difference between merely existing and actively living

†CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

*Angiotensin Converting Enzyme

Please see brief summary of prescribing information on last pages of this advertisement.

ACE*INHIBITOR

CAPOTEN®
(captopril tablets)

CAPOTEN has been associated with the development of neutropenia/agranulocytosis (0.3% of 4,000 patients) or proteinuria (1.2% of 4,000 patients).† These serious side effects are more likely to occur in patients with predisposing conditions, such as renal impairment or autoimmune disease, or in patients receiving therapy known to suppress the autoimmune response.

The following precautionary guidelines are recommended for all patients receiving CAPOTEN:

- **Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.**
- **Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.**
- **Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.**
- **The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.**

*Angiotensin Converting Enzyme

†Please see brief summary of prescribing information on last pages of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

Reference: 1. Data on file, Squibb Institute for Medical Research.

CAPOTEN® TABLETS
Captopril Tablets

INDICATIONS: Hypertension — Because serious adverse effects have been reported (see WARNINGS), CAPOTEN is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects.
Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.
WARNINGS: Proteinuria — Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients.

Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related. Most cases of proteinuria occurred by the 8th month of therapy. Patients should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine — the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

Neutropenia/Agranulocytosis — Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).

Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller. In these patients white blood cell counts should be performed every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Hypotension — Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).

In heart failure, where blood pressure was either normal or low, transient decreases in blood pressure >20% were recorded in about ½ the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTION: General: *Impaired Renal Function,* Hypertension — Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure — About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* — A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis, due to decreased afterload reduction.
Surgery/Anesthesia — If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.
Drug Interactions: *Hypotension: Patients on Diuretic Therapy* — Precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose in hypertensive patients.
Agents Having Vasodilator Activity: In heart failure patients vasodilators should be administered with caution.
Agents Causing Renin Release — Captopril's effect will be augmented by

 (Continued on next page.)

(continued from preceding page)

antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity — The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium — Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Usage in Pregnancy: There are no adequate and well-controlled studies in pregnant women. Embryocidal effects were observed in rabbits. Therefore, captopril should be used during pregnancy only if the potential benefit outweighs the potential risk to the fetus.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving about 4000 patients.

Renal — One to 2 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic — Neutropenia/agranulocytosis occurred in about 0.3% of captopril treated patients (see WARNINGS). Two of these patients developed sepsis and died.

Dermatologic — Rash (usually mild, maculopapular, rarely urticarial), often with pruritus and sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 100 patients — reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular — Hypotension in about 2 of 100 patients. See WARNINGS (Hypotension) and PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia — About 7 of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice and hepatocellular injury with secondary cholestasis have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern in correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN should be taken one hour before meals. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 25, 50, and 100 mg in bottles of 100, and in UNIMATIC® unit-dose packs of 100 tablets.

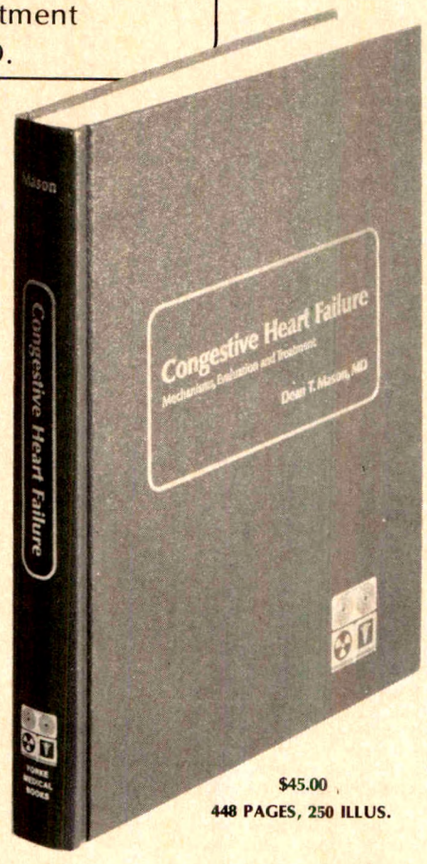
Congestive Heart Failure

Mechanisms, Evaluation and Treatment

Dean T. Mason, M.D.



This rare treatment of such a multifaceted subject provides an unusual opportunity for the busy clinician to add to his knowledge in a minimum amount of time. Any area of immediate interest can be rapidly located and as much data as needed can be quickly extracted. The concentration on improved clinical management will be appreciated by every internist, cardiologist, generalist, and any professional involved in cardiovascular medicine.

Dean Mason, President of the American College of Cardiology, has organized this monograph within the three areas relevant to an understanding of congestive heart failure: *mechanisms, evaluation* and *treatment*. Fifty-six recognized authorities have been assembled by Dr. Mason, each contributing their expertise to make this book the foremost text covering the highly important and common disorders of abnormal heart function.

This presentation of recent advances in basic research and clinical progress has been highly acclaimed for its major contribution to the improvement of patient care. We invite you to see if you don't agree. Order and take 30 days to look over the book. If you're not totally satisfied, return it.

Management of Adults With Congenital Bidirectional Cardiac Shunts, Cyanosis, and Pulmonary Vascular Obstruction: Successful Operative Repair in 3 Patients

VERDI J. DiSESA, MD, LAWRENCE H. COHN, MD, and WILLIAM GROSSMAN, MD

Patients with congenital cardiac shunts in whom marked functional disability, cyanosis and pulmonary arterial hypertension develop have been considered inoperable or at exceedingly high risk. Three adult patients, 2 with atrial septal defect (ASD) and 1 with patent ductus arteriosus (PDA), presented with New York Heart Association class IV symptoms, bidirectional shunting with cyanosis, polycythemia, severe pulmonary hypertension, and increased pulmonary vascular resistance. Pulmonary arterial pressure did not decrease in response to administration of 100% oxygen in any patient, and 2 had lung biopsy results showing advanced pulmonary vascular obstruction. While a right-to-left shunt caused cyanosis in all patients, the net shunt was left to right ($Q_p/Q_s > 1$) and the resistance ratio (R_p/R_s) <0.5. All 3 patients survived operation, became acyanotic with normal hematocrit, and are in functional class I or II a mean of 36 months postoperatively. At repeat cardiac catheterization, pulmonary arterial pressure and resistance had decreased substantially.

This high-risk group of patients with bidirectional shunts, in whom cyanosis due to pulmonary vascular obstruction and polycythemia develop and who appear to be at very high operative risk, should still be considered for surgical correction if the usual criteria for operability exist: net left-to-right Q_p/Q_s and R_p/R_s <0.50.

Patients with congenital left-to-right shunts in whom severe functional disability, cyanosis, and pulmonary hypertensive changes in the lungs develop have been considered at high operative risk. In adults, this complex is particularly ominous and often portends Eisenmenger's syndrome with a predominent right-to-left shunt.[1] However, a small group of patients presenting with this clinical syndrome are not inoperable because their *net* shunt remains left to right. Because of the longstanding uncorrected anomaly, they have a significant component of right-to-left shunting producing cyanosis.[2,3] Although simulating Eisenmenger's syndrome clinically, these patients may, in fact, be operated upon and may go on to lead a relatively normal life after precise catheter diagnosis and surgical correction. This report details experience with 3 such patients who appeared inoperable on initial clinical evaluation but who have done well in long-term follow-up after preoperative hemodynamic study and surgical correction.

From the Departments of Surgery and Medicine, Harvard Medical School and the Brigham and Women's Hospital, Boston, Massachusetts. This study was supported in part by Grant HL 19246 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received December 6, 1982; revised manuscript received January 31, 1983, accepted February 2, 1983.

Address for reprints: Lawrence H. Cohn, MD, Department of Surgery, Brigham and Women's Hospital, 75 Francis Street, Boston, Massachusetts 02115.

Clinical Material

These 3 consecutive patients were operated upon between 1977 and 1980. Two patients underwent closure of an atrial septal defect (ASD) and 1 had ligation of a patent ductus arteriosus (PDA). All patients underwent complete cardiac catheterization preoperatively and at least once postoperatively. Oxygen consumption for calculation of cardiac output was measured (not assumed), and pulmonary venous sampling was obtained in the 2 patients with ASD. In all patients, preoperative pulmonary arterial pressures and resistances were evaluated with and without the administration of 100% oxygen for 15 minutes. Other forms of pharmacologic pulmonary vasodilatation such as priscoline or prostacyclin were not administered. Two patients (1 with ASD, 1 with PDA) had concomitant lung biopsies at operation. The pre- and postoperative hemodynamic features are detailed in Table I. Pre- and postoperative chest x-rays of Patients 1 and 2 are shown in Figures 1 and 2.

Discussion

The development of cyanosis due to pulmonary vascular obstruction has long been considered an ominous prognostic sign in patients with a congenital left-to-right

shunt.[1–5] Efforts to develop criteria of operability in these patients have focused on histologic and hemodynamic assessments of the reversibility of pulmonary vascular disease.

Since 1958, when Heath and Edwards[6] described the morphologic changes in the lung in pulmonary hypertension, attempts have been made to correlate pathologic grade with reversibility of disease. Grade IV to VI pulmonary hypertensive changes have been generally considered to be irreversible.[7] Rabinovitch et al[8] and Wagenvoort[9] have recently suggested that analysis of lung biopsies may help determine operability in patients who have severe pulmonary hypertension with histologic pulmonary vascular changes. If irreversible changes are present on biopsy, surgery is not advised. Furthermore, Wagenvoort[9] contends that a 2 × 1 × 1 cm biopsy specimen is representative of the pulmonary vascular disease in the lung as a whole. This amount of lung tissue was available in the biopsies of our 2 patients who had changes of advanced pulmonary vascular obstruction (grade IV).

Other authors have proposed more dynamic tests of the reversibility of pulmonary vascular obstruction. For example, failure of pulmonary arterial pressure and vascular resistance to decrease after breathing 100% oxygen,[10,11] as used in our patients, has been considered a contraindication to surgery. However, all 3 of our patients had nonreversibility of pulmonary hypertension with 100% oxygen.

Despite the clinical appearance of inoperability due to the development of cyanosis and pulmonary hypertension, and failing the 2 aforementioned objective tests of operability, our 3 patients did well after surgical correction. Although all 3 patients had right-to-left shunts sufficient to cause cyanosis and polycythemia,

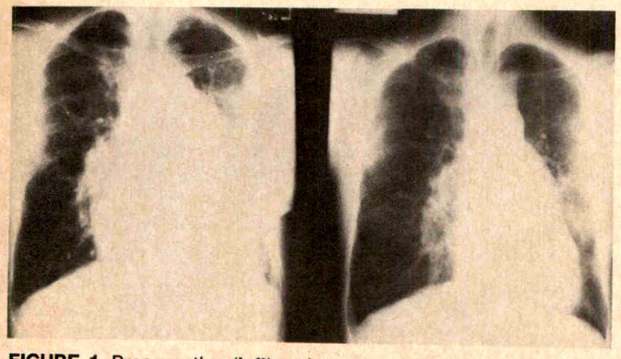

FIGURE 1. Preoperative (**left**) and postoperative (**right**) chest roentgenograms of Patient 1 documenting reduction in cardiomegaly and pulmonary plethora.

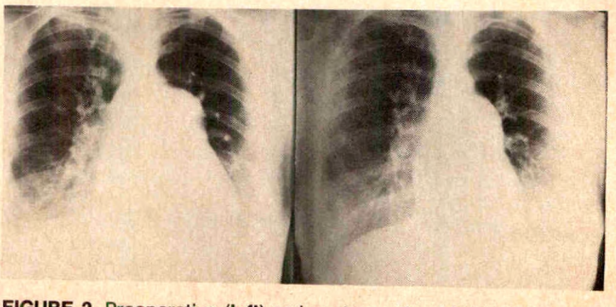

FIGURE 2. Preoperative (**left**) and postoperative (**right**) chest roentgenograms of Patient 2 showing substantial improvement.

the predominant shunt at cardiac catheterization was still left to right ($Q_p/Q_s > 1$). Obviously, when Q_p/Q_s is <1, pulmonary vascular obstruction is too severe to permit surgery. Second, the resistance ratio (R_p/R_s) was <0.5 in all 3 patients. This ratio takes into account miscellaneous factors (catecholamines and blood viscosity) that affect both pulmonary and systemic vascular beds. It therefore eliminates the need for specific corrections for these factors when assessing the severity of intrinsic pulmonary vascular changes.[12,13] These are the 2 key factors in assessing operability.

In addition, systemic arterial desaturation, observed preoperatively in our patients, can itself cause symptoms and hemodynamic abnormalities that exaggerate pulmonary vascular obstruction. Braunwald and Morrow[14] showed that despite persistent pulmonary hypertension after partial shunt closure, patients may have marked symptomatic improvement due to the amelioration of arterial oxygen desaturation alone.

Finally, the decrease in hematocrit and blood viscosity usually seen after elimination of cyanosis has been shown to cause a reduction in both pulmonary arterial pressure and resistance.[15,16] Hemodilution associated with cardiopulmonary bypass and the correction of hematocrit due to elimination of the right-to-left shunt probably contributed significantly to our patients' early clinical response. However, altered blood viscosity alone cannot explain the progressive improvements in pulmonary hemodynamic function that occurred after hematocrit and oxygen saturation had returned to normal.

Acknowledgment: We thank Stephen VanDevanter, MD, who operated on Patient 3 and permitted us to include this patient in our series, Gerald Angoff, MD, who performed postoperative cardiac catheterization on Patient 3, and Barbara Hebert for manuscript preparation.

Obstruction Within the Right Ventricular Body: Two-Dimensional Echocardiographic Features

LAURA J. Von DOENHOFF, MD and NAVIN C. NANDA, MD

Real-time 2-dimensional (2-D) echocardiograms were performed in 4 patients, all with considerable obstruction within the right ventricular (RV) body, in 3 patients due to muscle bundles and in 1 due to hypertrophic cardiomyopathy (HC). None had obstruction at the pulmonic valve level or immediately below. Echocardiographically, obstruction presented in 3 patients as localized bulging of the RV free wall in the subinfundibular region such that the RV cavity presented a typical "hourglass" appearance. Associated ventricular septal defect (VSD) was detected in 2 patients by echocardiography. In the fourth case, a patient with HC, RV obstruction was associated with a prominent bulge of the ventricular septum into the right ventricle. In 3 patients, the obstruction was convincingly demonstrated only in the subcostal RV inflow-apex-outflow plane, rather than in the standard echocardiographic planes. Pulse Doppler studies in 2 patients demonstrated disturbed RV flow. Obstruction within the RV body is a potentially serious condition which has been overlooked both at cardiac catheterization and at surgery. Demonstration of this lesion by 2-D echocardiography appears feasible and would greatly improve diagnostic accuracy.

Right ventricular (RV) body obstruction, although uncommon, is often surgically remediable. Its clinical diagnosis is difficult since the findings may mimic tetralogy of Fallot or other forms of RV obstruction, and the lesion may coexist with, as well as mimic, ventricular septal defect (VSD)[1,2] and valvular pulmonic stenosis.[3] The diagnosis has occasionally been missed even at cardiac catheterization[2] and at surgery.[3] We report here the first definitive application of real-time 2-dimensional (2-D) echocardiography in the diagnosis of RV obstruction at the subinfundibular level.

Methods

Four patients, 3 male and 1 female, aged 2 to 48 years (Table I) were studied. All had intracavitary RV pressure gradients and evidence of severe discrete RV cavity narrowing at biplane ventriculography. None had evidence of valvular or classic infundibular pulmonic stenosis. All patients underwent 2-D echocardiographic examinations which were performed with an Advanced Technology Laboratories (ATL) wide angle 90° sector scanner using the standard planes. Three of the 4 patients were examined echocardiographically either before or without knowledge of the catheterization findings. The subcostal RV inflow-apex-outflow (IAO) plane, which has proven particularly useful in the study of RV wall motion,[4] also was obtained in 3 patients. In this view, the transducer is pressed firmly into the epigastrium and directed superiorly and somewhat anteriorly so that the ultrasonic beam passes through the diaphragmatic wall to view the tricuspid valve apparatus, the RV apex, and the pulmonic valve (Fig. 1 to 3).

The RV diaphragmatic wall maximal end-diastolic thickness was measured at the onset of the QRS complex in the subcostal 4-chamber plane and was considered to be hypertrophied if the measurement was >5 mm[5]. HC was considered present if the ventricular septal thickness was ≥15 mm, if its ratio to posterior wall thickness was ≥1.5:1, and if narrowing of the left ventricular (LV) outflow tract to <20 mm and prominent systolic anterior motion of the mitral valve also were present.[6]

Pulse Doppler studies were performed in 2 patients using an ATL Mark V Duplex system in which blood flow patterns were sampled in the right ventricle along a cursor line placed on the 2-D image. Disturbed flow was characterized by multiple widely fluctuating frequencies in the Doppler shifts, outlined graphically on the time-interval histogram. All 2-D and Doppler echocardiographic studies were reviewed by 2 independent observers.

Results

The 2 observers agreed in their analysis of the echocardiographic findings which, along with the clinical findings, are summarized in Table I. In all patients the most dramatic finding was the demonstration of marked localized narrowing of the RV subinfundibular area, to one third or less the width of the adjacent cavity. In Patients 1, 2, and 3, there was localized bulging of the RV free wall well below the pulmonic valve in the subinfundibular region, such that the RV cavity presented a typical hourglass appearance. In Patients 1 and 2, this was identified convincingly only in the IAO plane (Fig. 4). In Patient 3, the obstruction was seen from a parasternal oblique short-axis view (Fig. 5) but was not well appreciated in the apical 4-chamber view. The IAO

TABLE I Summary of Patients' Data

Patient	Age (yr) & Sex	Symptoms, Murmur, Cardiomegaly	Pressure Gradient (mm Hg)		VSD at Cath	Echocardiographic	
			Right Ventricle	Left Ventricle		RVH	VSD
1	48M	0, +, +	25	0	+	+	0
2	2M	N, +, +	33	0	+	+	+
3	18F	0, +, +	58	0	+	+	+
4	27M	+, +, +	60	80	0	+	0

+ = present; 0 = absent; Cath = catheterization; N = not applicable; RVH = right ventricular hypertrophy; VSD = ventricular septal defect.

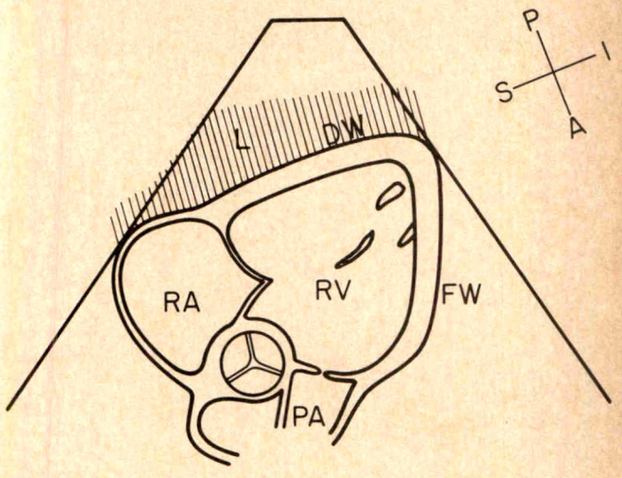

FIGURE 1. Subcostal right ventricular (RV) inflow-apex-outflow plane. In this view, the transducer is pressed firmly into the epigastrium and directed superiorly and somewhat anteriorly so that the ultrasonic beam passes through the diaphragmatic wall (DW) to view the right atrium (RA), tricuspid valve, right ventricle, and RV outflow area. In this plane, the pulmonic valve and pulmonary artery (PA) are relatively anterior (A) as well as superior (S) to the RV DW, and the RA is relatively superior as well as somewhat to the right of the RV apex. The orientation compass is simplified to depict only 4 directions, and they are approximate. FW = free wall; I = inferior; L = liver; P = posterior.

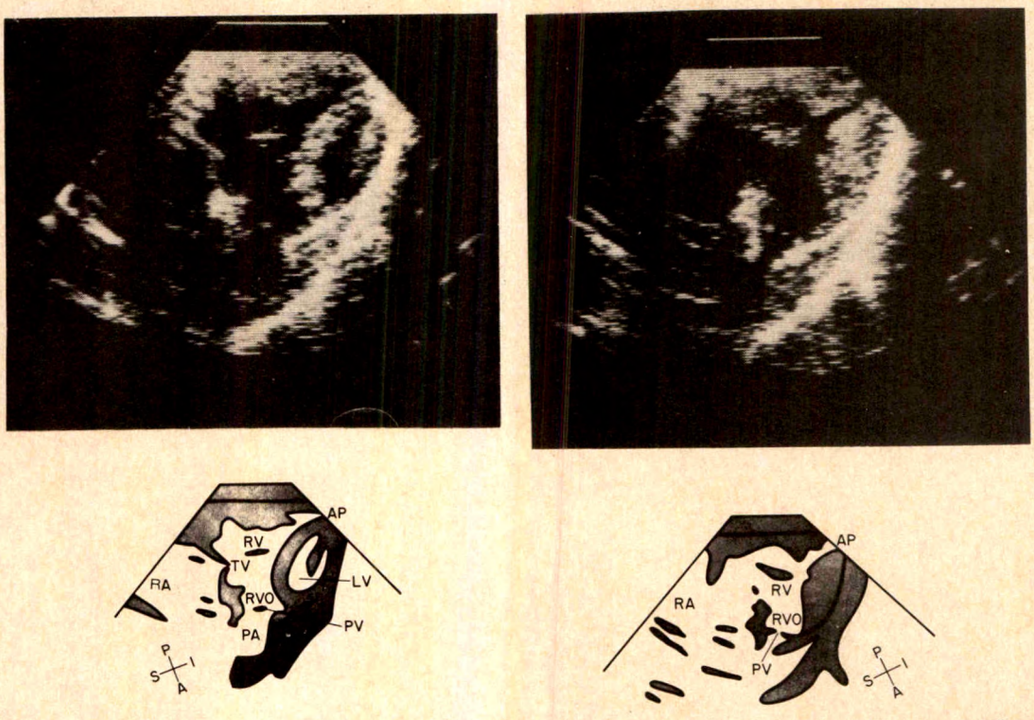

FIGURE 2. Subcostal planes in a normal subject. **Left,** as in Figure 1, the transducer is pressed firmly into the epigastrium and directed superiorly and somewhat anteriorly to display the RA and the right ventricular outflow tract, but it is also directed leftward to display the left ventricle (LV). Septal anatomy can thus be studied. **Right,** as the transducer is rotated in the same patient to exclude the LV from view, the FW of the RV appears and can be studied. Distinction can thus be made between prominences of the right ventricular FW and those of the right side of the septum. The aortic root is not included in this plane. AP = right ventricular apex; PV = pulmonic valve; RVO = right ventricular outflow tract; TV = tricuspid valve. Orientation and other abbreviations as in Figure 1.

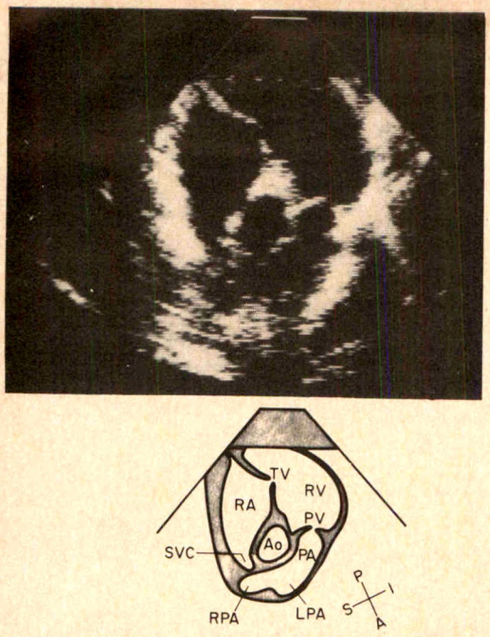

FIGURE 3. The subcostal inflow-apex-outflow plane is best visualized in children and in adult patients with RV dilatation without obstruction. In this adult, the right ventricle is dilated and the RV free wall is normal and creates no narrowing. Ao = aorta; LPA = left pulmonary artery; RPA = right pulmonary artery; SVC = superior vena cava. Orientation and other abbreviations as in Figures 1 and 2.

FIGURE 4. Subcostal inflow-apex-outflow plane in Case 1, a patient with RV subinfundibular obstruction. The free wall bulges markedly into the subinfundibular portion of the right ventricle, creating an hourglass narrowing. On the scale, the distance between 2 of the larger marks represents 10 mm. N = narrowing; RVA = RV apex; RVI = RV inflow area. Orientation and other abbreviations as in Figures 1 to 3.

plane was not obtained in this patient. In Patients 2 and 3, a VSD was observed echocardiographically. In Patient 4, HC was present, and a subinfundibular ventricular septal bulge was seen in the IAO plane, as well as apical RV cavity obliteration in the long-axis plane. In this patient, the ventricular septum was 40 mm thick, the LV posterior wall 10 mm thick, the LV outflow tract was 15 mm wide, and prominent systolic anterior movements of the mitral valve were present.

In both patients in whom pulse Doppler studies were performed (Patients 1 and 4), the time-interval histogram showed disturbed flow when the Doppler sample volume was positioned in the right ventricle. Figure 6 depicts the findings in Patient 1.

All patients had hypertrophy of the RV diaphragmatic wall. None had 2-D echocardiographic systolic doming of the pulmonic valve suggestive of pulmonic valvular stenosis. The pulmonic valve on the M-mode

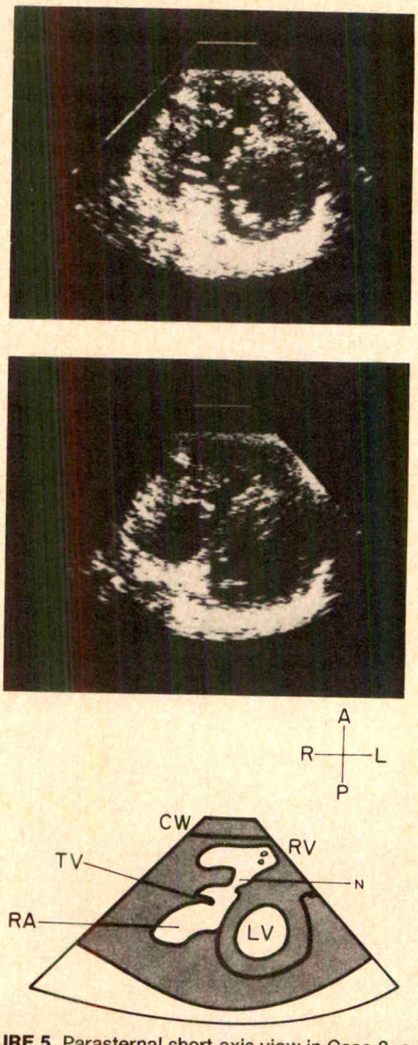

FIGURE 5. Parasternal short-axis view in Case 3, a patient with RV obstruction caused by a finger-like projection from the free wall of the right ventricle. CW = chest wall; L = left; R = right. Other abbreviations as in Figures 1 to 4.

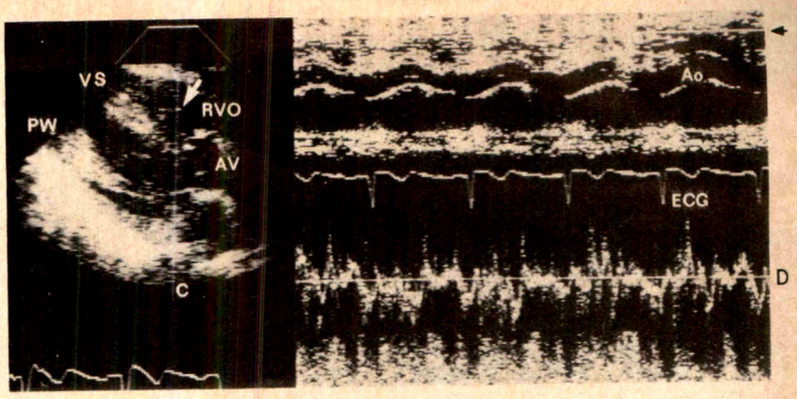

FIGURE 6. Pulse Doppler studies in Case 1, a patient with RV subinfundibular obstruction. **Left panel,** the long-axis view shows the site of the Doppler sample volume within the right ventricle (**white arrow**). **Right panel,** the time-interval histogram demonstrates multiple widely fluctuating frequencies in the Doppler shifts suggestive of disturbed flow. The **black arrow** denotes the sample site in the right ventricle on the M-mode tracing obtained along the cursor line. Ao = left ventricular outflow area; AV = aortic valve; C = cursor line; D = Doppler signals; ECG = electrocardiogram; PW = posterior wall; VS = ventricular septum. Other abbreviations as in Figures 1 to 5.

showed high frequency systolic fluttering in Patients 1, 2, and 3 and midsystolic notching in Patient 1; it was normal in Patient 4.

Discussion

Aberrant RV muscle bands may exist without interfering with flow, particularly if they are small. They may, however, be hypertrophied, and obstruction occurs when sufficiently enlarged muscle bands project into the subinfundibular region and create a pressure gradient.[2] The term "2-chambered right ventricle" has been applied to the division of the right ventricle into 2 chambers by aberrant, hypertrophied muscular bands.[1] HC also may result in right-sided obstruction, which is most likely a consequence of both anatomic abnormalities and dynamic factors.[7]

Our study indicates that either form of RV body obstruction can be characterized by 2-D echocardiography provided that a careful search is performed using not only the standard planes, but also several newer RV planes.[8] The optimal planes must be sought in each patient. For example, distinction can be made by 2-D echocardiography between prominences of the RV free wall and the right side of the septum. Figure 2 depicts the subcostal plane which includes the left ventricle as well as the RV outflow tract; septal anatomy can be studied in this view. As the transducer is rotated to exclude the left ventricle from view, the RV free wall appears and can be studied.

Doppler identification of disturbed RV flow is not specific for RV body obstruction, but reliable measurement of peak velocity with more advanced equipment may prove useful in computing RV pressure gradient noninvasively.

Quantitative Analysis of Pulmonary Vascular Disease in Simple Cardiac Anomalies With the Down Syndrome

SHIGEO YAMAKI, MD, PhD, TOGO HORIUCHI, MD, PhD, and YOSHIHITO SEKINO, MD

Intimal changes and medial thickness of small pulmonary arteries were morphometrically examined in 21 cases of simple cardiac anomalies with the Down syndrome, and their correlations with age and with pulmonary arterial peak pressure were then compared with those of 20 cases of simple cardiac anomalies without the Down syndrome and 17 cases of complete transposition of the great arteries (TGA). Results indicate that (1) intimal changes developed at an earlier age in patients with simple cardiac anomalies and the Down syndrome than in those without the Down syndrome, (2) the intimal changes were more severe than those in simple cardiac anomalies without the Down syndrome at the same level of pulmonary arterial pressure and milder than those in TGA, and (3) the media of small pulmonary arteries in simple cardiac anomalies with the Down syndrome was thinner than the media in cases without the syndrome at the same radius and the same level of pulmonary arterial pressure but thicker than the media in TGA. Retarded development of medial hypertrophy in the Down syndrome or TGA in response to pulmonary hypertension appears to make the pulmonary arteries susceptible to even moderate pressure load and appears to be responsible for early development of severe intimal changes.

Generally, pulmonary hypertension develops from infancy in cases of congenital heart disease with the Down syndrome, but the characteristics of the pulmonary vascular bed remain unclear. We previously investigated the mechanism of early development of severe pulmonary vascular disease in complete transposition of the great arteries (TGA) on the basis of morphometric assessment and hemodynamic consideration.[1] In the present study, we applied the same methods in cases of simple cardiac anomalies with the Down syndrome, and the results were compared with those obtained in cases of simple cardiac anomalies without the Down syndrome and in cases of TGA. The severity of intimal changes and medial thickness of small pulmonary arteries determined by morphometric assessment were correlated with pulmonary arterial peak pressure in each group. The results indicated that the development of pulmonary vascular disease in the Down syndrome differed from that in the group without the Down syndrome or TGA.

Methods

Patient selection: Twenty-one cases of simple cardiac anomalies with the Down syndrome including 12 cases of ventricular septal defect (VSD), 4 cases of patent ductus arteriosus (PDA), 4 cases of VSD with PDA, and 1 case of PDA with atrial septal defect (ASD) were examined in the present study. Lung specimens were obtained at biopsy in 15 cases and at autopsy in 6. The patients' ages varied from 6 months to 10 years (Table I).

Control material consisted of 20 autopsy cases of simple cardiac anomalies without the Down syndrome and 17 autopsy cases of TGA. The simple cardiac anomalies without the Down syndrome consisted of 12 cases of VSD, 2 of PDA, 2 of ASD, 3 of VSD with PDA, and 1 of ASD with PDA. Their ages ranged from 7 months to 24 years (Table II). The breakdown of TGA was as follows: 7 cases of TGA with intact ventricular septum, 9 with large VSD, and 1 with VSD and pulmonary stenosis; their ages ranged from 8 months to 12 years (Table III). Cases <6 months of age were excluded from all 3 groups of heart disease.

Cardiac catheterization was performed according to a previously reported method.[2] Pulmonary arterial pressure measured within 2 months before operation or death in all 3 groups of heart disease was taken into consideration.

19	1 yr 9 mo	PDA	30/11(19)	10.3	1.1	11.3
20	7 mo	VSD	125/60(85)	19.6	2.0	39.2

Abbreviations as in Table I.

Pathologic examination: Biopsy lung tissue 1.5 by 2 by 0.5 cm obtained primarily from the lingula was fixed in 10% formalin, and a total of 30 sections from 3 blocks were made by step section at every 100 μm. In the autopsy cases, a total of 30 sections were prepared in each case from both lungs. These were stained with Goldner's trichrome combined with Weigert's stain for elastic fibers and submitted to morphometric examination.

Grading of the pulmonary vascular disease: Grading of the pulmonary arterial intimal changes was made according to the previously introduced method using an index of pulmonary vascular disease.[1–5] All pulmonary arteries encountered in our biopsy and autopsy sections were evaluated. The thickness of the media of small pulmonary arteries was assessed by a method described in our previous studies.[1,3,4,6]

Results

Pulmonary arterial changes, expressed as an index of pulmonary vascular disease, were plotted against age in all cases of simple cardiac anomalies with and without the Down syndrome and TGA (Fig. 1). There was no significant difference in the index between cases of simple cardiac anomalies with and those without the Down syndrome. However, in children <6 years of age, the index was significantly higher ($p < 0.05$) in the Down syndrome cases than in the non-Down syndrome cases (Mann-Whitney U test). Results indicate that pulmonary arterial intimal changes developed at an early stage in the Down syndrome.

TABLE III Summary of Hemodynamics and Histometric Analysis in 17 Cases of Complete Transposition of the Great Arteries

17	10 mo	TGA	18/6(10)	7.5	1.0	7.5

PS = pulmonary stenosis; TGA = complete transposition of the great arteries; other abbreviations as in Table I.

A significant correlation ($p < 0.01$) was found between peak pulmonary arterial pressure and the index of pulmonary vascular disease in all 3 groups (Fig. 2). Significant differences were present in the elevation of the regression lines, whereas no differences in the slopes were found among the groups. The regression line of the Down syndrome group was slightly higher than that of the group of simple cardiac anomalies without the Down syndrome ($p < 0.05$) and significantly lower than that in cases of TGA ($p < 0.01$). In other words, the index of Down syndrome cases was higher than that in cases without the syndrome and lower than that in cases of TGA at any given level of pulmonary arterial pressure.

Consequently, it is concluded that the pulmonary arterial intimal changes in simple cardiac anomalies with the Down syndrome are more severe than those in simple cardiac anomalies without the Down syndrome even at the same pressure level and less severe than those in cases of TGA.

The pulmonary arterial peak pressure and medial thickness at a radius of 100 μm ($D_{R=100\ \mu m}$) in all cases in the 3 groups were plotted on a semilogarithmic coordinate system. The results showed significant correlation between them in all 3 groups ($p < 0.001$) (Fig. 3). In the slopes of the regression equations, there were no significant group differences. However, the elevation of the regression line in cases of simple cardiac anomalies with the Down syndrome was significantly lower than that of simple cardiac anomalies without the Down

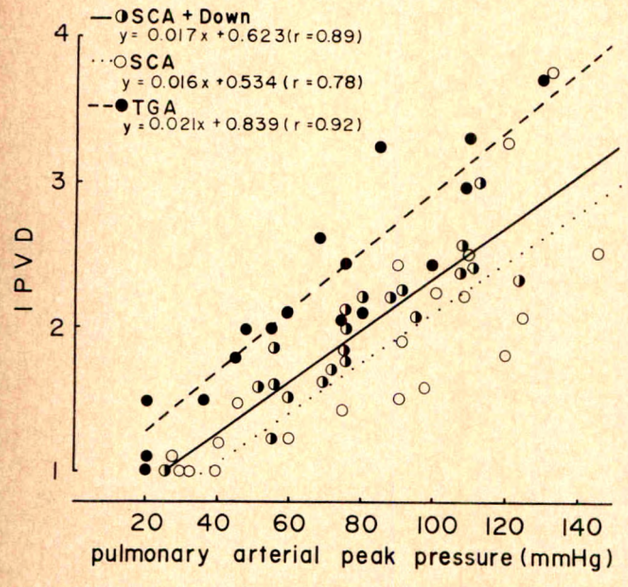

FIGURE 2. Indexes of pulmonary vascular disease (IPVD) against pulmonary arterial peak pressure in simple cardiac anomalies (SCA) with or without the Down syndrome and complete transposition of the great arteries (TGA). Correlation between the 2 parameters is observed in each group, and the regression equations obtained from the 3 groups have different elevations.

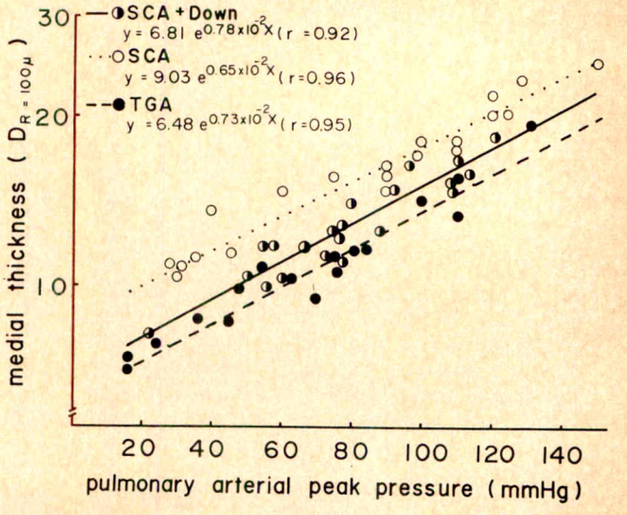

FIGURE 3. Medial thickness $D_{R=100\ \mu m}$ against pulmonary arterial peak pressure in simple cardiac anomalies (SCA) with or without the Down syndrome and complete transposition of the great arteries (TGA). Linear regressions differ among the groups. Note the difference in the elevations of regression lines among the groups.

syndrome ($p < 0.01$) and significantly higher than that of TGA ($p < 0.001$). Consequently, the media in the Down syndrome cases was thinner than that of the cases without the Down syndrome at the same level of pulmonary arterial pressure. On the other hand, it was thicker than that of TGA.

A score for the total of pulmonary vascular changes[4] was obtained by multiplying the index by the medial thickness, $D_{R=100\ \mu m}$, and the results were compared among the groups in relation to pulmonary arterial pressure on a semilogarithmic coordinate system (Fig. 4). A linear relation was found in all 3 groups, and the slopes and elevations were identical. Therefore, we conclude that the total pulmonary vascular alterations are directly proportional to the pulmonary arterial pressure and furthermore that similar scores for total pulmonary alteration are found at similar pulmonary arterial pressures, regardless of the different types of cardiac anomalies.

Discussion

Patients with congenital heart disease associated with the Down syndrome frequently develop severe pulmonary hypertension at an early age.[7–11] Park et al[12] reported severe pulmonary arterial intimal changes at an early age, but Plett et al[13] and Wilson et al[14] reported cases of TGA and complete atrioventricular canal with and without the Down syndrome and found no differences in the severity of intimal changes between the 2 groups. However, because intimal changes generally develop at an early age in cases of TGA[15] or complete atrioventricular canal[16] even without the Down syndrome, what influence the Down syndrome may have on the development of intimal changes would not be clarified in such a comparison. Therefore, the present study was undertaken to compare the intimal changes in cases with or without the Down syndrome associated with simple cardiac anomalies, in which such lesions are known to develop slowly. It could demonstrate that the index of pulmonary vascular disease in patients <6 years in age with simple cardiac anomalies associated with the Down syndrome was higher than that in patients without the syndrome. On closer investigation, there were differences among the 3 groups of simple cardiac anomalies with and without the Down syndrome and TGA with regard to the severity of intimal changes even at a certain given level of pulmonary arterial pressure. The most severe intimal changes were seen in TGA. The grade was followed by those in simple cardiac anomalies with the Down syndrome and then simple cardiac anomalies without the syndrome.

The pathogenesis of the intimal changes which are different in the Down syndrome and the non-Down syndrome must be considered. We previously investigated the mechanism of early development of pulmonary intimal changes in TGA by analyzing the response of the media of small pulmonary arteries to increasing pulmonary arterial pressure.[1] Hypertrophy of the media scarcely occurred in TGA in the first 5 months after birth even when pulmonary hypertension was present. For this reason, the media in complete transposition of the great arteries is thinner than the media in VSD in patients >6 months of age, even when similar levels of pulmonary arterial pressure are found. The present investigation using the same methods reveals that the medial thickness in simple cardiac anomalies with the Down syndrome was greater than that in TGA but less than that in simple cardiac anomalies without the Down syndrome at the same pulmonary arterial pressure level.

An increase in intraarterial pressure enhances the tension T of the arterial walls in accordance with Laplace's law: $T = (P \times R)/D$, where P is the intraarterial pressure, R the radius, and D the thickness of the media[6,17] (Fig. 5). Consequently, when P and R are constant, T is influenced by D. In the present study, the medial thickness D was found to be smallest in TGA. The order of medial thickness was followed by simple cardiac anomalies with the Down syndrome and then those without the Down syndrome under the condition that the radius and the pulmonary arterial pressure were held constant. Therefore, we can conclude that the tension of the arterial wall is greater in TGA followed, in descending order, by simple cardiac anomalies with the Down syndrome and simple cardiac anomalies without the Down syndrome. Intimal changes can occur earlier in that order. In other words, adequate medial hypertrophy in simple cardiac anomalies with pulmonary hypertension can protect the small pulmonary

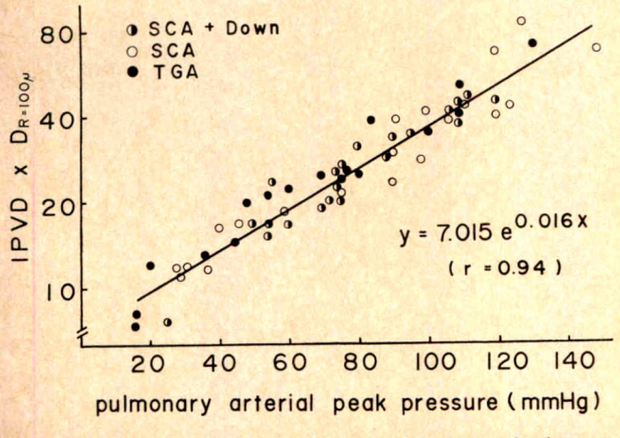

FIGURE 4. Products of medial thickness and the index of pulmonary vascular disease ($D_{R=100\ \mu m} \times$ IPVD) plotted against pulmonary arterial peak pressure in simple cardiac anomalies (SCA) with or without the Down syndrome and complete transposition of the great arteries (TGA). The 3 groups of cardiac diseases yield a common linear regression.

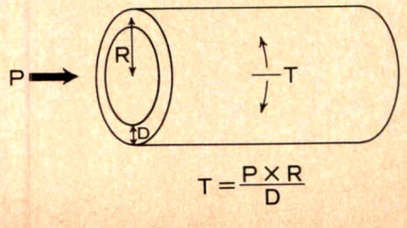

FIGURE 5. Diagram showing the relation among pressure (P), radius (R), medial thickness (D), and tension (T) in the arterial wall.

arteries from the development of intimal changes,[4] but insufficient hypertrophy of the media in cases of the Down syndrome or TGA with pulmonary hypertension fails to prevent early development of intimal changes.

Insufficient medial hypertrophy in TGA may be due to hyperoxic blood in the pulmonary circulation which is characteristic of this disease. It could suppress hypertrophy of the media.[2,18] However, in cases of simple cardiac anomalies with the Down syndrome, insufficient medial hypertrophy is unlikely to be brought about by hyperoxic blood in the pulmonary circulation. Congenital underdevelopment of the smooth muscle fibers of the media might be a probable cause.

The present study revealed different degrees of intimal changes and medial thickness of small pulmonary arteries even at a given level of pulmonary arterial pressure in 3 groups of congenital heart disease. However, the products of intimal changes and medial thickness at a given level of pulmonary arterial pressure were practically the same regardless of the type of cardiac disease, and their correlation with pulmonary arterial pressure could be represented by a regression equation common to the 3 groups of cardiac diseases. These findings suggest that the degree of pulmonary arterial pressure can be estimated histologically by the product of these 2 factors regardless of the type of cardiac disease, although these cardiac diseases have their own characteristic response of medial hypertrophy and intimal changes to increasing pulmonary arterial pressure.

Two-Dimensional Echocardiographic Recognition Of the Right Aortic Arch

VINCENZO CELANO, MD, DANIEL R. PIERONI, MD, ROBERT L. GINGELL, MD, and J-MICHEL A. ROLAND, MD

A mirror-image right aortic arch (RAA) is frequently associated with congenital heart disease. The chest roentgenogram with or without contrast remains the noninvasive diagnostic method of choice. While 2-dimensional (2-D) echocardiography has been used to elucidate the left aortic arch (LAA), detailed description of the technique for RAA has not been reported. This study was pursued to delineate the 2-D echocardiographic approach to the patient with RAA. Twenty-seven patients in this study had LAA (Group A) and 27 had RAA (Group B). The 2-D echocardiographic examinations concentrated on the standard suprasternal long-axis (SSNL), parasternal long and short axes, and the subcostal abdominal short-axis views. When the SSNL failed to demonstrate LAA, an alternate position for RAA was utilized.

The SSNL correctly identified the LAA in all Group A patients, but in Group B it located only the ascending aorta. This simulated an interrupted aortic arch anomaly. Transducer realignment to position 2 confirmed RAA in all Group B patients. In the parasternal axes, the left descending aorta was detected posterior to the atrioventricular groove or the left ventricle in every Group A patient but in no Group B patient. The descending aorta was found to the left of the spine on the abdominal short-axis view in both groups.

The 2-D echocardiographic technique proposed for RAA is simple, rapid, and definitive. It should be pursued whenever LAA cannot be demonstrated, especially in children suspected of having a congenital heart defect. Anticipation of RAA can expedite chest and cardiovascular surgery.

A right aortic arch (RAA) is a rare cardiovascular abnormality with an incidence of 0.1%.[1] When it does occur, it is commonly associated with a congenital heart defect. It is often seen in patients with tetralogy of Fallot, double outlet right ventricle, truncus arteriosus, isolated ventricular septal defect, tricuspid atresia, and transposition of the great arteries; it is less frequently seen with other congenital heart malformations.[2]

The anteroposterior chest radiogram is the current diagnostic technique of choice. If the aortic situs is equivocal or a prominent thymus obscures proper identification, then contrast esophagography should be performed. Angiography is seldom needed and represents obvious risk, especially in a critically ill infant.

Two-dimensional (2-D) echocardiography has been used to outline a left aortic arch (LAA), coarctation and interruption of the aorta, aortic aneurysm, and double aortic arch,[3–7] but the technique for examination of the patient with RAA has not been described in detail.

This study was pursued to establish the typical findings of RAA from various scanning angles with special reference to its delineation from the suprasternal notch approach.

Methods

Two-dimensional echocardiograms were obtained in a total of 54 patients. There were 27 patients with LAA, ranging in age from 2 days to 20 years (mean 6 years) (Group A) and 27 patients with RAA with an age range of 16 months to 25 years (mean 8 years) (Group B). All had or were about to undergo diagnostic cardiac catheterization for congenital heart defects (Table I). In both groups, the definitive assessment of the aortic arch situs was determined by aortography. Prospective echocardiography was recorded in 27 consecutive Group A patients before cardiac catheterization. Because of the scarcity of RAA, only 4 patients from Group B had echocardiography before the cardiac catheterization; the other 23 were recalled for their studies.

The 2-D echocardiograms were performed in the supine patient using a Toshiba SSH-10A real-time phased array 78° sector scanner with a variable focus 2.4 MHz transducer. The 2-D echocardiograms were reviewed from a standard 3/4- or 1/2-inch videotape recorder in real-time slow motion or

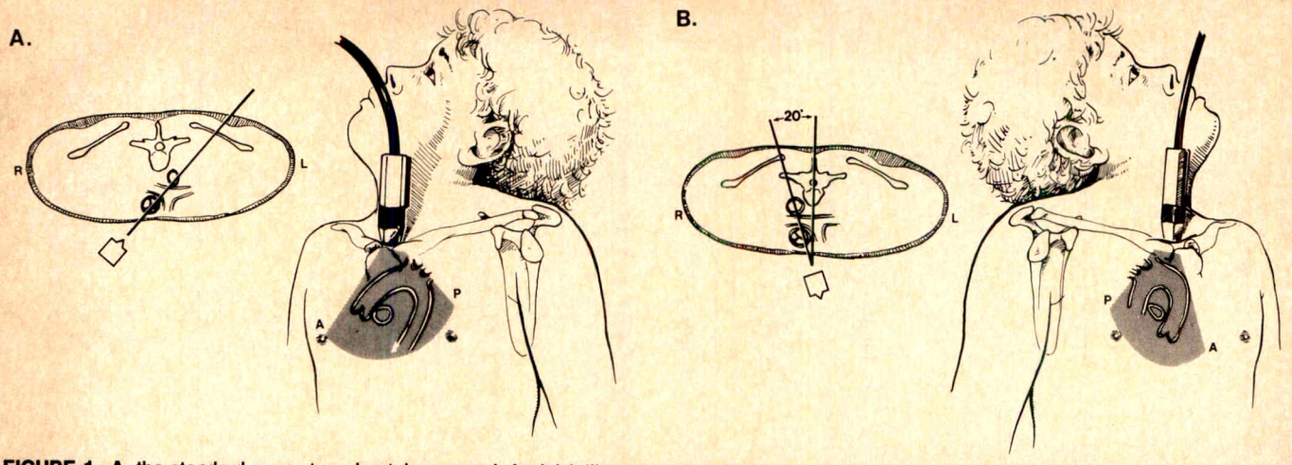

FIGURE 1. A, the standard suprasternal notch approach for LAA illustrates the sector plane extending anteriorly (A) from the right (R) nipple to the left (L) scapula posteriorly (P). The index marker of the transducer (**point**) was aimed to the back. **B,** the transducer was rotated clockwise to position 2 in search of a right aortic arch. The transducer index marker (**point**) was aimed away from the patient. The sector plane was from the left border of the sternum anteriorly to an area just to the right of the spine posteriorly. This formed an angle of approximately 20° from the midline.

frame-by-frame stop image. Photographs were made either in real-time or from a still videotape frame utilizing a Polaroid® camera. Gain settings were selected for optimal visualization of the far field in every study and then ranged from the minimum to the maximum damping positions.

All 2-D echocardiograms were obtained in 3 standard positions[8,9]: (1) standard suprasternal notch long-axis view (SSNL), (2) parasternal long-axis view, and (3) parasternal short-axis view of the left ventricle. In addition, a short-axis view of the abdomen in the subcostal position was recorded in each patient.

Special emphasis was placed upon visualization of the aorta from the suprasternal notch approach. The SSNL echocardiograms were performed with the head of the patient turned away from the midline and the neck slightly hyperextended. All SSNL studies were initiated by using position 1 (Fig. 1A). If the aortic arch could not be properly identified, then the transducer was rotated clockwise to position 2 in search of a right aortic arch (Fig. 1B). The sector plane extended from an area just to the right of the spine to the left border of the sternum. The transducer was tilted slightly toward the right and was approximately 15 to 20° from the midline.

Identification of the descending thoracic aorta was determined by noting its presence in the parasternal axes.[10] In the long-axis view, it is located posterior to the atrioventricular groove (Fig. 2A) and also posterior to the left ventricle in the short axis (Fig. 2B). The situs of the descending abdominal aorta was established from the subcostal short-axis scan of the abdomen by observing its position relative to the spine and inferior vena cava (Fig. 3).

TABLE I Findings on Diagnostic Cardiac Catheterization

Group A: LAA (n = 27)		Group B: RAA (n = 27)	
TOF	5	TOF	8
+ AVC	1	+ AVC	2
		+ COARC	1
		+ PAT	1
VSD	8	VSD	4
ASD	5	TGA complex	4
AVC	3	DORV	2
COARC	2	Ao arch anomaly	3
ASV	1	PSV	1
PSV	1	DXC	1

ASD = atrial septal defect; ASV = aortic stenosis valvar; AVC = complete atrioventricular canal; COARC = coarctation of the aorta; DORV = double outlet right ventricle; DXC = dextrocardia; PAT = pulmonary atresia; PSV = pulmonary stenosis valvar; TGA = complete transposition of the great arteries; TOF = tetralogy of Fallot; VSD = ventricular septal defect.

Results

It was possible to visualize the entire aortic arch in every (100%) patient with an LAA (Group A) by using the SSNL approach (position 1). The aortic valve marked the origin of the aorta at the lower-left margin of the video scan. The brachiocephalic vessels were easily recorded in all 27 patients just before the arch turned posteriorly to form the descending aorta along the right margin of the scan (Fig. 4). The parasternal long-axis view located the descending aorta which was characterized as a pulsatile circular or oval echo-free structure posterior to the left atrium or the atrioventricular groove in every patient (Fig. 2A). Likewise, in the parasternal short-axis view, it was universally noted behind the posterior left ventricle (Fig. 2B).

When the SSNL (position 1) approach was used in the Group B patients with RAA, it was possible to visualize only the ascending aorta (Fig. 5). It failed to elucidate either the aortic arch or descending aorta in every instance. Rotation of the transducer clockwise to position 2 revealed the 3 sections of the aorta in mirror image configuration in 100% of this group. The aortic valve appeared at the lower right edge of the video scan but the brachiocephalic vessels seemed to arise more distally on the arch than in the the Group A patients. The echocardiographic course of the aorta corresponded to the expected anatomy and the aortogram in all cases (Fig. 6).

In every Group B patient, the parasternal long- and short-axes views failed to illustrate the characteristic echo-free image of the descending aorta as it had been in the Group A patients (Fig. 7). In the last 2 RAA patients who were studied, a pulsatile echo-free round

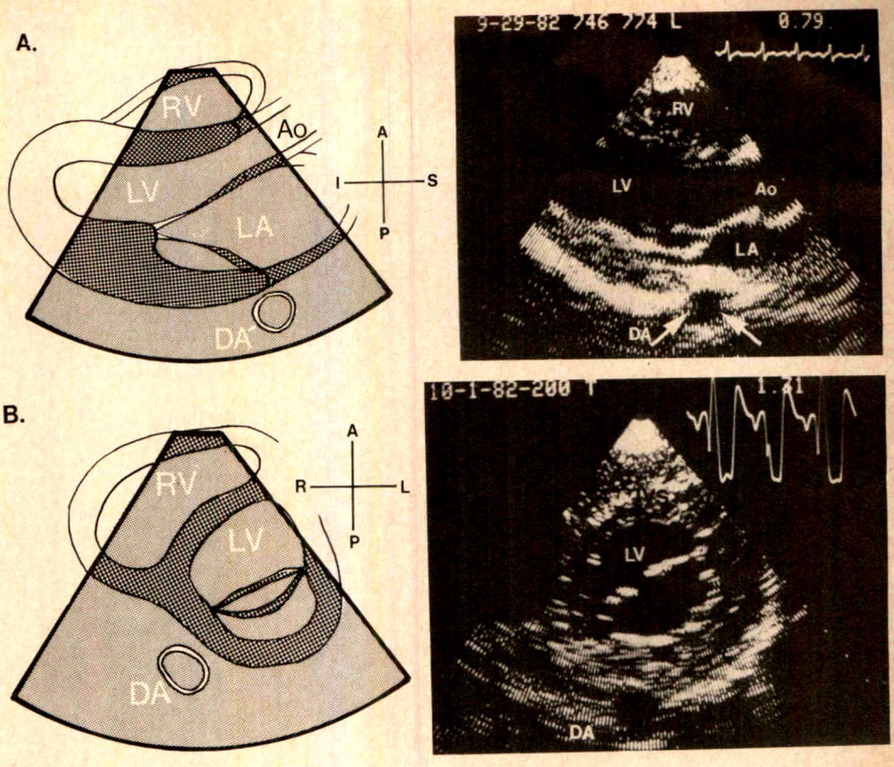

FIGURE 2. **A,** in the parasternal long-axis view, the typical left descending aorta (DA) was found behind the atrioventricular groove. **B,** the parasternal short-axis view at the level of the mitral valve classically located the left descending aorta posterior to the left ventricle (LV). Ao = aorta; LA = left atrium; RV = right ventricle; other abbreviations as before.

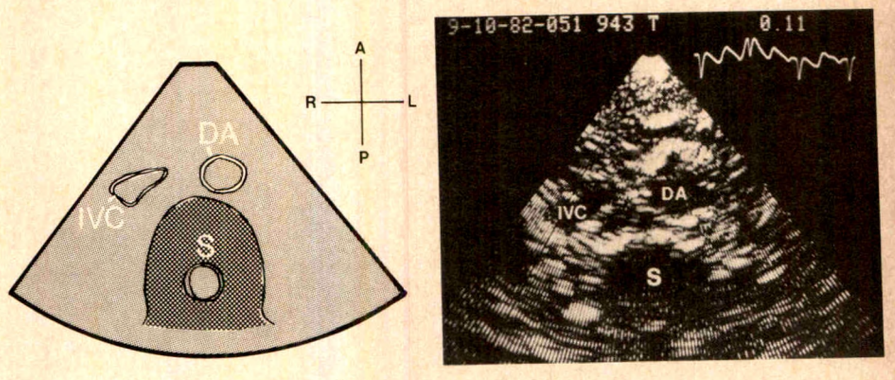

FIGURE 3. In the subcostal short-axis view of the abdomen, the descending aorta (DA) was noted as a round echo-free structure to the left of the spine (S). The inferior vena cava (IVC) was more triangular in appearance and to the right of the spine. Abbreviations as before.

structure was noted to the right of the spine in the short-axis view (Fig. 8).

The subcostal abdominal short-axis view visualized the descending abdominal aorta as a prominent pulsatile echo-free circular structure to the left of the spine in all 54 patients. The inferior vena cava, on the contrary, was always recorded to the right of the spine and appeared on the real-time image as a triangular space with venous pulsations (Fig. 3). These findings were consistent with the results of cardiac catheterization which confirmed abdominal situs solitus in every patient.

Discussion

Four major types of RAA have been described and classified.[2,11–13] They are characterized by (1) mirror-image branching of the brachiocephalic vessels, (2) an aberrant left subclavian artery, (3) an aberrant left innominate artery, and (4) isolation of the left subclavian artery from the aorta. Although RAA occurs in only 0.1% of the normal population, Stewart et al[13] reported a 98% incidence of congenital heart disease in the presence of a mirror-image RAA. Depending on the specific report, the incidence of RAA is 13 to 34% with tetralogy of Fallot, 20 to 25% with double outlet right ventricle, and 31 to 36% with truncus arteriosus.[1,2,14]

There are several situations in which identification of the situs of the aortic arch is of practical significance. Demonstration of RAA can provide indirect support when the clinician suspects associated congenital heart disease. It alerts the cardiologist that the infant with a ventricular septal defect might be at greater risk of developing a tetralogy-like physiology. Furthermore, the 2-D echocardiographic technique can be used to

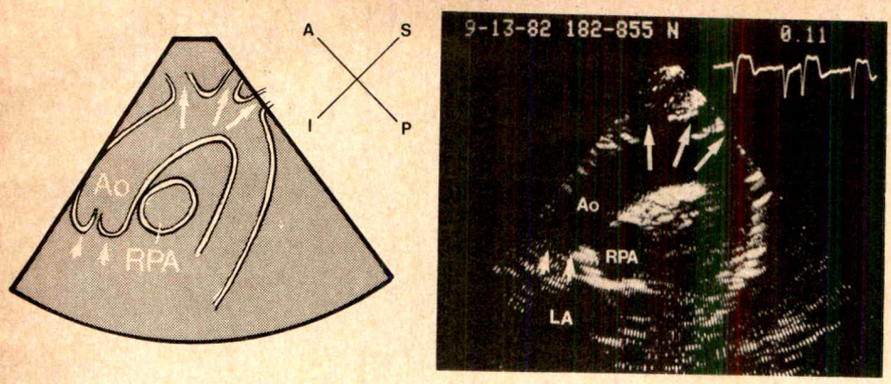

FIGURE 4. The typical left aortic arch was characterized by movement of the aortic valve leaflets (**short arrows**) at the lower-left margin of the scan followed by the brachiocephalic vessels (**long arrows**) and the descending aorta. RPA = right pulmonary artery; other abbreviations as before.

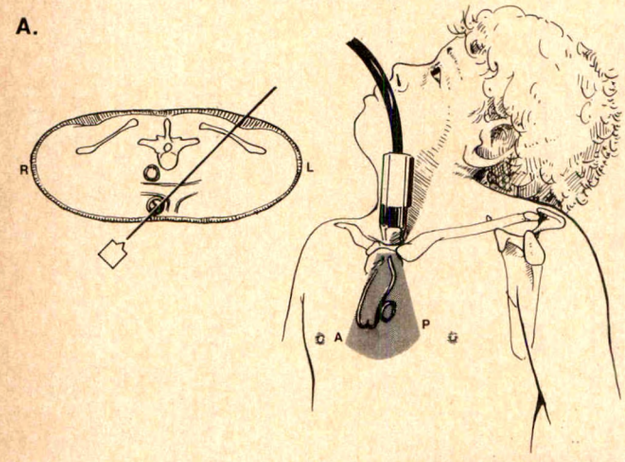

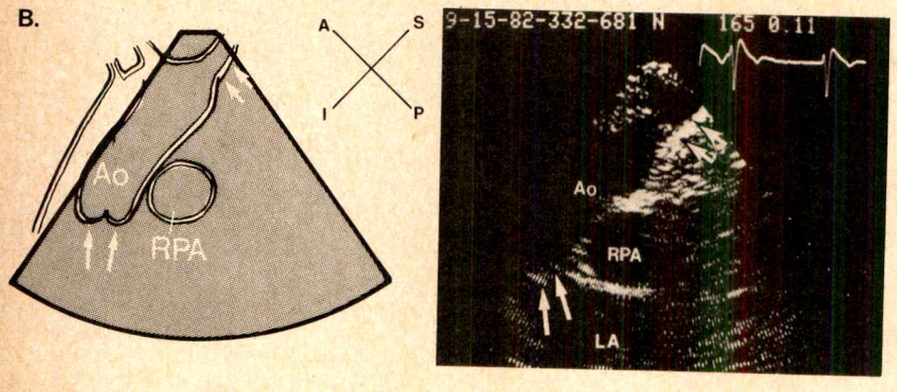

FIGURE 5. A, this illustration depicts why the standard suprasternal notch approach transects only part of the aorta in patients with RAA. **B,** only the ascending aorta was clearly visualized above the aortic valve (**long arrows**) when position 1 was pursued in this patient with RAA. It simulated an interrupted aortic arch anomaly (**short arrows**). Abbreviations as before.

confirm the presence of RAA in the tetralogy of Fallot patient awaiting a Blalock-Taussig shunt. A higher incidence of patency results when these anastomotic procedures are performed on the side opposite to the descending aorta.[15] Anticipation of the correct anatomy helps to avoid a less advantageous shunt. The infant with a tracheo-esophageal fistula represents another instance in which awareness of RAA is important. Chest surgeons prefer to approach such repairs without encountering the aorta. To expedite surgery, they use a thoracotomy contralateral to the descending aorta. If there is any question concerning the exact situs of the aortic arch from the chest roentgenogram, it can be easily resolved by the 2-D echocardiographic technique before cardiac catheterization or surgery.

Snider and Silverman,[5] in a large series detailing the standard suprasternal notch approach, were able to correctly identify RAA in 76% of their cases. However, they did not elaborate on the study technique for RAA. Although our study was somewhat retrospective, we encountered no difficulty in clearly locating the RAA. This was especially true when a systematic search was followed in all 3 scanning views. Under these conditions the correct situs of the aortic arch was easily detected in every patient. Lastly, it must be emphasized that the sector plane in search for RAA is usually only 15 to 20°

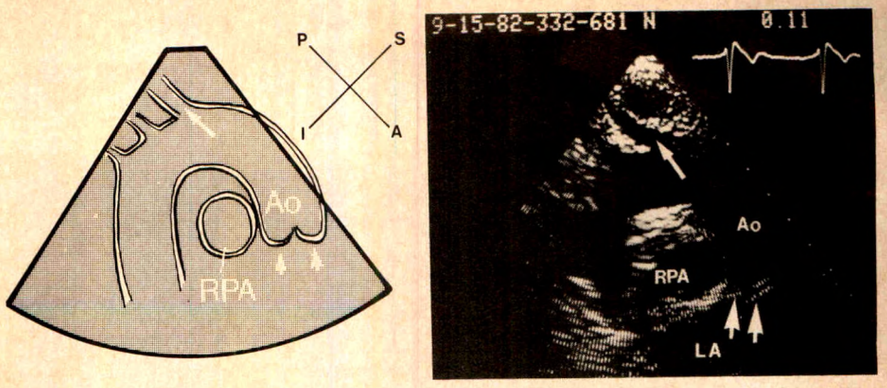

FIGURE 6. Clockwise rotation of the transducer to position 2 in patients with RAA revealed the arch corresponding to its anatomic configuration. The aortic valve (**short arrows**) was located at the lower right border of the scan and the brachiocephalic vessels (**long arrows**) pointed toward the side of the descending aorta. Abbreviations as before.

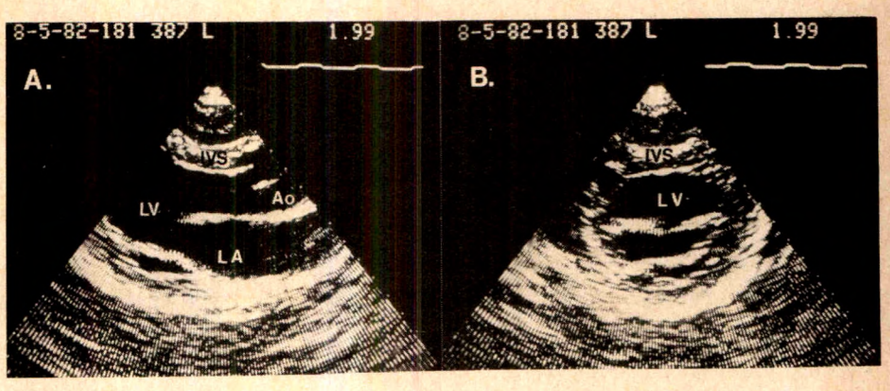

FIGURE 7. The parasternal long-axis (**A**) and short-axis (**B**) views in this patient with RAA failed to demonstrate the typical echo-free structure of the descending aorta in the far field. Abbreviations as before.

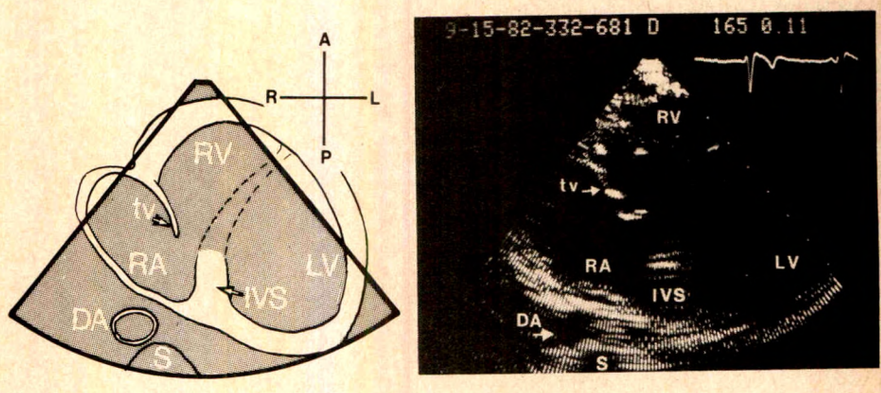

FIGURE 8. An echo-free pulsatile structure believed to be a right descending aorta (DA) was discovered on the parasternal short axis to the right of the spine (S) behind the right atrium (RA) in this Group B patient. tv = tricuspid valve; other abbreviations as before.

from the midline (Fig. 1B). This differs from the 45° angle that is commonly used with the standard suprasternal notch approach to identify LAA.[4]

The SSNL approach may be more tedious in uncooperative, unsedated, or severely ill pediatric patients. In these cases, the parasternal views exclude the possibility of RAA when the typical pulsatile circular or oval echo-free descending aorta is visualized posteriorly in the atrioventricular groove or behind the left ventricle. The 4 major types of RAA all remain to the right of the spine before crossing to the left a short distance above the diaphragm.

A round pulsatile echo-free structure resembling the usual cross-sectional aortic image was discovered on the parasternal short-axis view behind the right atrium in the last 2 patients with RAA. We believed it to be the right descending aorta. This would provide a positive diagnostic sign of RAA rather than a diagnosis of exclusion as described in the preceding paragraph. Unfortunately, we did not have the opportunity to confirm it by contrast studies. Additional study of the parasternal and 4-chamber views to outline the descending aorta should further define its course.

When the SSNL approach was used in the RAA patients, only the ascending aorta could be visualized. Failure to demonstrate the arch or descending aorta simulated an interruption of the aorta at the level of the arch (Fig. 5). This pattern may on occasion be confused

with other anomalies of the aortic arch including interruption, hypoplasia of the isthmus, or severe coarctation of the aorta. It is, therefore, advisable to thoroughly search for an RAA whenever this pattern is confronted.

We chose to rotate the transducer clockwise from the standard suprasternal notch approach in search of RAA because the resulting image corresponded to the anatomy and angiography of an arch looping to the right of the patient. Counterclockwise rotation[5] or turning the transducer indicator toward the patient produced a video image with the arch looping toward the left. Without labeling or indication of the transducer location, the counterclockwise technique displays an image indistinguishable from a true LAA.

The 2-D echocardiographic technique for recognition of RAA, as outlined, is simple, rapid, and definitive. The approach should be incorporated into the standard echocardiographic examination especially when LAA cannot be determined from the plain chest roentgenogram. Furthermore, it should be pursued in any child suspected of having a congenital heart defect where there is a strong association with RAA. Lastly, anticipation of an RAA can be used to expedite chest as well as cardiovascular surgery.

SYMPOSIUM ON RESULTS OF THE MUSTARD OPERATION FOR COMPLETE TRANSPOSITION OF THE GREAT ARTERIES

JAMES R. ZUBERBUHLER, MD, GUEST EDITOR

Introduction

JAMES R. ZUBERBUHLER, MD

Transposition of the great arteries (TGA) is an important congenital cardiac anomaly that regularly produces severe and life-threatening symptoms early in life. Before treatment was available, the outlook for survival was grim indeed, and although the introduction of surgical atrial septectomy provided a means of improving interatrial mixing, the mortality associated with this procedure was high. The development of balloon atrial septostomy by Rashkind and Miller[1] and of an intraatrial baffle repair technique by Mustard[2] in the mid-1960s resulted in a dramatic change in prognosis. The widespread use of balloon septostomy markedly decreased the early morbidity and mortality in TGA so that most patients survived early infancy.

One early attempt at surgically correcting the abnormal hemodynamics of TGA was directed at what seemed to be the central difficulty, the abnormal origin of the aorta and pulmonary artery.[3] Soon after, Baffes[4] pioneered the "venous" approach to the problem and Senning[5] devised still another "venous" operation, but the results of these procedures were not encouraging. Therefore, the apparently successful Mustard technique achieved widespread popularity shortly after the first report appeared in 1964. Further improvement in early morbidity and mortality was subsequently achieved by the Park blade septostomy technique[6] and by application of the Mustard operation to younger infants, in some institutions even during the first few weeks of life.

Problems remain, however, especially in patients with associated cardiac abnormalities. The presence of a large interventricular communication complicates the management of TGA, and whether an early intraatrial baffle repair with surgical closure of the ventricular septal defect is superior to early banding of the pulmonary trunk and a subsequent intracardiac procedure remains controversial. Pulmonary stenosis is also a difficult problem, especially because most obstruction is subvalvular. The left ventricular outflow tract is a thorny surgical path, because the anterior leaflet of the mitral valve is an integral part of this area and there is no true infundibulum to be "cored out." Conduits have been used to bypass the obstruction, but they have inherent limitations and hazards.

Long-term results are less well defined than are operative risk and short-term survival. There is concern over dysrhythmias, over the capacity of the tricuspid valve and its support apparatus to tolerate systemic pressures for many years, and over the continued integrity of the right ventricular myocardium, "designed" to pump at much lower than systemic pressure. The course of pulmonary stenosis, especially in patients with an intact ventricular septum, is another nagging worry.

In addition to concern about long-term survival of patients who have intraatrial repair, there is also apprehension about their functional capacity. Will it be possible for these individuals to hold down a job, to bear children, and to participate in recreational sports? These questions have become more pressing as alternative surgical techniques have appeared on the scene.[7,8] Is it justifiable to accept the higher surgical mortality of an "arterial switch" operation because of better long-term results? First, we must know the long-term results of intraatrial baffle operations so that we may have a standard against which other operative techniques may be judged.

This investigation was undertaken to address the question of long-term results. Admittedly, "long-term" is not really very long, but it is the best we have. Other studies have focused on specific measures of success or failure, such as postoperative hemodynamics, the incidence and nature of electrical abnormalities, and the results of exercise testing. To our knowledge, no comprehensive study of overall results in a group of patients from a single institution has been published, and the present study was carried out in the hope that several views of one "elephant" are more likely to describe accurately than are several views of as many "elephants."

From 1964 through 1980, 95 patients survived more than 1 month after a Mustard procedure performed at the Children's Hospital of Pittsburgh, and these patients form the basis of this study. Of the 95 survivors, 82 had both pre- and postoperative cardiac catheter-

ization; most had more than 1 preoperative study and several had serial postoperative catheterizations. The hemodynamic and cineangiographic findings are described in the first paper. Almost all patients had multiple electrocardiograms, and most had other electrical investigation such as intracardiac electrophysiologic studies in 60 patients and 24-hour electrocardiographic monitoring in 21. The results of the review of the electrocardiographic and electrophysiologic studies are reported in the second paper. The exercise and radionuclide evaluations were performed in a smaller subset of about 50 survivors who are now more than 7 years of age. Roughly 20 patients participated in each of these studies, not necessarily the same individuals in each group. The patients were selected only by distance from Pittsburgh and by willingness of the individuals and their parents to participate. A psychological evaluation of older survivors (to be published elsewhere) documented strong death fears in both patients and their parents and also an inability of patients to deal with their body image. It also showed a striking dearth of communication skills; patients found it very difficult to talk with friends or parents about the fears and concerns centered about their cardiac problem.

Hemodynamic Function After the Mustard Operation for Transposition of the Great Arteries

SANG C. PARK, MD, WILLIAM H. NECHES, MD, ROBERT A. MATHEWS, MD, FREDERICK J. FRICKER, MD, LEE B. BEERMAN, MD, DONALD R. FISCHER, MD, CORA C. LENOX, MD, and JAMES R. ZUBERBUHLER, MD

Pre- and postoperative cardiac catheterization data and cinenangiocardiograms of 82 patients who survived the Mustard operation for transposition of the great arteries (TGA) were reviewed. The postoperative catheterizations were performed 20 days to 10 years after operation (mean 2.5 years). Forty-six patients (56%) had no or insignificant associated cardiac lesions, whereas 36 (44%) had ventricular septal defect, pulmonary stenosis, or both, and required surgical intervention at the time of the Mustard operation. Postoperatively, 11 patients (13%) had significant systemic venous obstruction. Of the 11 patients, 6 required reoperation, and 2 patients had evidence of restenosis or complete obstruction in the superior vena cava after reoperation. In most patients, superior vena caval obstruction was well tolerated even in the presence of high pressure in the superior vena cava. Pulmonary venous obstruction occurred in 5 patients (6%), 3 of whom had no clinical symptoms despite severe pulmonary venous obstruction, although all had radiographic evidence of pulmonary venous congestion. The incidence of obstruction was drastically reduced after the Mustard operation was modified to include routine enlargement of the pulmonary venous atrium. Tricuspid regurgitation was uncommon (10%), but did occur in patients who had transatrial closure of a ventricular septal defect. Preoperatively, left ventricular outflow obstruction occurred in 38%. In 12 patients an attempt was made to relieve the obstruction at surgery. The 6 patients who had localized obstruction had a good result, but patients with more diffuse narrowing of left ventricular outflow had little or no relief of obstruction. Mild to moderate left ventricular outflow gradients regressed spontaneously in most patients after the Mustard operation.

From the Cardiology Division, Department of Pediatrics, University of Pittsburgh School of Medicine and the Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania. This project was supported in part by the Beaver County Heart Association, Beaver, Pennsylvania. Manuscript received June 3, 1982; revised manuscript received January 5, 1983, accepted January 7, 1983.

The introduction of both the Mustard operative technique[1] and Rashkind balloon atrial septostomy[2] in the mid-1960s resulted in a dramatic change in the management and prognosis of patients with transposition of the great arteries (TGA). Although in recent years various surgical techniques have been employed, the Mustard operation remains the most commonly used in physiologic correction of this cardiac lesion. Several previous reports described operative complications and short- and long-term hemodynamic problems after the Mustard operation.[3–10] Complex electrophysiologic disturbances[11–14] and abnormalities of ventricular function[15–17] have also been recognized. This study focuses on hemodynamic abnormalities documented by serial cardiac catheterization studies performed before and after operation. An attempt was made to determine if a correlation exists between specific postoperative hemodynamic abnormalities and preexisting associated cardiac malformations or operative techniques.

Methods

From 1964 to 1980, there were 95 long-term survivors of the Mustard operation for TGA at Children's Hospital of Pittsburgh. The study group consists of 82 of the 95 survivors, and all 82 had both pre- and postoperative cardiac catheterization and angiocardiography.

Associated cardiac lesions: Forty-six patients (56%) had either no associated intracardiac anomaly (34 patients) or only a tiny ventricular septal defect (4 patients), patent ductus arteriosus (2 patients) or aortic coarctation (1 patient). The remaining 36 patients had a significant intracardiac malformation such as a ventricular septal defect (24 patients), pulmonary stenosis (6 patients), or both (6 patients) and the defect was repaired at the time of the Mustard operation.

Operative technique: Before the Mustard operation, 30 patients had had 31 palliative surgical procedures: 20 patients a Blalock-Hanlon atrial septectomy, 7 a banding of the pulmonary trunk, and 4 a Blalock-Taussig shunt. At the time of the Mustard operation, age ranged from 0.3 to 13.7 years (mean 3.2) and weight from 4.9 to 37 kg (mean 12.3). In 18 patients intracardiac operations were performed using the standard normothermic cardiopulmonary bypass. Moderate systemic hypothermia (28°C) and cardiopulmonary bypass were used in 34 patients and deep hypothermia (18°C) and total circulatory arrest in 30. In 74 patients (90%) autogenous parietal pericardium was used to construct the baffle, whereas in the remaining 8 patients various materials were used: Dacron® in 4, bovine pericardium in 3, and Gore-Tex® in 1. The pulmonary venous atrium was enlarged in 39 patients, using Gore-Tex (30 patients), autogenous pericardium (6 patients), or bovine parietal pericardium (3 patients). Early in the series the coronary sinus was incised to permit coronary sinus blood drainage into the systemic venous atrium, but during the past 10 years the coronary sinus was left intact and the suture line was placed so that the coronary sinus blood drained into the pulmonary venous atrium.

Cardiac catheterization: Each patient had at least 1 preoperative and 1 postoperative cardiac catheterization. Sixty-seven (82%) had balloon atrial septostomy at the time of the first catheterization. Six patients had blade atrial septostomy at 1 to 5 months of age because of an inadequate interatrial opening after an initial balloon septostomy in the newborn period. All but 4 of the 82 patients had a second or third cardiac catheterization before the Mustard operation. The first postoperative cardiac catheterization was performed 20 days to 10 years after operation (mean 30 months). Twelve patients had a second postoperative catheterization and 2 had a third study.

Either a percutaneous or a cutdown technique was used, usually from an inguinal approach. An antecubital or axillary cutdown was performed when femoral or iliac venous thrombosis precluded a femoral approach (12 patients) or when a catheter could not be advanced into the superior vena cava from the systemic venous atrium because of severe baffle obstruction (3 patients).

No premedication was given to infants <6 months of age and morphine sulfate (0.1 mg/kg) was used in infants 6 to 12 months of age. For older children, a combination of meperidine (2 mg/kg), chlorpromazine (0.5 mg/kg), and promethazine (0.5 mg/kg) was used. In postoperative studies, the usual hemodynamic data were supplemented by withdrawal pressures from both the superior and inferior vena cava to the systemic venous atrium to identify systemic venous obstruction. Also, simultaneous pressure recordings were made in the right ventricle and in either the pulmonary arterial wedge position or the proximal pulmonary venous atrium or pulmonary vein to rule out pulmonary venous obstruction. The pulmonary venous atrium was entered by a catheter passed retrograde through the aortic and tricuspid valves or, in a few patients, from the systemic venous atrium through a baffle defect. Biplane cineangiograms routinely included injections of contrast medium into the right and left ventricles and the superior and inferior venae cavae. Other selective injections were performed as needed to define suspected anatomic abnormalities.

Statistics: All numerical data in this report are expressed as mean ± 1 standard deviation. Statistical analysis was performed using Student's *t* test.

Results

Baffle dysfunction was diagnosed when an interatrial communication could be demonstrated by catheter passage, oximetry, or cineangiography, or when there was cineangiographic or pressure recording evidence of systemic or pulmonary venous obstruction.

Baffle leakage: A baffle leak was noted in 22 patients (25%). Of the 4 patients with oximetric evidence of shunting, 1 had a large left-to-right shunt (Qp/Qs = 1.8:1) and another had a right-to-left shunt large enough to cause the systemic arterial saturation to decrease <90%. Both patients required reoperation. Two others had small shunts (Qp/Qs <1.2:1) detected by oximetry and did not require reoperation. In 18 (82%), trivial leakage was noted by cineangiography but not by oximetry.

Systemic venous obstruction: In the 78 patients in whom pressure in both the superior vena cava and systemic venous atrium could be measured, the mean gradient was >5 mm Hg in 22. Patients with a gradient <10 mm Hg had no clinical evidence of systemic venous obstruction, except for 1 patient who had transient facial edema in the early postoperative period. In 11 patients the gradient was between 10 and 18 mm Hg (Table I). Of these, 4 had clinical manifestations of superior vena caval obstruction, such as facial edema or a prominent venous pattern on the chest wall, but the remaining 7 had no signs or symptoms, even though obstruction was complete in 2 patients. In these latter patients superior vena caval obstruction was an incidental finding at cardiac catheterization. Simultaneous or near simultaneous pressure in the systemic venous

atrium and both venae cavae was not obtained in 13 patients (4 in the superior and 9 in the inferior vena cava). Eleven had no cineangiographic evidence of venous obstruction.

Four symptomatic patients and 2 with severe systemic venous obstruction without signs or symptoms underwent reoperation to relieve obstruction 3 months to 3 years after the initial Mustard operation (mean 16 months). One patient required operation for severe venous obstruction between the systemic venous atrium and both the superior and inferior venae cavae. No patient had isolated inferior vena caval obstruction. One of the 6 patients reoperated on for systemic venous obstruction died. The 5 survivors had repeat cardiac catheterization after reoperation. Three were improved but 2 had severe residual caval obstruction. One had complete obstruction of the superior vena cava but good collateral venous connections to the inferior vena cava through the azygos system. The other patient continued to have severe symptoms of superior vena caval obstruction but improved after a second surgical attempt to relieve the obstruction. Five patients with severe superior vena caval obstruction and gradients ranging from 10 to 18 mm Hg had adequate collateral venous drainage through the azygos or hemiazygos vein and have not undergone reoperation.

Pulmonary venous obstruction: When pulmonary arterial wedge pressure or pulmonary arterial diastolic pressure was >10 mm Hg, simultaneous pulmonary arterial wedge and right ventricular end-diastolic pressures were recorded. In some patients a retrograde catheter was passed across the tricuspid valve into the

proximal pulmonary venous atrium, and pressure was recorded there and on withdrawal to the distal pulmonary venous atrium to document the presence and severity of pulmonary venous obstruction. The pressure gradient was >10 mm Hg in 5 patients and ranged from 16 to 37 mm Hg (Table II). In 2 of these 5 patients symptoms of pulmonary venous obstruction developed 2 to 12 months after operation. Although each of the 5 had radiographic evidence of pulmonary venous obstruction, 3 patients had no symptoms. Reoperation was performed in all 5 patients 4 to 24 months (mean 6) after the initial Mustard operation. One patient also had repair of superior vena caval obstruction. There was 1 intraoperative death. The remaining 4 patients had repeat cardiac catheterization 13 to 24 months after reoperation and relief of pulmonary venous obstruction was documented in all.

Overall, reoperation for systemic or pulmonary venous obstruction, or both, was required in 10 patients. Their age and weight at the initial operation were slightly lower than those of the entire group, but the differences were not statistically significant (Table III). Because pericardium was used for the original baffle in most patients, the role of this material in the occurrence of venous obstruction cannot be assessed. Pulmonary venous obstruction was uncommon in the entire group, but was significantly more common among patients who did not have surgical enlargement of the pulmonary venous atrium.

Ventricular septal defect: In 39 (48%) of 82 patients a ventricular septal defect was demonstrated at the initial preoperative catheterization. The defect closed spontaneously in 11 (28%) and 4 had a very small defect that required no surgical intervention. The remaining 24 patients had surgical closure of the defect at the time of the Mustard operation. In 15 the defect was small and required only suture closure, whereas 9 had patch closure of a large defect. In 21 patients (88%) the defect was closed from a transatrial approach, whereas in the remaining 3 the defect was closed using a transpulmonary approach (2 patients) or by ventriculotomy (1 patient). Seven patients also required removal of a previously placed pulmonary artery band. Of the 24 patients who had surgical closure of a ventricular septal defect, 5 had a residual defect at postoperative cardiac catheterization. However, in only 1 patient was there a large enough left-to-right shunt (Qp/Qs >2:1) to require reoperation.

Tricuspid regurgitation: This was seen in 6 (25%) of 24 patients who had surgical closure of a ventricular septal defect. In 4 of these patients it was mild, but in 2 it was severe enough to require reoperation. One of the 2 had replacement of the tricuspid valve with a Hancock prosthesis and the other had repair of torn chordae. Three patients with tricuspid regurgitation had grossly abnormal right ventricular function on cineangiography. Mild tricuspid regurgitation and angiocardiographic evidence of right ventricular dysfunction were seen in 2 additional patients who did not have surgical closure of a ventricular septal defect (3%). Apparently, significant tricuspid regurgitation and severe right ventricular dysfunction were most commonly related to surgical closure of a ventricular septal defect through the tricuspid valve.

Pulmonary stenosis: Of 42 patients who had cardiac catheterization during the first week of life, 17 had measurement of pulmonary arterial pressure. None had a left ventricular outflow gradient >20 mm Hg, even though some had documented pulmonary stenosis at a subsequent catheterization. Data from serial preoperative cardiac catheterizations demonstrated that a gradient usually became evident during the first few months of life and then tended to increase with age (Fig. 1). Thirty-one patients were found to have pulmonary stenosis, defined as a pressure gradient between the left ventricle and the pulmonary artery >20 mm Hg at preoperative cardiac catheterization. Twelve of these 31 patients had attempted surgical repair of the obstruction. Six of the 12 had localized obstruction, consisting of pulmonary valve stenosis in 3, an aneurysm of the ventricular septum in 2, and a discrete membrane in 1. Each had substantial reduction of the gradient after operation (mean preoperative gradient 61 ± 5 mm Hg, mean postoperative gradient 32 ± 16 mm Hg, p <0.001) (Fig. 2). Another 6 patients had more diffuse left ventricular outflow obstruction and surgical results were poor, with no significant reduction in gradient (preoperative gradient 62 ± 17 mm Hg, postoperative gradient 55 ± 18 mm Hg, p not significant) (Fig. 2).

In the remaining 19 patients no attempt was made to relieve the pulmonary stenosis. In 9 the left ventricular outflow tract and pulmonary valve were inspected at surgery and no significant abnormalities were found. Most of the 19 patients had spontaneous regression of the pressure gradient after the Mustard operation

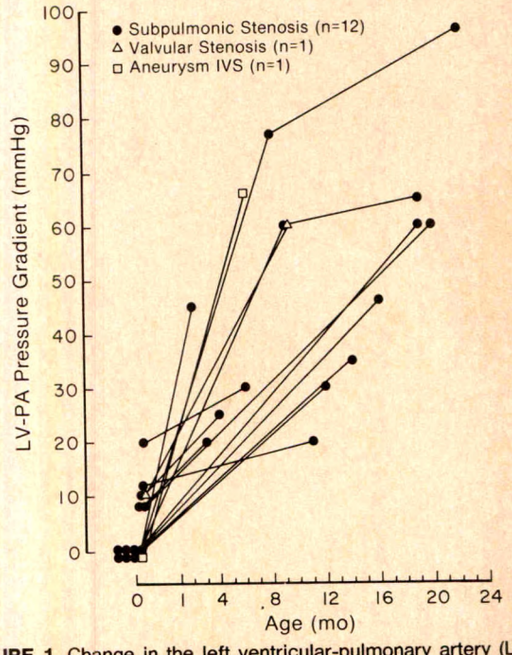

FIGURE 1. Change in the left ventricular-pulmonary artery (LV-PA) pressure gradient before the Mustard operation in patients <1 month of age when the gradient was measured. IVS = interventricular septum.

(mean preoperative gradient 32 ± 12 mm Hg, mean postoperative gradient 18 ± 14 mm Hg, p <0.001) (Fig. 3).

In summary, most (56%) patients had some degree of hemodynamic abnormality after the Mustard operation (Table IV), but only 15 patients (18%) have required reoperation. There were 3 surgical deaths in patients requiring repeat operation and the remaining patients have been clinically well despite the presence of minor hemodynamic abnormalities.

Discussion

With increasing experience with the Mustard operation, significant postoperative hemodynamic problems have become less common. Controversy as to the optimal baffle material and surgical technique persists.[18–20] Because surgical morbidity and mortality vary among institutions, it is difficult to substantiate the superiority of one surgical technique or a specific baffle material over another.

A hemodynamic abnormality related to baffle dysfunction was the most common problem demonstrated in this study. The severity of obstruction as judged by the gradient between the superior vena cava and the systemic venous atrium does not always correlate well with clinical symptoms. All patients with clinical evidence of superior vena caval obstruction had a pressure gradient ≥14 mm Hg between the superior vena cava and the systemic venous atrium, but 4 other patients with even higher gradients had no clinical signs of superior vena caval obstruction. The severity of symptoms is clearly related to the adequacy of collateral venous drainage. All asymptomatic patients with severe or complete superior vena caval obstruction were shown to have collateral venous drainage through the azygos or hemiazygos system, or both. Despite the absence of signs and symptoms of severe caval obstruction and the presence of collateral channels, superior vena caval pressure ranged from 15 to 24 mm Hg. Most symptomatic patients also had collateral channels on angiographic study. Therefore, neither the level of pressure in the superior vena cava nor the status of collateral vessels seems to be the sole determinant of clinical symptoms. Some patients with high superior vena caval pressure and severe obstruction are doing well ≥15 years postoperatively. In others, the gradient may actually decrease. One patient had moderate superior vena caval obstruction (gradient 8 mm Hg) documented at a 3-month postoperative cardiac catheterization, but repeat study 3 years after operation showed spontaneous regression of the gradient to only 2 mm Hg. The importance of the azygos vein as a major collateral

channel makes it desirable to preserve the azygos venous system at the time of the Mustard operation if at all possible. Venous obstruction at the junction of the inferior vena cava and right atrium is rare and was seen in only 1 patient. The combination of superior and inferior vena caval obstruction is poorly tolerated but fortunately is rare.

Pulmonary venous obstruction is relatively uncommon. The frequency was even further reduced after routine enlargement of the pulmonary venous atrium was introduced at the time of the Mustard operation. In contrast to superior vena caval obstruction, there are no collateral channels in this type of venous obstruction. Consequently, pulmonary venous congestion and pulmonary hypertension are inevitable when the obstruction is severe. Stark et al[4] reported that pulmonary venous obstruction is poorly tolerated and may cause sudden death. However, 3 of 5 patients had no symptoms despite severe pulmonary venous obstruction and radiographic evidence of pulmonary venous congestion. Each patient with significant pulmonary venous obstruction had a soft continuous murmur at the left lower sternal border or xyphoid area, orginating at the site of obstruction in the surgically created pulmonary venous atrium.[21] Therefore, the presence of a continuous murmur after the Mustard operation should suggest significant pulmonary venous obstruction.

Right ventricular dysfunction has been reported in patients who have undergone the Mustard operation and has been documented by angiocardiographic volumetric studies as well as by echocardiography.[15–17] Also, the potential for dysfunction of the tricuspid valve as the systemic atrioventricular valve has often been discussed in the past and a high incidence of tricuspid regurgitation has been reported.[22] However, the incidence of significant tricuspid regurgitation in this study was low and was usually related to closure of a ventricular septal defect through the tricuspid valve, as reported by others.[9,23]

Left ventricular outflow tract obstruction can be a difficult problem in patients with TGA. In our patients a significant gradient between the left ventricle and pulmonary artery was never apparent in the newborn period, even in patients who were subsequently shown to have developed pulmonary stenosis at a later age. It is not uncommon to find a mild to moderate pressure gradient between the left ventricle and pulmonary artery at preoperative cardiac catheterization, and yet have the left ventricular outflow tract appear unobstructed at surgery. Mild to moderate gradients regressed postoperatively in most of our patients, probably because of the decrease in pulmonary blood flow after physiologic correction.

Localized valvular or subvalvular obstruction (discrete subpulmonary membrane or aneurysm of the membranous septum) is rare but was always surgically correctable in our patients. In contrast, diffuse obstruction was not effectively relieved. Fortunately, true tunnel-like subpulmonary stenosis is rare, because surgical relief of such obstruction is quite difficult and may require a conduit from the left ventricle to the pulmonary artery to relieve left ventricular hypertension.

Although the exact nature of the subpulmonary stenosis is difficult to define angiographically, the "4-chamber" view facilitates definition of the left ventricular outflow and is superior to the anteroposterior, lateral, or regular oblique views. Nevertheless, the correlation between the severity of left ventricular outflow obstruction and the angiocardiographic findings is still poor. Because a significant number of patients with pulmonary stenosis, particularly those with pressure gradients <50 mm Hg, improved spontaneously after the Mustard operation, the obstruction was most likely functional. Rarely, the gradient increases postoperatively.[9,24]

Rest and Exercise Right and Left Ventricular Function Late After the Mustard Operation: Assessment by Radionuclide Ventriculography

JUDITH H. MURPHY, MD, MARTHA M. BARLAI-KOVACH, CNMT, ROBERT A. MATHEWS, MD, LEE B. BEERMAN, MD, SANG C. PARK, MD, WILLIAM H. NECHES, MD, and JAMES R. ZUBERBUHLER, MD

To evaluate ventricular function late after atrial repair of transposition of the great arteries (TGA), 26 asymptomatic patients had rest and exercise radionuclide ventriculography performed a mean of 9 years (range 5 to 15) after undergoing the Mustard operation. The mean resting right (systemic) ventricular (RV) ejection fraction (EF) was 0.50 ± 0.10 (±1 standard deviation); the RVEF was <0.45 in 8 patients. With exercise the RVEF increased in 9 patients and either failed to increase or decreased in 15 (including all 8 patients with resting values <0.45). The weight-adjusted work load performed was a first predictor of RV exercise response (sensitivity 87%, specificity 92%); patients whose RVEF increased did more work.

The mean resting left (pulmonary) ventricular (LV) EF was 0.58 ± 0.09; the LVEF was <0.50 in 3 patients. With exercise the LVEF increased in 14 patients and did not increase in 10 (including all 3 with resting values <0.50). The presence of complex ventricular arrhythmia documented on Holter monitoring was a first predictor of failure of the LVEF to increase with exercise (sensitivity 84%, specificity 71%).

The patient's age, operative age, postoperative interval, residual arterial desaturation, preoperative large ventricular septal defect or pulmonary stenosis, postoperative pulmonary stenosis or superior vena caval obstruction, or performance of a second open-heart procedure was predictive of the rest or exercise EF of either ventricle.

The Mustard operation is a well-established method of relieving cyanosis in patients with transposition of the great arteries (TGA).[1] It is not a true total correction, however, because the anatomic right ventricle remains the systemic ventricle and the anatomic left ventricle the pulmonary ventricle. The long-term effects on the right ventricle of functioning at systemic pressure are not known.[2,3] Previous studies using cardiac catheterization and contrast ventriculography have demonstrated right (RV) and left ventricular (LV) dysfunction in some patients after the Mustard operation.[2–5] Radionuclide ventriculography enables noninvasive measurement of RV and LV ejection fraction (EF) at rest[6–10] and during exercise.[11–18] To evaluate the long-term results of the Mustard operation with regard to ventricular function, rest and exercise radionuclide ventriculography was performed on a group of patients late after they had undergone the Mustard operation for TGA. The relation between rest and exercise EF and clinical data was examined. In addition, radionuclide findings were compared with results from exercise testing and 24-hour Holter monitoring to examine the relation between ventricular function and exercise capacity and ventricular arrhythmias.

From the Division of Pediatric Cardiology, Children's Hospital of Pittsburgh and the University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania. This study was supported in part by the Beaver County Heart Association, Beaver, Pennsylvania. Manuscript received June 3, 1982; revised manuscript received January 5, 1983, accepted January 7, 1983.

Methods

Patient population: Twenty-six patients who underwent the Mustard operation for TGA and who are being followed at Children's Hospital of Pittsburgh constituted the study group (Table I). There were 17 male and 9 female patients aged 8 to 23 years (mean 13) who were studied 5 to 15 years (mean 9) postoperatively. Their age at the time of the Mustard operation ranged from 2 to 11 years (mean 4); 10 patients were under 3 years of age at the time of repair, but none was <1.8. None had cardiovascular symptoms at the time of testing. Five took cardiac medications for arrhythmias, 3 digoxin alone, 1 digoxin and quinidine, and 1 digoxin and propranolol. One patient had a permanent epicardial pacemaker which had been implanted postoperatively for complete heart block.

Eleven patients had arterial oxygen saturation measured by ear oximetry at rest within 5 months of the radionuclide study. Twenty-two had 24-hour Holter monitoring performed within 33 months (21 within 3 months) of radionuclide study. Each patient had at least 1 postoperative catheterization performed from 18 days to 10 years after surgery (mean 3 years). The time from the most recent catheterization to radionuclide study ranged from 1 to 8 years (mean 5). Operative reports were reviewed for 32 procedures in the 26 patients.

Radionuclide studies—data acquisition: The patients were shown the equipment and were given a brief practice session pedaling the bicycle ergometer. The patient's red blood cells were labeled with technetium-99m pertechnetate using a modified in vivo technique. The stannous pyrophosphate dose was adjusted for the patient's weight and the technetium dose adjusted for the patient's age (See Appendix). A high-count density resting supine radionuclide ventriculogram was obtained in the left anterior oblique projection which provided maximal ventricular separation, using a portable single-crystal gamma camera with a parallel-hole collimator (Dynamo, Picker) interfaced with a dedicated on-line computer (MUGA-CART, Medical Data Systems). A 2-minute image was obtained with the patient's feet in the bicycle pedals and analyzed for adequacy of count density.[19] Supine exercise was performed using a bicycle ergometer (Quinton Instruments). Patients began exercising at 200 kg·m/min with increments in work load adjusted according to a protocol.[20] Patients exercised to a symptom-limited maximum, and all stopped because of fatigue or leg weakness. Leads aVF, V_1, and V_5 were recorded at rest and for at least 5 seconds every minute during the exercise and recovery periods. Cuff brachial blood pressure was recorded at rest and every 2 to 2.5 minutes during the exercise and recovery periods. The patient's heart rate was allowed to stabilize for the first minute of exercise at each stage; radionuclide images were obtained in the left anterior oblique projection during the last 2 to 3 minutes of each stage, with the acquisition time determined from the count analysis of the preexercise image. Patients who required 2.5 minutes of acquisition time exercised for 3.5 minutes at each work level, those requiring 2.25 minutes of acquisition time exercised for 3.25 minutes at each work level, and those requiring 2 minutes of acquisition time exercised for 3 minutes at each work level.

Radionuclide studies—data analysis: Analysis of the scintigraphic data was performed using a general nuclear medicine computer (A^2, Medical Data Systems). All studies were filtered temporally and spatially to enhance edge detection. Preliminary right and left ventricular regions of interest were generated using a semiautomatic computer program and hand-corrected when necessary by 2 experienced observers. Corrected regions were applied over the unfiltered data to obtain the ventricular counts used in the final EF determination. The computer-generated LV background posteriorly and inferiorly was determined, the average counts per pixel were calculated, and the area-normalized background subtracted from each image for both RVEF and LVEF calculation. At least 2 images (rest and peak exercise) from each patient were analyzed independently by each observer and analyzed by 1 observer on 2 different days to insure accuracy and reproducibility. When multiple determinations yielded different values that agreed within 0.05, the values were averaged to provide the final EF result. When the multiple determinations differed ≥0.05, the entire analysis procedure was repeated until agreement was reached. If no reproducible EF could be obtained, the data were excluded from consideration in this study. Using these methods we excluded (1) 1 patient in whom ventricular separation was too poor for quantitative analysis of the entire study, and (2) images at peak exercise in 5 patients, 1 in whom exercise and imaging was terminated before acquisition of sufficient counts for analysis and 4 in whom excessive patient motion caused blurring of the ventricular edges. In these 5 patients the RV and LVEF values from the next highest exercise level were used in this study. In no patient did exclusion of the peak exercise image result in a change in classification of the patient's exercise ejection fraction response. Additionally, exercise values were deleted in 2 patients in whom bigeminy developed with exercise, because the arrhythmias rendered EF determination invalid.

Rest and exercise electrocardiographic data were analyzed for change in heart rate and rhythm with exercise and for the presence of ST-T wave changes at rest as well as during exercise.

Other clinical data: Oxygen saturation was measured noninvasively at rest using an ear oximeter (model 47201A, Hewlett-Packard). Twenty-four–hour ambulatory electrocardiographic monitoring was performed using a dual-channel recorder (Holter II, International Medical) which scanned continuously and recorded for 10 seconds every 2 minutes and during each event, using modified leads V_2 and V_5. Pre- and postoperative cardiac catheterizations were performed.

Statistical analysis: Results are reported as means ± 1 SD. To assess the relation of ventricular function to the patient's age, operative age, postoperative interval, pre- and postoperative defects, ventricular arrhythmias, and exercise work

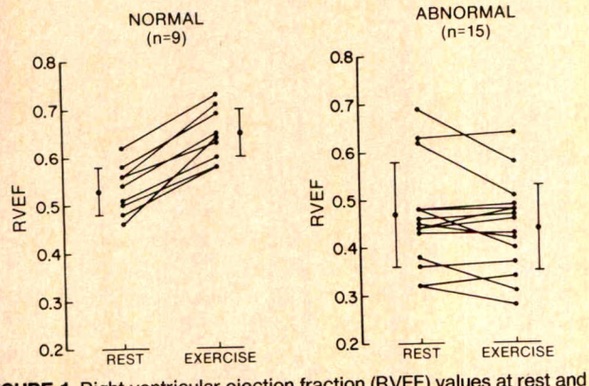

FIGURE 1. Right ventricular ejection fraction (RVEF) values at rest and at peak exercise for the 24 patients whose exercise ejection fractions could be calculated. The mean RVEF was 0.53 ± 0.05 at rest and 0.65 ± 0.05 at peak exercise in the 9 patients whose RVEF increased normally with exercise. The RVEF was 0.47 ± 0.10 at rest and 0.44 ± 0.10 at peak exercise in the 15 patients whose RVEF exercise response was abnormal.

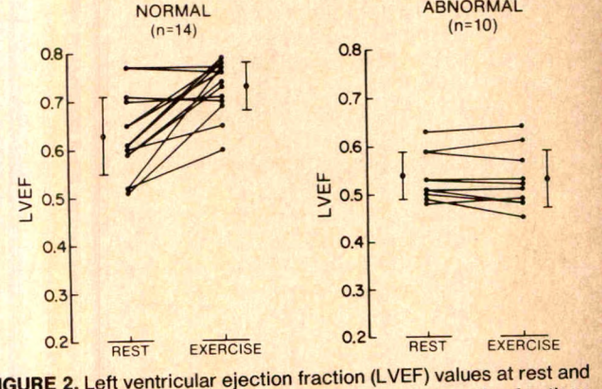

FIGURE 2. Left ventricular ejection fraction (LVEF) values at rest and at peak exercise for the 24 patients whose exercise ejection fractions could be calculated. The mean LVEF was 0.63 ± 0.08 at rest and 0.73 ± 0.05 at peak exercise in the 14 patients whose LVEF increased normally with exercise. The LVEF was 0.54 ± 0.05 at rest and 0.53 ± 0.06 at peak exercise in the 10 patients whose LVEF exercise response was abnormal.

BP = blood pressure; LVEF = left ventricular ejection fraction; O_2 = oxygen; PB = pulmonary band; PH = pulmonary hypertension; PS = pulmonary stenosis; PVO = pulmonary venous obstruction; RVEF = right ventricular ejection fraction; SVO = systemic venous obstruction; TVA = tricuspid anuloplasty; TVR = tricuspid valve replacement; VSD = ventricular septal defect.

load, BMDP (Dixon and Brown, 1979) program P7M, a stepwise discriminant analysis, was used. All predictors were given an equal weight and each ventricle was analyzed separately, grouped by normal and abnormal function as defined by EF. The opposing ventricle also was included in each analysis to determine whether dysfunction in 1 ventricle significantly impairs the other. When comparisons were made between 2 groups, Student's t test for unpaired data was used, with $p < 0.05$ considered as significant.

Definition of normal ejection fraction values: Because all patients with TGA have a reversed ventricular relation, there is no control group from which normal values for RVEF and LVEF can be ascertained. Based on several reports[2,3,10–18,21–24] as well as on this laboratory's experience with patients with other forms of heart disease, the following criteria were used: (1) a resting RVEF ≥ 0.45 and a resting LVEF ≥ 0.50 were normal; (2) an increase ≥ 0.05 in RVEF or LVEF with exercise was normal; (3) if the resting EF was ≥ 0.70, any increase or no change with exercise was normal. An EF increase or decrease < 0.05 with exercise was within the error of the technique and therefore not considered a change.

Results

Radionuclide results: Individual rest and exercise RVEF values are shown in Figure 1. The mean resting RVEF was 0.50 ± 0.10 and ranged from 0.32 to 0.69. The RVEF was < 0.45 in 8 patients (31%); in 4 of these the value was < 0.40. With exercise the RVEF increased ≥ 0.05 in 9 patients, decreased ≥ 0.05 in 4, did not change in 11, and could not be analyzed in 2 because of arrhythmias. The mean RVEF of patients whose exercise EF response was normal was 0.53 ± 0.05 at rest and 0.65 ± 0.05 at peak exercise. The mean EF of patients whose exercise EF response was abnormal was 0.47 ± 0.10 at rest and 0.44 ± 0.10 at peak exercise. The difference between the resting EF of the normal responders and that of the abnormal responders was not statistically significant ($0.10 > p > 0.05$). The RVEF exercise response was abnormal in all 8 patients whose resting EF was < 0.45.

The individual rest and exercise LVEF values are shown in Figure 2. The mean resting LVEF was 0.58 ± 0.09 and ranged from 0.44 to 0.77. The LVEF was < 0.50 in 3 patients (12%). With exercise, the EF increased ≥ 0.05 (or did not change if resting EF was ≥ 0.70) in 14 patients, did not change in 10, and could not be analyzed in 2. In no patient did the LVEF decrease ≥ 0.05 with exercise. The mean LVEF of the patients whose exercise EF response was normal was 0.63 ± 0.08 at rest and 0.73 ± 0.05 at peak exercise. The mean LVEF of patients whose exercise EF response was abnormal was 0.54 ± 0.05 at rest and 0.53 ± 0.06 at peak exercise. The difference between the resting EF of the normal responders and that of the abnormal responders was significant ($p < 0.005$). The exercise response was abnormal in the 3 patients whose resting EF was < 0.50.

Six patients (25%) had a normal EF response to exercise in both ventricles; 7 patients (29%) had an abnormal response in both ventricles. Ventricular response was discordant in 11; 3 (13%) had a normal RVEF and an abnormal LVEF response and 8 (33%) had an abnormal RVEF and a normal LVEF response.

Neither the patient's age at the time of the radionuclide study, the operative age, nor the postoperative interval was predictive of resting dysfunction or of an abnormal exercise response in either ventricle. Dysfunction of 1 ventricle did not predict dysfunction of the other.

Exercise results: Rest and exercise heart rate and systolic blood pressure and the rate-pressure product are given in Table I. The exercise data for the patients grouped according to RV and LV exercise response are summarized in Table II. There was no significant difference in any exercise value between those whose RVEF exercise response was normal and those whose response was abnormal. The patients whose LVEF exercise response was normal had a higher mean systolic blood pressure at peak exercise than did those whose exercise response was abnormal ($p < 0.05$), but the difference in rate-pressure product between the 2 groups was not significant ($0.10 > p > 0.05$).

At rest, 14 patients were in regular sinus rhythm, 10 had marked sinus arrhythmia with or without junctional escape beats, 1 had complete heart block with junctional

TABLE II Heart Rate, Systolic Blood Pressure, and Rate-Pressure Product for Those With Normal and Abnormal RVEF and LVEF Exercise Response*

	RVEF Normal	RVEF Abnormal	p	LVEF Normal	LVEF Abnormal	p
Heart rate						
Rest	62 ± 12	69 ± 13	NS	64 ± 14	70 ± 12	NS
Exercise	134 ± 31	135 ± 25	NS	141 ± 19	124 ± 35	NS
Systolic BP						
Rest	109 ± 7	107 ± 11	NS	108 ± 10	109 ± 10	NS
Exercise	149 ± 21	136 ± 19	NS	148 ± 23	131 ± 12	<0.05
Rate pressure product (10^2)	205 ± 66	185 ± 44	NS	209 ± 45	167 ± 59	NS

* All values mean ± 1 standard deviation.
BP = blood pressure; LVEF = left ventricular ejection fraction; NS = not significant; RVEF = right ventricular ejection fraction.

rhythm, and 1 had complete heart block with a permanent ventricular pacemaker. With exercise, 17 patients had regular sinus rhythm, 3 had marked sinus arrhythmia with junctional escape beats, 1 had complete heart block with junctional rhythm, 1 had sinus rhythm with frequent premature ventricular systoles, 1 had 2:1 atrioventricular block, 1 had atrial bigeminy, and 1 had ventricular bigeminy. The patient with paced rhythm did not change with exercise. The incidence of arrhythmias at rest or during exercise was no greater among patients with an abnormal response than among those with a normal response in each ventricle. Sixteen patients had resting S-T segment and T-wave changes related to right ventricular hypertrophy or to right bundle branch block. In no patient did ischemic S-T segment changes develop during or after exercise.

The peak work load achieved by each patient, in kilogram·meters per minute, was divided by that patient's weight in kilograms to give a maximal weight-adjusted work load performed for each patient (Table I). Patients performing a greater weight-adjusted work load were more likely to have a normal right ventricular exercise response. The weight-adjusted work load was a first predictor of RV exercise response with a sensitivity of 87% and a specificity of 92%. The relation between peak weight-adjusted work load and RV exercise response is illustrated in Figure 3. The relation between exercise response and RVEF held when total weight-adjusted work performed (calculated by multiplying each work level by the duration performed, summing the results, and dividing by body weight) was compared with RVEF exercise response.

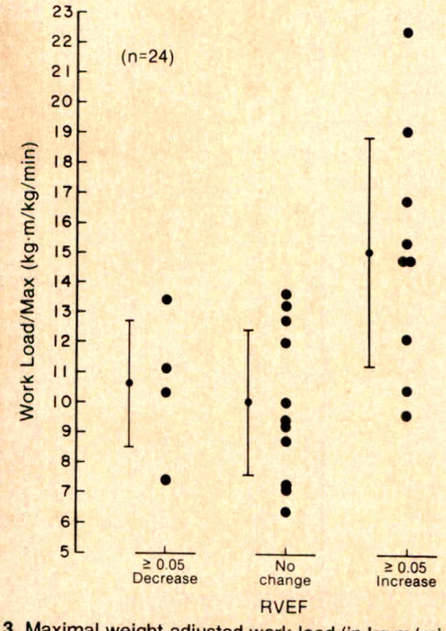

FIGURE 3. Maximal weight-adjusted work load (in kg·m/min/kg) performed plotted against the right ventricular ejection fraction (RVEF) response to exercise for the 24 patients whose RVEF exercise value could be calculated.

Holter monitor results: Of the 22 patients who had 24-hour Holter monitoring, 13 had premature ventricular systoles (Table I). In 4, the premature ventricular systoles were occasional and unifocal. In 9, the ventricular arrhythmias were complex: 2 had frequent premature ventricular systoles, 1 had bigeminy, 4 had multiformed ventricular systoles, 3 had couplets, and 1 had ventricular tachycardia. The resting RVEF of the 9 patients with complex ventricular arrhythmias was not different from that of the other 13 patients (0.48 ± 0.11 versus 0.50 ± 0.11) and the resting LVEF was also not different (0.60 ± 0.09 versus 0.59 ± 0.10). Patients with complex ventricular arrhythmias were more likely to have an abnormal LV exercise response. The presence of complex ventricular arrhythmias was a first predictor of an abnormal LV exercise response with a sensitivity of 84.5% and a specificity of 71.4%. Complex ventricular arrhythmias were not predictive of normal or abnormal RV response.

Other clinical data: Radionuclide data were compared with data obtained at pre- and postoperative cardiac catheterization and noninvasive determination of arterial oxygen saturation. Associated pre- and postoperative defects are listed in Table I. Only ventricular septal defects that would have required therapy had they been the sole defects were included. Pulmonary stenosis was defined as a LV to pulmonary arterial gradient >30 mm Hg. Superior vena caval obstruction was demonstrated either angiographically or by a ≥5 mm Hg gradient between the superior vena cava and systemic venous atrium. No patient had pulmonary venous obstruction, residual ventricular septal defect, patent ductus arteriosus, or hemodynamically significant valvular regurgitation or baffle leak at the time of radionuclide study. None of the following was predictive of an abnormal RVEF or LVEF at rest or exercise: preoperative large ventricular septal defect or pulmonary stenosis, postoperative superior vena caval obstruction or pulmonary stenosis, or resting arterial oxygen saturation <94%. The performance of a second open-heart procedure with cardiopulmonary bypass was also not predictive of abnormal RVEF or LVEF.

Technical considerations: There were several technical problems in performing radionuclide imaging in patients with TGA. RV enlargement necessitated imaging in a steep (75° to 90°) left anterior oblique projection to separate the 2 ventricles, and even then apical septal definition was poor in some cases. Several patients had a small left ventricle, making separation of ventricular activity from pulmonary arterial and atrial activity difficult. Therefore, rest and exercise EF was determined at least twice. Because in most patients the right ventricle contained more counts than the left ventricle, RVEF values were more reproducible.

Discussion

This study demonstrated an abnormal resting RVEF in 8 of 26 asymptomatic patients with TGA who underwent the Mustard operation. In addition, 3 had an abnormal resting LVEF. Right or left ventricular ejection fraction response to exercise, or both, was abnormal

in 18 patients, suggesting a decrease in myocardial reserve.[13–18] The EF is only 1 indicator of ventricular function and is affected by several other factors, such as preload, afterload, and heart rate.[2,5,25–28] In this patient population, however, no differences in any of these factors could be identified to explain the EF changes. Arrhythmias can falsely decrease the EF as measured by equilibrium radionuclide techniques,[29–32] but because the frequency and type of arrhythmias were similar in all groups, arrhythmias alone cannot explain the EF results. Therefore, the EF appears useful as a measure of ventricular function in these patients.

Several hypotheses have been proposed to explain RV dysfunction in these patients. Hagler et al[3] suggested that the structure, the myocardial fiber array, or the pattern of contraction intrinsic to the right ventricle may make it less adaptable to a high afterload. Although this study did demonstrate a high incidence of RV dysfunction, 9 patients had normal RV function at rest and during exercise. This finding argues against an inherent RV problem as the exclusive explanation of RV dysfunction in these patients. Graham et al[2] suggested that histologic damage from ischemia as well as from pressure and volume overload may be responsible for RV dysfunction. This study and the work of others[3,4] did not show any correlation between age at surgical correction and RV function, suggesting that duration of hypoxemia is not the sole explanation for RV dysfunction. However, only 2 of our patients were operated on when <2 years of age and no patient was operated on when <1.5 years of age. Because RV function was not related to patient age in this study, the duration for which the right ventricle has to work against systemic afterload does not appear related to RV dysfunction. However, our oldest patient was 23 years of age, and the possibility that RV dysfunction might be more prevalent in an older population cannot be excluded.

LV dysfunction has been described in some patients after the Mustard operation,[2–4] and Hagler et al[3] reported that it was less frequent in patients who underwent correction at a younger age. This study showed no relation between LV dysfunction and age at correction, but again the patient population did not permit assessment of early corrective surgery. Fewer patients had LV than RV dysfunction.

Several studies have shown that ventricular septal defects and preoperative pulmonary stenosis adversely affect ventricular function.[4,5,31] This study showed no long-term deleterious effect on RV or LV function from either defect. This finding may be consistent with that of Graham et al,[32] who demonstrated a return of increased LV volume measurements to normal in patients with TGA and ventricular septal defect after surgical repair. Our study also found that postoperative pulmonary stenosis, postoperative superior vena caval obstruction, or residual systemic desaturation did not adversely affect RV or LV function.

Several investigators have shown no significant change in ventricular function after the Mustard operation.[2,5] In our study, patients who underwent a repeat open-heart procedure did not have a higher incidence of ventricular dysfunction than did those who did not require reoperation.

Patients with normal RV function as judged by radionuclide angiography performed a significantly greater weight-adjusted work load than did those whose RV function was abnormal. These results indicate that RV function may influence the exercise capabilities of these patients.

Because the presence of complex ventricular arrhythmias predicted an abnormal LV exercise response, it is possible that ventricular arrhythmias are related to LV dysfunction. There was no relation between ventricular arrhythmias and resting RVEF or LVEF or RV exercise response.

Acknowledgment: We wish to express appreciation to Drs. Charles A. Boucher, Richard R. Liberthson, and H. William Strauss for reviewing the manuscript, to Gail Grant and John Newell, PhD, for their help with the statistical analysis, and to Eleanor Plati for secretarial assistance in the preparation of this manuscript.

Appendix

The stannous pyrophosphate dose was calculated as follows: 0.2 mg PYP/10 kg body weight. The technetium dose was calculated as follows: (Patient Age + 7 × Adult Dose ^{99m}Tc)/Patient Age + 1.

Exercise Studies After the Mustard Operation in Transposition of the Great Arteries

ROBERT A. MATHEWS, MD, FREDERICK J. FRICKER, MD, LEE B. BEERMAN, MD, ROBERT J. STEPHENSON, CET, DONALD R. FISCHER, MD, WILLIAM H. NECHES, MD, SANG C. PARK, MD, CORA C. LENOX, MD, and JAMES R. ZUBERBUHLER, MD

Twenty-one postoperative patients with transposition of the great arteries (TGA) underwent graded exercise testing 4 to 15 years (mean 9) after the Mustard operation. No patient had subjective exercise intolerance before testing, although some had symptomatic resting arrhythmias. Correlations were made between cardiac catheterization data and 24-hour ambulatory monitoring. Exercise tolerance was diminished in nearly half of the patients. No statistically significant differences were found in heart rate or blood pressure responses, but maximal oxygen consumption values were lower than the control values ($p < 0.001$) in the larger patients. Arrhythmias were present or provoked in most patients during exercise testing. Only 28% remained in normal sinus rhythm during and after exercise. Multifocal premature contractions were the most serious arrhythmias demonstrated. Some long-term survivors of the Mustard operation may have abnormal exercise dynamics, even though they may be asymptomatic and have normal physical activities and endurance. Mean maximal systolic blood pressure, heart rate, oxygen consumption, and maximal treadmill times were consistently in the low-normal range or were statistically lower than normal.

Graded maximal exercise testing provides an objective way to measure the exercise capability of patients with congenital heart disease and occasionally discloses abnormalities not clinically apparent in the resting state.[1–13] Such testing is particularly useful in determining the postoperative functional capacity of patients with congenital heart disease, because postoperative resting hemodynamics and other noninvasive studies may not demonstrate significant abnormalities found during exercise. A group of clinically well postoperative patients with transposition of the great arteries (TGA) were tested to determine their exercise endurance,

From the Division of Pediatric Cardiology and the Exercise Physiology Laboratory, Children's Hospital of Pittsburgh, and the University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania. This study was supported in part by a grant from the Beaver County Heart Association, Beaver, Pennsylvania. maximal oxygen consumption, blood pressure and arterial oxygen responses, and electrocardiographic changes during dynamic exercise.

Methods

Twenty-one patients >8 years of age (8.8 to 22 years, mean 13) underwent graded treadmill exercise testing in the Exercise Physiology Laboratory. These patients who volunteered to participate in the exercise test were selected from a group of 35 asymptomatic patients who had survived ≥3 years after the Mustard operation. Eleven patients had simple TGA, whereas the remainder had additional associated defects including ventricular septal defect (4 patients), pulmonary stenosis (3 patients), or both (3 patients). Age at the time of the Mustard operation ranged between 1.6 and 11 years (mean 4.6), and the postoperative interval ranged from 4 to 15 years (mean 9). No patient had apparent exercise intolerance and all participated in noncompetitive physical activities at the time of their exercise study. Four patients were taking cardiac medications at the time of their exercise study, including digoxin (2 patients), propranolol (1 patient), and both (1 patient).

Sixty-one youngsters without heart disease (range 9 to 20 years, mean 14) constituted the control group which was comprised of normal volunteers and individuals who were tested because of a history of chest pain or a suspected arrhythmia. None was regularly involved in strenuous competitive athletics at the time of the exercise test. The age and sex distributions were comparable in the control and study groups. Both groups were divided into 3 subgroups by body surface area (Group I: 0.7 to 1.09 m^2, 5 patients; Group II: 1.10 to 1.39 m^2, 11 patients; Group III: 1.40 to 1.89 m^2, 5 patients).

Four limb and 6 precordial electrodes were placed after superficial skin abrasion with a dental burr. All patients and control subjects underwent progressive exercise testing on a treadmill using a modified Balke protocol (International Medical Corporation Viagraph I Electrocardiographic Stress Monitor and Treadmill). Eighteen patients walked at 3.4 mph, but 3 younger patients performed at 3.0 mph to prevent running. A 4% increment in treadmill elevation was made every 3 minutes. Resting blood pressure, heart rate, and a 12-lead electrocardiogram were obtained in sitting, standing, and supine positions and after hyperventilation. One precordial lead was continuously monitored (V_1 in the transposition group and V_5 in the control group) during each test and a 12-lead strip was recorded every minute. Blood pressure was obtained every 3 minutes with a programmed sphygmomanometer (Narco Biosystems model PE-300) and an appropriate-sized arm cuff. Oxygen consumption was measured in the sitting position at rest and continuously throughout the exercise test (Waters model MRM-1 Oxygen Consumption Computer). Validation studies comparing this instrument and the Douglas bag method for oxygen consumption by us and others[14] have shown a high correlation in results (r = 0.90) between the 2 methods. In both groups, arterial oxygen saturations were measured noninvasively at rest and during exercise with an ear oximeter (Hewlett-Packard model 47201A). Correlation studies have previously been performed in our laboratory and by others[15] comparing the ear oximeter method and direct blood gas analysis of arterial blood samples obtained during diagnostic cardiac catheterization. In a study of 30 patients (aged 6 to 20 years, mean 12) undergoing elective cardiac catheterization in whom left heart or systemic arterial blood samples were obtained, correlation with noninvasive ear oximeter values was high (r = 0.91).

All patients and control subjects were encouraged to proceed to exhaustion. Monitoring was continued for 6 minutes after exercise or until the patient's vital signs returned to baseline values. Oxygen consumption reached a plateau at the end of exercise.

Cardiac catheterization: All 21 patients had at least 1 postoperative catheterization. This procedure occurred an average of 55 months (range 8 to 86) before exercise study. Intracardiac pressure, oxygen saturation, and cineangiographic studies were performed in all patients. Eleven of the 21 patients also had electrophysiologic studies to evaluate sinus node function, conduction intervals, and response of the atrioventricular (AV) node to rapid atrial pacing.

Twenty-four-hour ambulatory monitoring: Sixteen of the 21 patients with TGA had at least one 24-hour ambulatory electrocardiographic monitoring period with the International Medical Corporation Holter II dual-channel recorder. This unit scans continuously and records a 10-second trace every 2 minutes automatically as well as during any abnormal electrical event.

TABLE I Summary of Exercise Data

Parameter	Group	TGA (n = 21)	Control (n = 61)	p Value
Treadmill time (min)	I	9 ± 4	12 ± 4	NS
	II	11 ± 4	13 ± 3	NS
	III	8 ± 3	16 ± 4	<0.001
Maximal heart rate (beats/min)	I	148 ± 2	172 ± 11	<0.01
	II	156 ± 30	188 ± 10	NS
	III	160 ± 38	189 ± 10	NS
Maximal systolic blood pressure (mm Hg)	I	119 ± 12	129 ± 8	NS
	II	127 ± 19	135 ± 16	NS
	III	132 ± 17	158 ± 23	NS
Maximal oxygen consumption (ml/kg/min)	II	45.8 ± 5	54.2 ± 10	NS
	III	34.0 ± 7	51.1 ± 10	<0.001

BP = blood pressure; NS = not significant; TGA = transposition of the great arteries.

Results

Cardiac catheterization and electrophysiology: These studies were performed from 1 to 9 years postoperatively (mean 4) and demonstrated a variety of hemodynamic abnormalities including superior vena caval obstruction in 3 patients (superior vena cava—systemic venous atrial gradient ≥5 mm Hg); pulmonary venous obstruction in 2 patients (pulmonary capillary wedge-pulmonary venous atrial gradient ≥5 mm Hg); pulmonary stenosis in 4 patients (left ventricular—pulmonary artery gradient ≥50 mm Hg); residual ventricular septal defect in 4 patients; right ventricular dysfunction in 1 patient (resting right ventricular end-diastolic pressure ≥10 mm Hg + poor contractility of right ventricle); interatrial baffle leak in 5 patients. Electrophysiologic studies in 11 patients consisted of measurement of A-H and H-V intervals (7 patients), rapid atrial pacing (10 patients), and sinus node recovery time (10 patients). Of the 10 patients with measured sinus node recovery time, 6 had a normal time (<250 ms, corrected for R-R interval) and in 4 it was prolonged. Nine of 10 patients with rapid atrial pacing had a normal response (1:1 conduction to pacing rates of 200 beats/min). In 1 patient AV block developed at a pacing rate of 140 beats/min. Atropine did not change his maximal pacing rate. Of the 7 patients in whom an

H-V interval could be measured, 5 had normal (H-V <55 ms) whereas 2 had prolonged conduction. Three patients who developed premature ventricular contractions and another who developed junctional rhythm during exercise testing had previously had normal electrophysiologic studies.

Exercise tolerance: Graded exercise tests were performed 8 to 86 months (mean 56) after postoperative cardiac catheterization (Table I). Ten (47%) of 21 patients had decreased exercise tolerance (treadmill time <8 minutes with a maximal oxygen consumption <40 ml/kg/min). No statistically significant difference was seen in the maximal duration of exercise between control Groups I and II and TGA Groups I and II, but a significantly lower treadmill time was apparent in Group III TGA patients compared with Group III normal subjects ($p < 0.001$) (Table I).

Heart rate response: Maximal heart rate was evaluated in 18 of the 21 patients. (Three patients were excluded because of propranolol therapy in 2 patients and a permannent pacemaker in 1.) There was no statistically significant difference in heart rate response between TGA patients and control subjects in all subgroups. However, the TGA groups were at the lower limit of the maximal heart rate range.

Blood pressure response: Maximal systolic blood pressure was determined in 19 of the 21 patients after the Mustard operation (Table I). (Two patients who were receiving propranolol were excluded.) No statistically significant difference was seen between normal subjects and TGA patients. However, the mean systolic blood pressure in each of the TGA groups was at the lower end of the normal range. No significant difference in diastolic blood pressure during exercise was evident between the TGA and the control groups.

Oxygen consumption: Maximal oxygen consumption values are summarized in Table I. Data were not obtained in Group I patients. No significant difference was present between Group II TGA patients and control subjects, but a significantly lower maximal oxygen consumption was found in the larger patients (Group III) after the Mustard operation ($p < 0.001$).

Arterial oxygen saturation: Systemic arterial oxygen saturations were noninvasively determined by ear oximetry in 16 patients during exercise testing. Only 9 patients (56%) had a normal oxygen saturation (>94%) at rest. Of these, 4 developed mild desaturation during exercise (90 to 92%). None of the 4 patients had had any evidence of right-to-left intracardiac shunting by indicator dye dilution study or cineangiography during their previous postoperative cardiac catheterization. Review of their operative notes showed that all 4 had been left with coronary sinus blood draining to the systemic venous atrium. Seven patients were desaturated at rest (75 to 93%). Right-to-left shunts due to interatrial baffle leaks were found in 5 patients at the time of postoperative cardiac catheterization, but 4 of the 7 patients with arterial desaturation had coronary sinus blood draining to the pulmonary venous atrium. Further desaturation developed in all 7 patients with resting arterial desaturation during exercise testing. All normal control subjects had systemic arterial oxygen saturations of ≥95% at rest and during exercise.

Analysis of S-T segments: Only 2 of 21 patients had S-T segment depression of >1 mm at rest. Fourteen of 21 in the TGA group had >1 mm depression of the S-T segment from baseline level in precordial lead V_1 during exercise. In view of preexistent right ventricular hypertrophy in most patients, this S-T segment shift during exercise could not be considered diagnostic of true myocardial ischemia. No abnormal S-T segment shifts were seen in any normal individuals.

Arrhythmias: Abnormal cardiac rhythms were present in 6 patients at rest and became apparent in 5 more during exercise (Table II). Fifteen of 21 patients had sinus rhythm at rest, but only 6 of these 15 remained in sinus rhythm throughout exercise. Premature ventricular contractions were frequently provoked during exercise and occurred in patients who were in normal sinus rhythm (5 patients) or in AV dissociation (1 patient) at rest. One patient with resting multifocal ventricular premature beats continued to show the same abnormality with similar frequency throughout exercise. An additional patient who was in normal sinus rhythm at rest and also during exercise developed extreme sinus bradycardia in the early postexercise period. One other patient with surgically induced complete heart block required implantation of an epicardial artificial pacemaker in the early postoperative period. His paced rate did not change during the exercise test. Atrial tachycardia or flutter was not seen during exercise. No arrhythmia was present in any of the normal control subjects.

Long-term electrocardiographic monitoring: Twenty-four hour ambulatory electrocardiographic monitoring was performed in 16 patients with TGA who underwent exercise testing. In most, arrhythmias found during exercise testing were also seen during the longer recording period. Discordance between ambulatory monitoring and the exercise study occurred in 2 patients. In 1, premature ventricular contractions and brief periods (<4 consecutive beats) of ventricular tachycardia were detected only by ambulatory monitoring, whereas in the other patient, ventricular arrhythmias were found only during exercise testing.

Relation of abnormal cardiac catheterization findings to exercise performance: Abnormal cardiac catheterization findings were observed in 17 of 21

TABLE II Cardiac Rhythms and Arrhythmias

Rest		Exercise
NSR (15)	6	NSR
	2	PAC
	2	Junctional
	4	PVC, unifocal
	1	PVC, multifocal
AV dissociation (3)	2	AV dissociation
	1	PVC, unifocal
Junctional (1)	1	Junctional
PVC, multifocal (1)	1	PVC, multifocal
Complete AV block (1)	1	Complete AV block

AV = atrioventricular; NSR = normal sinus rhythm; PAC = premature atrial contractions; PVC = premature ventricular contractions.

postoperative patients including patients with ventricular septal defect, systemic and pulmonary venous obstruction, pulmonary stenosis, and/or pulmonary hypertension. Decreased work performance was seen in 7 patients with exercise-induced arrhythmias and in 3 of 6 patients who demonstrated arterial desaturation at rest or during exercise, or both. Normal exercise responses were found in only 4 patients who had "normal" hemodynamics during postoperative cardiac catheterization.

Discussion

Graded exercise testing has become an important diagnostic tool and may uncover potentially serious cardiac abnormalities not evident in the resting state. Recent studies in the pediatric population emphasize its usefulness and reproducibility.[9–12] Several long-term studies of patients with TGA who had undergone the Mustard operation have shown hemodynamic and electrocardiographic abnormalities,[1–8,13,16] and some recent reports also document abnormal exercise performance in such patients.[17–19]

All patients in this study were attending school or working, or both, and none reported exercise intolerance. Only 4 were receiving cardiac medications. Despite this apparently normal functional state, during the physical stress of exercise a number of parameters, including duration of exercise, maximal heart rate, systolic blood pressure, and oxygen consumption may be abnormally low, either statistically or in the low range of normal. This subnormal response was particularly evident in older patients. Ear oximetry detected arterial desaturation in each patient with a previously documented right-to-left atrial shunt and discovered desaturation during exercise in several more patients who were fully saturated at rest and in whom no right-to-left shunt had been demonstrated at previous cardiac catheterization. Presumably, small interatrial baffle leaks that became more significant with increased systemic venous return were responsible for the desaturation noted during exercise, although intrapulmonary shunting must also be considered.

A variety of hemodynamic abnormalities were documented in some postoperative patients despite a functionally normal clinical status. These residual problems were occasionally associated with abnormal exercise responses. Two patients with significant postoperative pulmonary stenosis (left ventricular-pulmonary artery gradient >50 mm Hg) had coexistent premature ventricular contractions at rest or during exercise, or both, and both had diminished exercise tolerance (maximal oxygen consumption <30 ml/kg/min and treadmill time <9 minutes). Two patients with a resting systemic oxygen saturation <85% had decreased exercise tolerance. Mild pulmonary hypertension (pulmonary arterial pressure 40/15 mm Hg) in 2 patients and complete superior vena caval obstruction in 2 additional patients did not interfere with exercise performance. Arrhythmias at rest and arterial desaturation, determined during cardiac catheterization or noninvasively, appeared to be predictors of an abnormal exercise response.

Because of preexistent right ventricular hypertrophy in most patients, the resting and exercise electrocardiogram was of no help in suggesting myocardial ischemia. Of particular concern was the frequency of arrhythmias noted during maximal exercise testing. Only 6 (28%) of 21 patients remained in normal sinus rhythm both during and after exercise. Premature ventricular contractions were provoked during exercise in 6 patients, and 2 of these 6 had multifocal premature ventricular contractions. The long-term significance of such arrhythmias is unknown, but 1 patient with exercise-induced unifocal premature ventricular contractions died suddenly 6 months after the study, presumably because of an arrhythmia.

Although 24-hour ambulatory electrocardiographic monitoring may detect many arrhythmias, exercise testing *and* ambulatory monitoring should be performed periodically to detect potentially life-threatening arrhythmias. Whether these arrhythmias are related to a lowered maximal heart rate during exercise or are caused by true ischemia, sinus node dysfunction, or depressed right ventricular function remains unknown.

Arrhythmias in Transposition of the Great Arteries After the Mustard Operation

LEE B. BEERMAN, MD, WILLIAM H. NECHES, MD, FREDERICK J. FRICKER, MD, ROBERT A. MATHEWS, MD, DONALD R. FISCHER, MD, SANG C. PARK, MD, CORA C. LENOX, MD, and JAMES R. ZUBERBUHLER, MD

Disorders of rhythm or conduction in patients with transposition of the great arteries (TGA) after the Mustard operation have been widely reported. This study provides a systematic evaluation of the electrophysiologic function of 87 survivors of the Mustard operation at a single institution. Surface electrocardiograms were reviewed in all 87 patients, Holter monitoring data in 26 patients, exercise electrocardiograms in 21 patients, and invasive electrophysiologic data in 61 patients. Surface electrocardiograms showed normal sinus rhythm in 52%, sinus node dysfunction in 27%, and atrioventricular block in 16%. Holter monitoring was obtained in an unselected subgroup of 26 patients who had a mean age of 12 years and a mean interval from operation of 9 years. Sinus node dysfunction was found in 58%, atrioventricular block in 27%, ventricular ectopy in 50%, supraventricular ectopy in 27%, and no abnormalities in only 8%. Intracardiac electrophysiologic evaluation showed a high frequency of abnormal sinus node recovery times and suboptimal response of the atrioventricular conduction system to rapid atrial pacing. When all modalities used in this study were considered, sinus node dysfunction occurred in 47%, ectopy in 34%, and atrioventricular block in 23%. Although only 30% of patients had no evidence of arrhythmia, symptoms of rhythm or conduction disturbances were rare.

One of the most widely recognized problems in patients with transposition of the great arteries (TGA) who have undergone the Mustard operation is the occurrence of arrhythmias. An early report from this institution indicated that 2 of 5 operative survivors had persistent arrhythmias, presumably related to surgical trauma to the sinus node in 1 and the atrioventricular node in the other.[1] Subsequently, various studies have reported the frequency of rhythm or conduction disturbances to be 13 to 100%.[2–9] The most commonly described abnormalities are sinus node dysfunction, supraventricular and ventricular tachyarrhythmias, and, to a lesser extent, atrioventricular conduction disturbances. This study provides a systematic evaluation of the electrophysiologic function of 87 survivors of the Mustard operation at a single institution. The parameters reviewed included surface electrocardiograms in all patients and Holter monitoring, invasive electrophysiologic studies, and exercise electrocardiograms in unselected subgroups.

From the Department of Pediatrics, Children's Hospital of Pittsburgh, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania.
This study was supported in part by the Western Pennsylvania Heart Association, Pittsburgh, Pennsylvania. Manuscript received June 3, 1982; revised manuscript received January 5, 1983, accepted January 7, 1983.

Methods

Eighty-seven survivors of the Mustard operation performed at Children's Hospital of Pittsburgh since 1965 had recent surface electrocardiograms available for review. All electrocardiograms from these patients were analyzed, and pertinent data regarding rhythm and conduction were tabulated. The time from operation to the most recent electrocardiogram ranged from 4 months to 15 years (mean 5.6 years).

Twenty-four–hour ambulatory Holter monitoring was performed in an unselected subgroup of 26 patients aged 7 to 22 years (mean 12). They were part of a group of older children who were chosen for more extensive evaluation and were not selected because of symptoms or suspected abnormalities. The interval from operation to Holter monitoring ranged from 4 to 15 years (mean 9). A dual-channel recorder (International Medical Cooperation Holter II) was used. The unit scanned continuously and recorded a 10-second trace every 2 minutes automatically and during each abnormal event.

The following definitions were used in the analysis of the surface electrocardiogram and Holter monitoring data. Sinus node dysfunction was defined as inappropriate sinus bradycardia for age, prolonged sinus pauses, or a nonsinus pacemaker by default, that is, junctional or ectopic atrial rhythm. The specific criteria used are shown in Table I. Ventricular ectopy was categorized as simple or complex on the basis of the modified Lown classification.[10] Grades 2 through 5 were considered complex, whereas Grade 1 ectopic activity (uniform, isolated premature ventricular beats occurring in a frequency <30/h) was considered simple. An exception to this categorization was made for rare couplets which were included

in the simple group. A similar classification was applied to supraventricular ectopy.

Invasive electrophysiologic studies were performed in 61 pre- and postoperative patients as part of the routine cardiac catheterization protocol which included hemodynamic and angiographic evaluation. The postoperative patients ranged in age from 1.5 to 14 years (mean 5.3). The mean postoperative interval until the time of the study was 2.3 years (range 0.3 to 10.7). Standard procedures utilizing 1 or 2 intracardiac electrode catheters were used for His bundle recordings and atrial pacing studies.[11] Atrioventricular conduction was evaluated by His bundle recordings in 32 pre- and 32 postoperative patients, with 13 patients having studies both before and after surgery. The upper limits of normal used in our laboratory for A-H and H-V intervals are 120 and 55 ms, respectively. Incremental atrial pacing was also used to assess atrioventricular conduction integrity in 31 pre- and 45 postoperative patients, including 15 patients who had both. A normal response was defined as 1:1 atrioventricular conduction up to and including an atrial pacing rate of 160 beats/min. Sinus node recovery time was evaluated in 24 pre- and 45 postoperative patients (13 had both) by pacing the right atrium at various rates between 120 and 200 beats/min for ≥30 seconds. The absolute sinus node recovery time was determined by measuring the interval between the last pacing artifact and the first spontaneous sinus recovery time and using the longest interval obtained at the different pacing rates. A corrected sinus node recovery time (absolute sinus node recovery time minus resting sinus cycle length) of ≤275 ms was considered normal.[12] Either a longer corrected sinus node recovery time (CSNRT) or a nonsinus recovery was considered abnormal.

Atrial extrastimulus studies were performed to evaluate refractory periods of the atrium and atrioventricular node in 13 patients, 3 pre- and 10 postoperatively. Standard techniques and normal values as described by Dubrow et al[13] were used. Intraatrial conduction was assessed in 8 patients, 2 pre- and 6 postoperatively, by measuring the conduction time from the high right atrium to the low right atrium (as recorded from a His bundle catheter) during spontaneous sinus rhythm. A normal conduction time was considered to be ≤35 ms.[14]

Twenty-one patients undewent stress exercise testing by treadmill according to a modified Balke protocol. The results of this study are the subject of another report, but rhythm and conduction abnormalities detected during exercise were tabulated and correlated with the results from the other variables evaluated in this study.

Results

Surface electrocardiogram: All patients were in normal sinus rhythm before the Mustard operation except 2 patients who had ectopic atrial rhythms. The only other abnormality of rhythm or conduction noted preoperatively was first degree atrioventricular block in 1 patient. The results of the review of the current electrocardiograms of the 87 survivors of surgery are summarized in Table II. Only 45 patients (52%) remained in normal sinus rhythm. The next largest subgroup consisted of 23 patients (27%) who manifested evidence of sinus node dysfunction. Atrioventricular block was present in 14 patients (16%) and was usually first degree. Two patients had third-degree atrioventricular block, 1 of whom required a permanent artificial pacemaker. Combinations of sinus node dysfunction and atrioventricular block or ectopy occurred in a few patients, but ectopics, either supraventricular or ventricular, in the total group were quite rare.

TABLE I Criteria for Sinus Node Dysfunction

	Heart Rate (beats/min)	
	Day	Night
1. Sinus bradycardia		
Age		
>11 yr	<50	<40

Total	87	100

* One patient had an artificial pacemaker.
AVB = atrioventricular block; PVCs = premature ventricular contractions; SND = sinus node dysfunction; 1° = first degree; 2° = second degree.

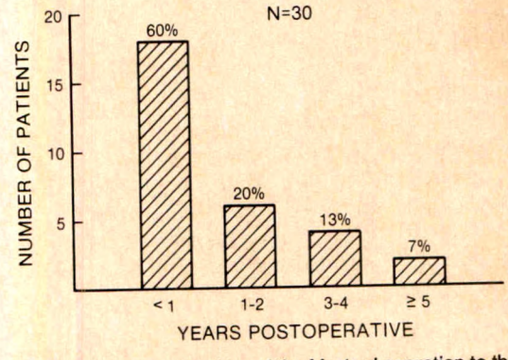

FIGURE 1. Interval from the time of the Mustard operation to the onset of sinus node dysfunction on the surface electrocardiogram.

All electrocardiograms after the Mustard operation until the most recent electrocardiogram also were reviewed and 20 patients showed abnormalities that were not seen on the most recent tracing. The most common finding, occurring in 8 patients, was the bradycardia-tachycardia syndrome with atrial flutter alternating with a slow junctional or sinus rhythm. There were 6 patients who had evidence of sinus node dysfunction on interim electrocardiograms who were in normal sinus rhythm on the current electrocardiogram. Ventricular

† Four patients had both ventricular and supraventricular ectopy.

ectopy, supraventricular ectopy, and atrial flutter (without evidence of sinus node dysfunction) were seen in 3 patients each. First degree atrioventricular block was present in 2 patients.

The interval from operation to the first electrocardiographic evidence of sinus node dysfunction could be determined in 30 patients and these results are illustrated in Figure 1. Although 60% of these patients showed sinus node dysfunction within the first postoperative year, 40% had a delayed onset of this abnormality. In half of the latter patients there were no electrocardiographic signs of sinus node dysfunction until ≥3 years after the Mustard operation.

Holter monitor: Results from 24-hour ambulatory monitoring of 26 patients are shown in Table III. As expected, all abnormalities were more frequently seen on Holter monitoring than on routine surface electrocardiography. Sinus node dysfunction was the most common abnormality, occurring in 15 patients (58%). In contrast to the low incidence of ectopy of any kind detected on routine electrocardiograms, 62% of the group undergoing Holter monitoring had ectopy (9 had ventricular alone, 3 supraventricular alone, and 4 both). Thirteen of the monitored group had ventricular ectopy, 6 complex and 7 simple. Supraventricular ectopy was present in 7 patients, but was frequent in only 1. Four patients with supraventricular ectopy also had ventricular arrhthymias. Atrioventricular block occurred in 7 patients (27%) and was first degree in 2, second degree in 4, and third degree in 1. Many patients had a combination of abnormalities and only 2 (8%) in the entire group had 24-hour ambulatory recordings free of any rhythm or conduction disturbances. The Holter technique was superior to the surface electrocardiogram in detecting both sinus node dysfunction and ectopy. A normal surface electrocardiogram was found in 50% of the patients with evidence of sinus node dysfunction on Holter monitoring, whereas only 2 of 17 patients with ectopy were identified by surface electrocardiography. Both Holter monitoring and exercise testing were performed in 17 patients and each was valuable in finding ventricular ectopy. Each technique found patients with significant ventricular dysrhythmias that would have been missed by using only the other method.

TABLE IV Intracardiac Electrophysiology After the Mustard Operation: His Bundle and Rapid Atrial Pacing

	A-H Interval >120 ms		H-V Interval >55 ms		RAP AVB <160 beats/min	
	n	%	n	%	n	%
Preoperative	2/32	6	1/32	3	1/31	3
Postoperative	1/32	3	3/32	9	8/45	18

AVB = atrioventricular block; RAP = rapid atrial pacing.

TABLE V Intracardiac Electrophysiology After the Mustard Operation: Sinus Node Function

	n	%
Normal CSNRT	33	73
Abnormal CSNRT	12	27

Total	45	100

CSNRT = corrected sinus node recovery time.

TABLE VI Intracardiac Electrophysiology After the Mustard Operation: Extrastimulus Studies

	Normal	Prolonged n	Prolonged %
Refractory periods (n = 10)			
AERP or AFRP	9*	1	10
AVNERP or AVNFRP	10	0	0
Intraatrial conduction (n = 6)	4	2	33
HRA-LRA			

* Three of these patients had values >1 standard deviation above the mean. Note: One patient had atrioventricular node reentry.
AERP = atrial effective refractory period; AFRP = atrial functional refractory period; AVNERP = atrioventricular node effective refractory period; AVNFRP = atrioventricular node functional refractory period; HRA = high right atrium; LRA = low right atrium.

Intracardiac electrophysiology: Invasive electrophysiologic studies were performed in 61 patients. The results of His bundle recordings and rapid atrial pacing are shown in Table IV. Prolonged A-H or H-V intervals occurred in very few patients either pre- or postoperatively. However, 8 postoperative patients (18%) compared with only 1 preoperative patient (3%) developed atrioventricular block at a pacing rate ≤160 beats/min.

Sinus node function was assessed by using the longest CSNRT obtained by atrial pacing. Twelve of 45 postoperative patients (27%) had an abnormal CSNRT, whereas only 2 of 29 patients (7%) in the preoperative group had abnormal results. Table V illustrates the degree and type of abnormality found in the 12 patients with electrophysiologic evidence of sinus node dys-

function. The large number of patients with abnormal CSNRT correlated with the high incidence of sinus node dysfunction detected by other means, as 67% of these patients had evidence on the surface electrocardiogram or Holter monitor of sinus node dysfunction. However, discrepant clinical and electrophysiologic findings were not unusual. An abnormal CSNRT was present in 13% of those patients with no evidence of abnormal sinus node function on surface electrocardiogram or Holter monitor. Conversely, 21% of those with a normal CSNRT had clinical evidence of sinus node dysfunction.

Atrial extrastimulus studies were performed to evaluate refractory periods of the atrium and atrioventricular node, and intraatrial conduction was also assessed (Table VI). Because normal values were obtained in all preoperative patients, only postoperative data are shown. Although only 1 patient had a prolonged atrial refractory period, defined as >2 standard deviations greater than the mean values determined by Dubrow et al,[13] there were 3 additional patients who had values >1 standard deviation above the mean. None of this group had abnormal AV nodal refractory periods, although in 1 patient Wenckebach block had developed during rapid atrial pacing at 160 beats/min. Intraatrial conduction was prolonged in 2 patients. During the extrastimulus study, 1 patient had readily inducible supraventricular tachycardia with characteristics of AV nodal reentry, although he had no clinically detected arrhythmia.

Combining the results of all modalities used to evaluate electrical function in this study, there was a very high incidence of arrhythmias. Evidence of sinus node dysfunction occurred in 47% and ectopy in 34%. Although atrioventricular block was seen in 23%, only 2 patients had third degree atrioventricular block and only 1 of these required a permanent artificial pacemaker. Only 26 patients (30%) had no demonstrable abnormalities of electrical function.

Discussion

Postoperative disturbances of rhythm and conduction in patients with TGA after the Mustard operation have been widely reported and the frequency has varied between 13 and 100%.[1–9] Several possible explanations exist for this discrepancy in the frequency of abnormalities among the various series, including a varying duration of follow-up, different methods of evaluation (that is, surface electrocardiography, invasive electrophysiologic studies, Holter monitoring, or exercise testing), and lack of agreement on what actually constitutes an abnormality. As expected, ambulatory 24-hour monitoring greatly increases the yield of conduction and rhythm disturbances compared with analysis only of random surface electrocardiograms. However, as Southall et al[5,15] have pointed out, many bradyarrhythmias detected on 24-hour ambulatory recordings in postoperative patients that are presumed to be abnormal may actually occur in a normal population. Further studies on normal children are needed before valid criteria for abnormalities can be firmly established.

The higher frequency of abnormalities detected by ambulatory monitoring also may be related to the longer duration of follow-up since operation in the 24-hour monitored group (mean 9.2 years) than in the group whose electrocardiograms were reviewed (mean 5.6 years). Clearly, the frequency of sinus rhythm decreases as patients are followed up for longer periods postoperatively.[8,16]

The types of arrhythmias that have been described fall into 2 categories, passive or bradyarrhythmias and active or tachyarrhythmias. The former group includes sinus node dysfunction and atrioventricular conduction disturbances, whereas the latter category includes supraventricular and ventricular ectopy. The sites of potential damage during placement of the interatrial baffle include the sinoatrial node and its artery, atrial conduction pathways, the atrioventricular node, and the proximal His bundle. In patients with associated anomalies, such as ventricular septal defect and subpulmonary stenosis, requiring surgical intervention, the infrahisian conduction system and ventricular tissue may also be injured.

Although all factors involved in the pathogenesis of arrhythmias in patients after the Mustard operation may not be completely understood, interruption of normal sinus node function is undoubtedly of major importance. It is not surprising that sinus node dysfunction is the most commonly reported arrhythmia in view of the extensive surgical manipulation required in the vicinity of the sinoatrial node and its artery during the Mustard procedure. Histologic evidence of sinoatrial node degeneration and damage to the sinoatrial node artery has been demonstrated in postoperative patients.[8] This same study showed surface electrocardiographic evidence of sinus node dysfunction in approximately half those patients followed up >3 years. Saalouke et al[4] found that 63% of patients had a prolonged CSNRT on intracardiac electrophysiologic testing, and a study of 52 postoperative patients by Gillette et al[17] demonstrated a 58% incidence of abnormal sinus node recovery after rapid atrial pacing. In the latter study, 3 of 9 patients also had prolonged sinoatrial conduction times.

Although Clarkson et al[2] reported that 87% of their patients remained in normal sinus rhythm after the Mustard operation, their analysis involved only surface electrocardiograms and the average follow-up time was only 31 months. The present study demonstrates that the use of multiple parameters of evaluation and longer duration of follow-up greatly increases the number of abnormalities detected. Both Holter monitoring and intracardiac electrophysiologic testing detected evidence of sinus node dysfunction not present on the surface electrocardiogram and resulted in an overall incidence of 47%. Furthermore, 20% of the patients in this series with surface electrocardiographic evidence of sinus node dysfunction did not show this abnormality until >3 years after the Mustard operation.

Various modifications in surgical technique have been recommended to avoid damage to the sinoatrial node and its artery.[2,3,5,9] Although several series have demonstrated a decrease in the incidence of sinus node

dysfunction after these modifications,[3,9] the occurrence rate of this abnormality remains significant. It is likely that the moderate improvement in results is related more to a heightened awareness of the anatomy and importance of the sinoatrial node and its artery than to any specific changes in technique. At our institution, modifications in the surgical approach to the Mustard operation since the early 1970s have generally paralleled the increased appreciation of the importance of preserving sinoatrial node integrity. These include avoiding cannulation near the superior vena cava-right atrial junction and taking care in suturing the superior portion of the interatrial baffle.

In addition to concern over surgically induced damage to the sinoatrial node, the effect of the Mustard operation on atrial and atrioventricular nodal electrophysiologic function has also been the subject of investigation. Although Gillette et al[17] showed that intraatrial conduction between the high right atrium and the low septal right atrium was abnormal in only 2 of 41 patients studied, several patients had isolated areas of delayed atrial conduction in the low lateral right atrium. Saalouke et al[4] demonstrated a prolonged atrial effective refractory period in 33% of their patients. Both studies showed that atrioventricular nodal function was almost always normal postoperatively. The number of patients who had atrial extrastimulus studies and evaluation of intraatrial conduction in the current series was small, but the occurrence of abnormal atrial refractory periods and prolonged intraatrial conduction in some of these patients indicates that further studies are warranted. Although this series showed a significant number of patients with evidence of abnormal atrioventricular conduction by either surface electrocardiogram or response to rapid atrial pacing, third degree atrioventricular block occurred only twice and only once did it necessitate a permanent artificial pacemaker. Other studies have also shown that atrioventricular conduction disturbances may be found in postoperative patients.[18,19]

Tachyarrhythmias, either supraventricular or ventricular, have also been recognized as a source of morbidity after the Mustard operation.[4,5] In electrophysiologic studies of the cause of supraventricular tachycardia after the Mustard operation, Gillette et al[17] found reentry within either the sinus node or the atrial myocardium to be the predominant mechanism. Although sudden death in patients with a good hemodynamic result from the Mustard operation has been associated with atrioventricular conduction disturbances,[3] it is becoming apparent that ventricular arrhythmias may be an even more important factor in this distressing late complication. Previous studies using ambulatory monitoring showed considerable variation in the frequency of ventricular premature beats or tachyarrhythmias. Hayes et al[16] found that 12% of their patients had multiple premature ventricular contractions, whereas Saalouke et al[4] detected complex ventricular arrhythmias in 40%. The use of Holter monitoring and exercise testing in addition to routine surface electrocardiography demonstrated complex ventricular ectopy in 23% of our patients. No patient in our series has been symptomatic from ventricular arrhythmias and none has received chronic antiarrhythmic therapy, because complex ectopy occurred infrequently during the monitoring period. Recently, however, a 23-year-old woman who had exercise-induced multiform premature ventricular contractions died suddenly. Another 14-year-old boy had an unexplained sudden death that was most likely due to a rhythm or conduction abnormality. He had never been studied by ambulatory monitoring, exercise testing, or invasive electrophysiology, but surface electrocardiograms demonstrated first-degree atrioventricular block and a QRS duration of 0.14 second.

Some series have related the incidence of postoperative rhythm and conduction abnormalities to associated cardiovascular anomalies complicating the surgical repair (that is, closure of a ventricular septal defect or resection of subpulmonary stenosis).[5,20] In this series no significant relation was found between associated anomalies and the incidence of postoperative arrhythmias.

Summary

JAMES R. ZUBERBUHLER, MD

The reports in this Symposium have detailed some anatomic, hemodynamic, and electrophysiologic abnormalities discovered in 95 survivors of the Mustard operation for complete transposition of the great arteries (TGA). Abnormalities were common and most patients had demonstrable residua, some natural and some iatrogenic. The frequency of residual abnormalities could be viewed as an indictment of intraatrial repair and as support for a change to the "arterial switch" operation. However, few demonstrated abnormalities have required treatment, are currently producing symptoms, or are limiting individuals in their daily activities. No residual anatomic or hemodynamic abnormalities seem life-threatening, although we know little of the potential hazards of the electrical derangements.

There have been 8 late deaths among the 95 survivors: 1 occurred just over 1 month after operation, 3 were related to reoperation for important residual hemodynamic abnormalities, 2 were due to infection not related to the congenital cardiac anomaly or to its surgical repair, and 2 others were sudden, presumably caused by dysrhythmia. Each of the latter had premature ventricular contractions, on a 24-hour electrocardiogram in 1 patient and on resting electrocardiogram in the other. Otherwise, both patients had been thought to have had an excellent result.

My current attitude toward the Mustard operation is one of cautious optimism. However, there is little doubt that attrition will continue among our group of survivors, from dysrhythmia and perhaps from right ventricular failure. Whether the Mustard operation or some other form of intraatrial repair will continue to be widely used will depend on other studies like this one and, even more importantly, on similar studies of patients with other types of repair, including the arterial switch operation. Currently a high operative mortality is associated with the switch operation and it is uncertain whether there will be fewer residua than there are in patients who have undergone intraatrial repair. In our institution intraatrial repair continues to be the operation of choice, although more of the Senning than of the Mustard variety of intraatrial repair is currently being performed, largely because of the personal preference of one surgeon. Whether we continue with the intraatrial repair technique will depend on the appearance of studies detailing the "long-term" results of alternative procedures.

Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal*. All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

Journal: Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.

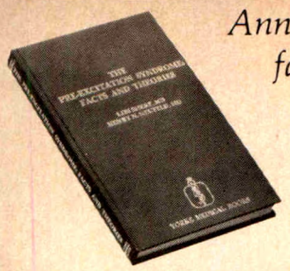
Chapter in Book: Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.

Book: Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.



Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, M.D., FACC, Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

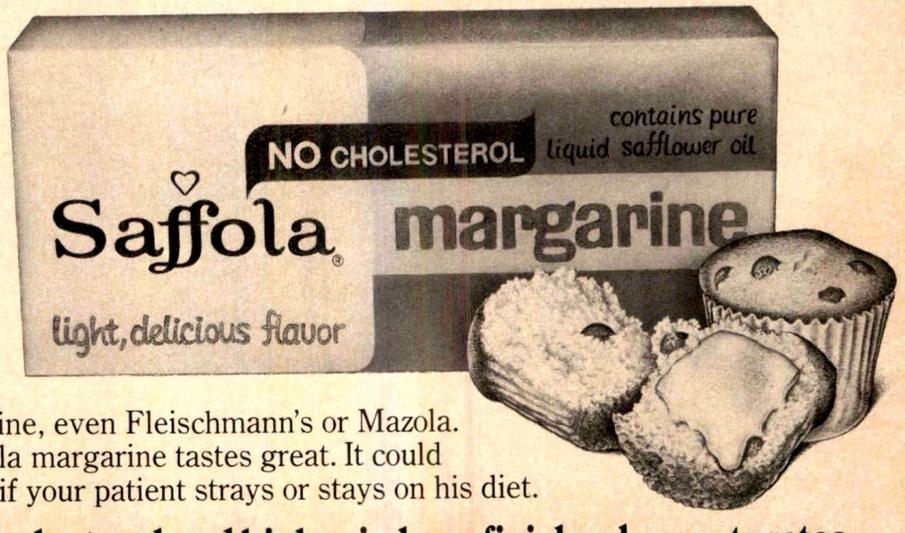
Cheer up a low cholesterol diet with Saffola.



Saffola margarine is perfect for your patients following a low-cholesterol diet.

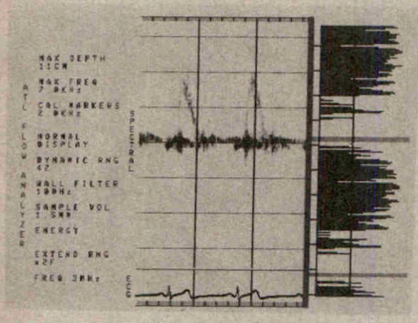
First of all, Saffola has no cholesterol. And it is higher in beneficial polyunsaturates than corn oil margarine, even Fleischmann's or Mazola.

But because Saffola margarine tastes great. It could mean the difference if your patient strays or stays on his diet.

Absolutely no cholesterol and higher in beneficial polyunsaturates.

WE'VE TAKEN TECHNOLOGY TO HEART.

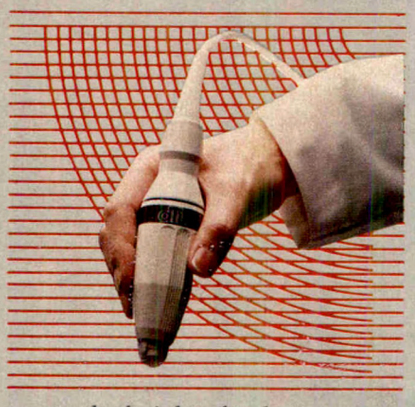
When it comes to high technology, ATL has its heart in the right place—a place where you can find even more diagnostic information about the entire cardiovascular system than you ever thought was possible. Today, it's not just possible—it's available. Improved 2D echocardiography and Adaptive Doppler™ bring ATL innovation to the noninvasive evaluation of cardiac function. We see it assuming a stronger role day by day in both adult and pediatric cardiac examination, in many cases obviating the need for angiography.



Our goal is to improve the information content of your diagnostic studies...to give you maximum benefit from this valuable resource.

Getting the best of technology.

We at ATL have one of the largest technology bases in the ultrasound industry—research scientists and engineers who have innovated their way from the ground floor of ultrasound technology a decade

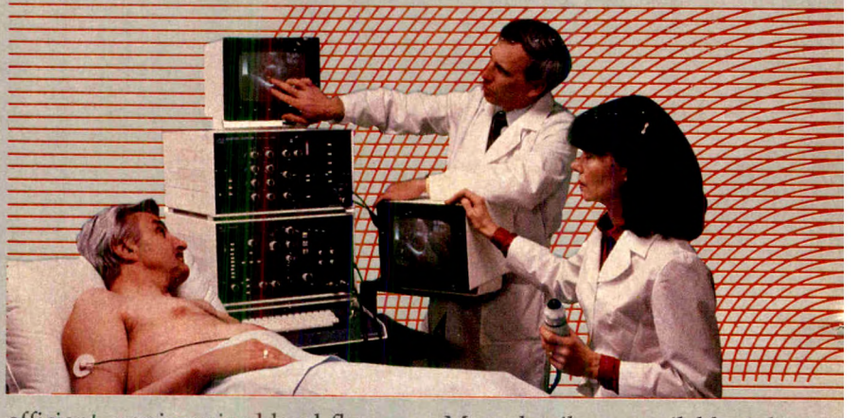


ago to the height of today's imaging techniques. Adaptive Doppler technology, recently introduced in the MK 600 Ultrasound System, is the latest of their contributions—a major step in highly accurate, efficient, noninvasive blood-flow measurement.

To achieve complete diagnostic significance, your examination also requires a 2D real-time image of the highest quality—the quality image for which ATL has been widely recognized. Our CardioSeries™ Ultrasound Systems have all incorporated a new wide-range receiver, new "Blue Label" Scanheads with improved sensitivity, larger memory, and selective gray-scale M-mode. The immediate advantages are greater penetration and improved resolution, ultimately increasing the information content of your exam and helping you complete more exams in less time.

There are still innumerable informational bits to be uncovered within the human machine. We invite you to take ATL technology to heart and explore the cardiovascular system with new-found efficiency and accuracy.

The diagnostic possibilities are astronomical.



More details are available right now about our CardioSeries Ultrasound Systems. Call 800-426-2670, ask for "Customer Information." Or write: Advanced Technology Laboratories, Inc., 13208 Northup Way, P.O. Box 4639, Bellevue, WA 98009-0639.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

EDITED BY

DEAN T. MASON, M.D.
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-In-Chief, AMERICAN HEART JOURNAL

JOHN J. COLLINS, JR., M.D.
Professor of Surgery
Chief, Division of Thoracic and Cardiac Surgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Sample Table of Contents:

Section 1 - Stable Angina Pectoris and Asymptomatic Coronary Disease

Section 2 - Variant Angina Pectoris

Section 3 - Unstable Angina Pectoris

Section 4 - Acute Myocardial Infarction

Section 5 - Myocardial Preservation

Section 6 - Pharmacologic and Related Approaches to Coronary Dilatation

Section 7 - Percutaneous Transluminal Coronary Angioplasty

Section 8 - Intracoronary Thrombolysis in Evolving Myocardial Infarction

Section 9 - Long-Term Achievements of Myocardial Revascularization by Medical and Surgical Therapy

Your Right to Know... The Facts in Black and White

FACT: Calan® (verapamil HCl) is the calcium antagonist consistently demonstrating antianginal benefits equal to, or greater than, propranolol, at clinically used doses in angina of effort.[1,2,3,4,5,6]

- Calan is also effective in variant angina[7] (where spasm may be exacerbated by propranolol[8]) as well as in unstable angina.[9]

FACT: In direct-comparative studies, the antianginal benefits of Calan were reported to be unsurpassed by nifedipine.[10,11,12]

- In stable effort angina: "The trial demonstrated a clear difference in the antianginal efficacy of [verapamil (Calan) and nifedipine]. . . .Verapamil [Calan] was more effective . . . ."[10] In another study, the efficacy differences were not statistically significant.[11] The doses used in both studies were Calan 120 mg tid and nifedipine 20 mg tid.

  In variant angina, in the one published comparative study, Calan and nifedipine showed equal efficacy. However, this study was neither blinded nor randomized.[12]

- Studies were directly comparative, and responses to each drug were measured objectively.[10,11,12]

FACT: Calan is indicated as single-agent initial therapy for all types of angina, while nifedipine is not.[13,14]

- Nifedipine is indicated in stable effort angina only in patients refractory to or intolerant of nitrates and/or beta-blockers.[14]
- Nifedipine is indicated for unstable angina only when ECG findings indicate vasospasm or the disease is refractory to nitrates and/or beta-blockers.[14]

FACT: The potential serious cardiovascular side effects of Calan are similar to those of beta-blockers.

- Calan and propranolol have basically the same cardiovascular cautions and contraindications such as in patients with ventricular dysfunction, second- or third-degree AV block, or cardiogenic shock.[13,15] Calan is also contraindicated in the presence of sick sinus syndrome or hypotension.
- Calan rarely causes extreme fatigue or mental depression.
- Impotence, memory loss, or nightmares have not been associated with Calan use. Calan may cause constipation.
- Calan can be used without special caution in patients with angina who also have asthma, chronic obstructive pulmonary disease, diabetes mellitus, or peripheral vascular disease such as Raynaud's phenomenon.

FACT: The incidence of adverse effects of Calan and nifedipine merits comparison (see chart below).

Adverse Reactions Reported	nifedipine — Uncontrolled U.S. experience in 2,100 patients. The incidence of adverse reactions in controlled studies was generally the same or higher.[14]	(Calan) verapamil — Clinical studies in 1,166 patients — NOTE that similar results were seen in both controlled clinical trials and uncontrolled clinical experience.[13]
Dizziness, light-headedness	About 10%	3.6%
Constipation	2% or less	6.3%
Flushing	About 10%	*
Headache	About 10%	1.8%
Weakness	About 10%	*
Fatigue	*	1.1%
Nausea	About 10%	1.6%
CHF or pulmonary edema	**	0.9%
Peripheral edema	About 10%	1.7%
AV block: third-degree	*	0.8%
Transient hypotension	About 5%	2.9%
Palpitation	About 2%	*
Bradycardia: HR<50/min	*	1.1%
Syncope	About 0.5%	<0.5%

*Not reported in the prescribing information.[13,14]

**About 2%, "not readily distinguishable from the natural history of the disease." "It remains possible, however, that some or many of these events were drug related."[14]

Calan® (verapamil HCl) **TABLETS** 80 mg and 120 mg

Effective Angina Therapy

Please see reverse side for a brief summary of the complete prescribing information.

© 1982, Searle Pharmaceuticals Inc.

The Facts of Effective Angina Therapy

FACT: Calan® (verapamil HCl) has pharmacologic effects complementary to those of nitrates.[13]

- Like propranolol, Calan decreases myocardial contractility. Calan's effect on the SA node tends to minimize heart rate response to arterial vasodilation, leaving the rate unchanged or slightly reduced.[13]
- Nifedipine tends to cause slightly increased heart rate due to a sympathetic response to arterial dilation.[14]

FACT: Calan provides truly additive effects with propranolol when such combination therapy is necessary in the treatment of chronic stable angina.[3,4]

- In two studies involving a total of 33 patients, the additive effects of Calan with propranolol on exercise tolerance could be seen.

	Study A[3]	Study B[4]
Propranolol alone	+2 min *	+1.3 min
Calan alone	+3.2 min	+3.4 min
Calan with propranolol	+5.3 min	+4.7 min

*Difference from placebo to maximally tolerated exercise

- Combined therapy should be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function. Because of the still limited experience with combination therapy, Calan should be used alone, if possible.

FACT: Safety considerations are important with Calan, beta-blockers, and nifedipine.

- In patients with normal conduction, Calan's electrophysiologic effects are rarely clinically important.[13] However, Calan's contraindications include patients with sick sinus syndrome or second- or third-degree AV block.
- The concomitant use of digitalis with Calan or nifedipine requires caution because digoxin serum levels may increase.[16,17]
- Both Calan and nifedipine, as well as propranolol and nitrates, require monitoring during upward dose titration.[13,14,15]

For Your Patients With Angina...

Calan® TABLETS 80 mg and 120 mg
(verapamil HCl)

- Calan is the calcium antagonist with consistently demonstrated antianginal benefits equal to or greater than propranolol.
- Calan is effective in variant angina where spasm may be exacerbated by propranolol.[8]
- Calan, unlike nifedipine, has a first-line indication for stable effort angina.

Calan® (verapamil HCl) TABLETS 80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings),* hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Occasional elevations of liver enzymes have been reported; patients receiving verapamil should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil. **Precautions:** Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefuly monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR< 50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** Calan (verapamil HCl) is supplied in 80-mg and 120-mg sugar-coated tablets.

Trial of Combined Warfarin Plus Dipyridamole or Aspirin Therapy in Prosthetic Heart Valve Replacement: Danger of Aspirin Compared With Dipyridamole

JAMES H. CHESEBRO, MD, VALENTIN FUSTER, MD, LILA R. ELVEBACK, PhD, DWIGHT C. McGOON, MD, JAMES R. PLUTH, MD, FRANCISCO J. PUGA, MD, ROBERT B. WALLACE, MD, GORDON K. DANIELSON, MD, THOMAS A. ORSZULAK, MD, JEFFREY M. PIEHLER, MD, and HARTZELL V. SCHAFF, MD

Despite the use of oral anticoagulation in patients with prosthetic heart valves, persistent thromboembolism over time warrants a search for improved methods of prevention. Thus, patients receiving 1 or more mechanical prosthetic heart valves were randomized to therapy with warfarin plus dipyridamole (400 mg/day) or warfarin plus aspirin (500 mg/day) on the basis of location and type of valve and surgeon, and followed up with a concurrent, nonrandomized control group taking warfarin alone. In 534 patients followed up 1,319 patient-years, excessive bleeding (necessitating blood transfusion or hospitalization) was noted in the warfarin plus aspirin group (23 of 170 [14%], or 6.0/100 patient-years) compared with warfarin plus dipyridamole (7 of 181 [4%], or 1.6/100 patient-years, p <0.001), or warfarin alone (9 of 183 [5%], or 1.8/100 patient-years, p <0.001). A trend was evident toward a reduction in thromboembolism in the warfarin plus dipyridamole group (2 of 181 [1%], or 0.5/100 patient-years) as compared with warfarin plus aspirin (7 of 170 [4%], or 1.8/100 patient-years), or warfarin alone (6 of 183 [4%], or 1.2/100 patient-years). Adequacy of anticoagulation (based on 12,720 prothrombin time determinations) was similar in all 3 groups with 65% of prothrombin times in the therapeutic range (1.5 ≤prothrombin time/control ≤2.5), 30% too low, and 5% too high. Warfarin plus aspirin therapy resulted in excessive bleeding and is contraindicated. Longer follow-up study is needed to determine whether further separation of the incidence of thromboembolism can be detected.

Thromboembolism in patients with mechanical heart valves remains a major time-related problem. Only 58% of patients with mitral and aortic Starr-Edwards prostheses were free of thromboembolism at 15 years.[1] Although the incidence of thromboembolism has been decreasing in patients with more recent models of prostheses[1] and more recent operations,[2] it remains undesirably high in patients on conventional anticoagulant therapy alone.[1–10] Thus the use of an anticoagulant plus a platelet inhibitor was tested in 6 completed prospective trials.[5–10] Patients given the anticoagulant agent plus either dipyridamole[5–8] or aspirin[9,10] had the lowest incidence of thromboembolism. In 1 study, results did not reach statistical significance. Aspirin has been used in only a small number of patients and never compared with dipyridamole. With the use of aspirin, excessive bleeding ensued with a dosage of 1 g/day[10] but not with 500 mg/day.[9] Therefore, we began a prospective, randomized clinical trial of an orally administered anticoagulant agent plus either dipyridamole or medium-dose aspirin. We report the initial results.

From the Mayo Clinic and Mayo Foundation, Rochester, Minnesota. Manuscript received June 22, 1982; revised manuscript received February 14, 1983, accepted February 15, 1983.

Address for reprints: James H. Chesebro, MD, Division of Cardiovascular Diseases, Mayo Clinic, Rochester, Minnesota 55905.

Methods

From February 1979 to June 1981, patients receiving a mechanical prosthetic heart valve (aortic, mitral, or both) were randomized to treatment with warfarin sodium plus dipyridamole or warfarin sodium plus aspirin on the basis of location of valve (aortic, mitral, or both), type of valve (Starr-Edwards, Björk-Shiley, or other), and name of surgeon. A randomized control group treated with warfarin alone was not a part of the original protocol because we believed that

TABLE I Baseline Patient Characteristics (All Values Are Percentages)

	Warfarin + ASA (n = 170, Median Age 60 yr)	Warfarin + DIP (n = 181, Median Age 59 yr)	Warfarin (n = 183, Median Age 61 yr)
≥70 years old	18	19	12

treatment with more than warfarin alone was needed. However, within a few months of starting randomization, we decided to retrieve a control group treated with warfarin alone from patients who had had prosthetic valve replacement starting 2 months before the onset of our study and patients inadvertently not randomized by the surgical services. Thus we have 3 treatment groups for follow-up comparison: (1) warfarin plus dipyridamole 100 mg orally 4 times a day; (2) warfarin plus aspirin 250 mg orally twice a day; and (3) warfarin alone. Anticoagulant therapy and platelet-inhibitor therapy were started 48 hours after operation. Patients with peptic ulcer disease, previous gastrointestinal bleeding, or a bleeding disorder were excluded from the study.

Follow-up endpoints and information (obtained from patients and their physicians every 3 to 6 months) included the following: (1) thromboembolism, (2) bleeding necessitating blood transfusion or hospitalization, (3) adverse effects or problems necessitating discontinuation of the platelet-inhibitor therapy, (4) adequacy of anticoagulation based on prothrombin time determinations, and (5) taking platelet-inhibitor therapy regularly (>95% said yes, consistent with previous objective tests in Mayo Clinic patients[14] and with need for new supplies of platelet-inhibitor drug provided free of charge every 6 months). No blood levels or urine tests of compliance were done. If patients were not reexamined at the Mayo Clinic, hospital records were requested for documentation of thromboembolism or bleeding. Follow-up in this report is through August 1981, when aspirin was stopped because of bleeding (endpoint 2, above).

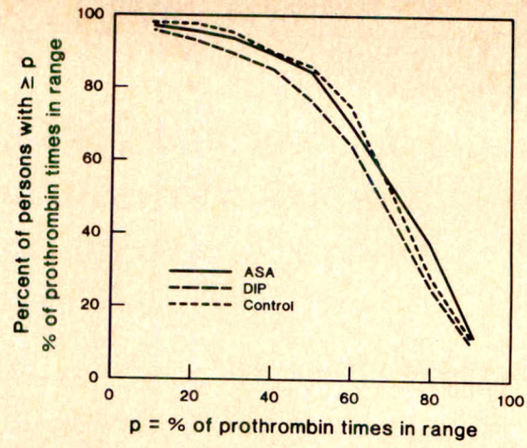

FIGURE 1. Adequacy of anticoagulation in the 3 treatment groups. The **abscissa** shows the percentage of prothrombin times in range ($1.5 \leq x \leq 2.5$). The **ordinate** shows the percentage of patients with at least the percentage of prothrombin times in therapeutic range as indicated on the **abscissa.** For example, 50% of patients had ≥70% of their prothrombin times in the therapeutic range. The percentage of persons with a given percentage of prothrombin times in therapeutic range did not differ significantly in the 3 groups. ASA = acetylsalicylic acid; DIP = dipyridamole.

Thromboembolism was defined as a temporary or permanent neurologic deficit of sudden onset with focal motor weakness or visual deficit unexplained by other factors. Thromboembolic events were tabulated starting immediately after platelet-inhibitor and anticoagulant therapy were initiated. Twenty-three patients died within 48 hours of operation and thus could not be entered. Two patients were excluded from the study because of cerebral emboli (completed stroke) 1 and 2 days after operation before antithrombotic therapy was started. Cerebral bleeding was confirmed either at autopsy or by a computed tomographic scan. A single valve thrombosis was verified at autopsy.

Operations were performed with the use of cardiopulmonary bypass and systemic hypothermia to 20° to 25°C. Multidose, cold (4°C) potassium cardioplegia was used for myocardial protection. The location and type of valve is shown in Table I. The Starr-Edwards valves were of the 6120 and 1260 series (bare strut, Silastic ball) in the mitral and aortic positions, respectively.

Standard chi-square tests were used in the group comparisons.

Results

Patient data (Table I): The baseline characteristics of the 534 patients in the 3 treatment groups are shown in Table I. There were only minor differences among the 3 groups. The main risk factors for thromboembolism, (prior thromboembolism, left atrial enlargement, atrial fibrillation, and left atrial thrombus observed at operation) also show only minor differences.

Adequacy of anticoagulation (Fig. 1, Table II): There were 12,720 prothrombin times and corresponding control values tabulated during the follow-up period. Adequacy of anticoagulation was not different in all 3 groups. In approximately 50% of patients in all 3 groups, ≥70% of their prothrombin times were in the therapeutic range ($1.5 \leq$ prothrombin time/control ≤ 2.5) (Fig. 1). Of all the prothrombin times approxi-

mately 65% were in the therapeutic range, 30% were low, and 5% were high in all 3 groups.

Bleeding and thromboembolism (Tables III and IV): Bleeding episodes were mainly gastrointestinal or intracerebral and predominated in the group taking aspirin ($p < 0.001$). All patients with intracerebral bleeding died. The prothrombin time at the time of hospital admission for bleeding was >2.5 times the control value in a similar percentage of patients in all 3 groups (15/39 or 38% overall, Table III). Patients with bleeding (except those taking aspirin) had more high prothrombin times, $p > 0.05$ (Table II). Because of the excessive bleeding, aspirin was discontinued in all patients in August 1981, and patients were advised to continue taking warfarin alone.

The reduced incidence of thromboembolism in the warfarin plus dipyridamole group did not reach statistical significance. All but 3 thromboemboli occurred during the first year after operation. Thromboemboli occurred as early as 8 days after operation in patients receiving antithrombotic therapy, but 1 and 2 days after operation in 2 patients excluded from the study before starting antithrombotic therapy. Seven of the 15 epi-

sodes (47%) resulted in a permanent neurologic deficit, and 5 resulted in death. One patient in the warfarin plus aspirin group with adequate anticoagulation fell down his basement stairs, struck his head, had right leg weakness and a skull fracture, and became comatose and died within 24 hours. Autopsy showed a thrombosed Björk-Shiley aortic valve. Of the 15 patients with thromboemboli, 9 had mitral valve replacement, 5 had aortic valve replacement, and 1 had both. The prothrombin time was low (Table III) at the time of the thromboembolic episode in 7 of 15 patients. There was a trend toward more low prothrombin times in patients with thromboembolism (Table II).

Reasons for cessation of platelet-inhibitor therapy: The reasons for cessation of therapy are listed in Table V. Most of these decisions were made by the local physician. All of these patients are included in the analysis of thromboemboli and bleeding.

Discussion

The preliminary results of this prospective, randomized trial of warfarin plus dipyridamole in comparison with warfarin plus aspirin show the danger of bleeding from warfarin plus regular aspirin use at 500 mg/day and a trend toward a reduction in thromboembolism in the warfarin plus dipyridamole group. The dose of platelet-inhibitor therapy, the adequacy of anticoagulation, and the design of the trial will also be discussed.

Bleeding: Therapy with anticoagulant plus aspirin was compared with therapy with anticoagulant alone in only 2 previous prospective, randomized trials with smaller numbers of patients.[9,10] No severe bleeding was seen in 57 patients treated with anticoagulant therapy plus aspirin at 500 mg/day after follow-up for a mean of 2 years, although 4 (7.0%) of 57 patients had melena as compared with only 1 (1.5%) of 65 patients on anticoagulant therapy alone.[9] In another study,[10] gastrointestinal bleeding occurred in 11 (14.7%) of 75 patients taking anticoagulant therapy plus 1 g of aspirin per day in contrast to 2 (2.7%) of 73 patients taking only an anticoagulant agent. Our results in a large group of patients substantiate the increased risk of bleeding when even a medium dose of aspirin (500 mg/day) is added to anticoagulant therapy. Patients taking anticoagulant therapy should not use aspirin.

Thromboembolism: No previously reported clinical trial has compared therapy with anticoagulant plus dipyridamole with therapy with anticoagulant plus aspirin. Our study showed a trend toward reduction in thromboembolism in the warfarin plus dipyridamole group compared with the warfarin plus aspirin or warfarin alone groups. These results are consistent with previous clinical trials that compared therapy with anticoagulant therapy plus dipyridamole with anticoagulant therapy alone.[5–8] The rate of thromboembolism in the anticoagulant plus aspirin group (1.7/100 patient-years) is similar to the aspirin groups in the study of Altman et al[9] (1.8/100 patient-years) and Dale et al[10] (2.5/100 patient-years), but the rate in our anticoagulant alone group (1.5/100 patient-years) is lower than those from Altman et al (9.3/100 patient-years) and Dale et al (10.7/100 patient-years). The low rate of thromboembolism may in part reflect the decreasing rate observed in recent years as valve design has improved[1] and valve replacement is performed earlier in the course of the valvular disease.[2] Nevertheless, thromboembolism is a continued, cumulative risk that increases over a period of years, involves the cerebral circulation in more than 85% of clinical emboli, leads to a permanent neurologic deficit in 50% of patients, and leads to death in 10%.[1]

Platelet deposition starts intraoperatively on the sewing ring in the canine model.[11] Because we observed thromboemboli causing stroke within 48 hours after operation before anticoagulant therapy could be started, platelet-inhibitor therapy should probably be administered 1 to 2 days before operation and as well as immediately before and after operation (similar to the rationale for perioperative platelet-inhibitor therapy in aortocoronary bypass surgery[13,14]). Preoperative and intraoperative use of dipyridamole has been shown to be safe,[12–14] but preoperative use of aspirin appears to increase bleeding[15] in patients undergoing cardiopulmonary bypass surgery.

Reasons for no reduction of thromboembolism in the anticoagulant plus aspirin group as compared with the anticoagulant alone group are unknown, but contributing factors may be the lack of randomization in the latter group, the small number of clinical events to date, or a low incidence of responders in the aspirin group.[16]

Dose of platelet-inhibitor therapy: The aspirin dosage twice daily was chosen to reproduce the trial by Altman et al.[9] The optimal dose of aspirin alone appears to differ from the optimal dose to be combined with dipyridamole.[16,17] The dose of dipyridamole was chosen because of the success in previous trials[5–8] and the necessity for a larger dose to prolong a shortened platelet survival when used alone without aspirin.[17]

Adequacy of anticoagulation: Adequacy of anticoagulation appears to influence the thromboembolic risk after prosthetic (especially mitral) valve replacement.[1,3,18] Friedli et al[18] found that when more than 15% of the total number of prothrombin times in a patient

were too low (<1.5 times the control value), the rate of thromboembolism increased greatly. Only 19% of their patients (16% of our patients) had this ideal control, less than 50% their (and our) patients had ≥75% of their prothrombin times in therapeutic range, and 56% of their patients (47% of ours) with a thromboembolic event had a low prothrombin time at the time of the event. The adequacy of anticoagulation in our patients (Fig. 1, Table II) was very similar in the 3 treatment groups and was also very similar to results in the patients of Friedli et al studied nearly 10 years ago.

Similarly, an increased risk of bleeding is present when the prothrombin time is too high.[19] Approximately 50% of patients in the report by Forfar[19] and 40% of our patients with bleeding had a prothrombin time >2.5 times the control value at the time of the event. The adequacy of anticoagulation achieved and the relationship of thromboembolism and bleeding to this adequacy emphasizes the difficulty of and the need for good anticoagulant control.

No intracerebral bleeding has been seen so far in the warfarin plus dipyridamole group despite similar anticoagulant control, raising a question of whether preexisting cerebral thromboembolism may predispose to intracerebral bleeding. Thus, a reduction in cerebral thromboembolism might then lead to a reduction in intracerebral bleeding.

Trial design: The ideal clinical trial should be prospective, randomized, double-blind, placebo-controlled with the appropriate dose and timing of drug administration, and of adequate size and duration to have sufficient patients with a sufficient number of events defined as endpoints for meaningful subgroup analysis.[13,20] Patients should be adequately characterized to ensure that the risk factors influencing the endpoints are equal in all treatment groups.[13]

This trial was not blinded or placebo-controlled, and compliance was not assessed by pill counts or urine tests. Initially a randomized control group was not included because the addition of a platelet-inhibitor had lowered the high incidence of thromboembolism in previous trials,[5,6,9,10] but a decreasing incidence of thromboembolism in the last few years[2] makes a randomized control group very important. Platelet-inhibitor therapy should probably be started before operation and given immediately before and after operation to minimize the early postoperative risk of thromboembolism. The safety of starting dipyridamole before operation has been documented,[12–14] but the hypothesis of reducing early thromboembolism needs to be tested in a new clinical trial.

Despite the absence of randomized, placebo control subjects and a subjective inquiry for compliance, the adequacy of anticoagulation was similar in all groups, and preliminary results show excessive bleeding in the warfarin plus aspirin group. There was also a trend toward a reduction of thromboembolism in the warfarin plus dipyridamole group as compared with the warfarin plus aspirin group. All aspirin in our patients has been discontinued, and follow-up will continue for 3 to 4 more years to see whether further separation of the groups can be detected.

Acknowledgment: We thank LaVon N. Hammes, Margaret C. Timmons, and Janet A. Matz for their assistance in patient follow-up and data tabulation, Pamela Haase for her help in dispensing study medications, and the resident surgeons, nurses, and pharmacists who helped make this study possible. We are grateful to the programmer, Jon L. Kosanke, for his excellent work. We also thank Carol A. Stocker for preparation of the manuscript. The dipyridamole was kindly supplied by Boehringer Ingelheim, Ridgefield, Connecticut. The aspirin was kindly supplied by Plough, Memphis, Tennessee.

Early Detection of Left Ventricular Dysfunction in Chronic Aortic Regurgitation as Assessed by Contrast Angiography, Echocardiography, and Rest and Exercise Scintigraphy

ROBERT L. HUXLEY, MD, F. ANDREW GAFFNEY, MD, JAMES R. CORBETT, MD, BRIAN G. FIRTH, MD, DPhil, RONALD PESHOCK, MD, PASCAL NICOD, MD, JAMES S. RELLAS, MD, GEORGE CURRY, MD, SAMUEL E. LEWIS, MD, and JAMES T. WILLERSON, MD

The best method for detecting early left ventricular (LV) dysfunction in patients with chronic aortic regurgitation is uncertain. Variables used previously to identify LV dysfunction have included (1) angiographic measurements to identify an LV end-systolic volume index (LVESVI) $\geq$60 ml/m^2, (2) echocardiographic measurements to identify LV end-systolic dimension (LVESD) $\geq$5.5 cm or LV fractional shortening $\leq$25%, and (3) depressed LV ejection fraction (EF) at rest and/or an LVEF or LVESVI that deteriorates with exercise as detected by myocardial scintigraphic measurements. The hypothesis was tested that radionuclide ventriculography with exercise allows earlier detection of important LV dysfunction in patients with aortic regurgitation than the other variables. In 15 consecutive asymptomatic or only minimally symptomatic patients (8 men and 7 women, mean age 44 years) with isolated 2 to 4+ aortic regurgitation (1) rest and exercise-gated radionuclide ventriculography, (2) M-mode echocardiography, and (3) LV angiography were performed. No other cause of LV dysfunction was apparent in 13 patients; 1 patient had moderate systemic arterial hypertension and 1 had 50% luminal diameter narrowing of the proximal left anterior descending coronary artery. Ten patients did not have an increase in LVEF >0.05 EF units at peak exercise (0.58 $\pm$ 0.11 to 0.50 $\pm$ 0.12, mean $\pm$ standard deviation [SD]) (Group 2), whereas 5 had a normal LVEF response to exercise (0.63 $\pm$ 0.08 to 0.69 $\pm$ 0.07) (Group 1). Eight of the 10 patients with abnormal LVEF responses to exercise had a decrease in LVEF >10% during exercise. The same 8 patients also had an increase in LVESVI with exercise, whereas the 5 patients with normal LVEF responses to exercise had normal or blunted LVESVI responses to exercise. Only 4 of the 10 patients with exercise-induced LV dysfunction had an angiographic LVESVI $\geq$60 ml/m^2, and only 1 had an echocardiographically determined LVESD $\geq$5.5 cm. Serial follow-up rest and exercise scintigraphic and echocardiographic measurements were made in 8 of the patients a mean of 9.4 months after the initial measurements; 3 patients were in Group 1 and 5 in Group 2. The 5 patients in Group 2 again demonstated abnormal LV function during exercise stress, and 2 of the 3 patients in Group 1 then demonstrated an abnormal LV functional response during exercise.

Therefore, it is concluded that (1) exercise radionuclide ventriculography identifies LV dysfunction earlier than traditionally used assessments, (2) LV dysfunction appears to persist in patients that demonstrate it and develop in others that did not have it originally, and (3) echocardiographic dilatation of the LVESD to 5.5 cm appears to be a late and relatively unusual occurrence.

The ideal time for aortic valve replacement in asymptomatic or mildly symptomatic patients with chronic aortic regurgitation is difficult to determine. Once symptoms develop, surgical replacement of the valve is recommended because continued medical therapy is associated with progressive clinical deterioration.[1–3] However, if surgery is delayed until the occurrence of symptoms and marked cardiomegaly, some patients have left ventricular (LV) dysfunction and do not improve symptomatically postoperatively.[4–9] Consequently, the early identification of LV dysfunction before it becomes irreversible in asymptomatic patients with chronic aortic regurgitation is a goal.

Variables used previously to identify LV dysfunction in such patients include (1) contrast angiographic

measurement of LV ejection fraction (LVEF) <0.50 or an end-systolic volume index (LVESVI) ≥ 60 ml/m^2,[5,10] (2) M-mode echocardiographic measurement of LV end-systolic dimension (LVESD) ≥5.5 cm or LV fractional shortening ≤25%,[11,12] and (3) scintigraphic evidence at rest of an abnormal LVEF or LVESVI or an abnormal response to exercise in these variables, or both.[13,14] In this study, we tested the hypothesis that exercise radionuclide ventriculography allows earlier detection of LV dysfunction in patients with chronic aortic regurgitation than other previously described variables.

Methods

Patients: Fifteen consecutive patients (8 men, 7 women, aged 18 to 73 years, mean 44) (Table I) with chronic aortic regurgitation were evaluated with (1) cardiac catheterization and cineangiography, (2) M-mode echocardiography, and (3) rest and exercise radionuclide ventriculography. The patients were maintained on medications that the referring physician had prescribed before any objective evaluation of LV function (Table I). The average interval between catheterization and scintigraphic study was 15 days, the mean interval between scintigraphy and echocardiography was 27 days, and the mean interval between echocardiography and cardiac catheterization was 22 days. No major clinical event requiring a change in medication or hospitalization occurred in any patients during the period of these evaluations. No other cause of LV dysfunction was apparent from history or physical examination. Specifically, no patient had a history of excessive alcohol consumption, only 1 patient had a history of systemic arterial hypertension, and none had coronary arterial stenosis >50% of the luminal diameter.

LV cineangiography, supravalvular cineaortography, and intracardiac oximetry were performed in all patients to determine the presence and severity of aortic regurgitation, to exclude significant mitral valve disease, and to exclude intracardiac shunting. A coronary arterial stenosis ≥70% of the luminal diameter was considered significant. An M-mode echocardiogram was performed on a commercially available unit (Smith-Kline 20A) with the patient in the left lateral decubitus position.

The patients were exercised in the supine position on a bicycle ergometer. Electrocardiograms were monitored during rest and exercise. Graded exercise was performed beginning at either 150 or 300 kilopond meters (kpm)/min. Exercise continued with additional increments of 150 kpm every 4 minutes until 1 of the following endpoints was reached: angina, fatigue or dyspnea, 85% of the maximal age-predicted heart rate, or an S-T segment change ≥2 mm compared with the resting electrocardiogram. Blood pressure was monitored at rest and during each level of exercise.

Technique for contrast angiographic LV volume determination and quantitation of regurgitation: In each patient, a single-plane left ventriculogram in the right anterior oblique projection was performed at the time of cardiac catheterization. A lateral fluoroscopic system was used to visualize the catheter tip within the left ventricle, thus allowing accurate placement of a calibration grid with respect to the center of the ventricle. Angiographic volumes were calculated by the area-length method and corrected with use of the Kennedy regression equation.[15,16]

Forward cardiac output was determined with either the Fick or indicator dilution method. The regurgitant fraction was determined in the standard manner from angiographic and forward output measurements. Angiographic aortic regurgitation also was graded on a scale of 0 to 4+ using standard criteria.[17]

Technique for multigated equilibrium blood pool scintigraphy: Multigated equilibrium blood pool imaging was performed using a previously described technique combining both in vivo and in vitro labeling of red blood cells with 30 mCi of technetium-99m sodium pertechnetate.[18–20] Data were collected with a standard gamma scintillation camera (Ohio Nuclear Series 100, Solon, Ohio) equipped with an all purpose parallel-hole collimator and interfaced with a dedicated on line computer system (Ohio Nuclear VIP-450). At rest, equilibrium gated blood pool scintigrams were obtained in multiple projections, including a modified left anterior oblique projection, to allow the clearest separation of the left ventricle and left atrium. Supine exercise studies were gated for 32 frames per cardiac cycle and 100% of the cardiac cycle. Thereafter, each patient exercised for 1 minute at each work load before beginning a 3-minute acquisition period. Background subtraction was accomplished using a modification of the linear interpolated method described by Goris et al.[21] LVEF was determined from background corrected LV activity measured from manually constructed regions of interest placed over the end-diastolic and end-systolic frames.[22–24] The number of counts within the region of interest was used to calculate the LVEF using the following formula: (End-diastolic counts − end-systolic counts)/end-diastolic counts. This method correlates well with results obtained by contrast ventriculography.[22] An increase in LVEF of >0.05 units with maximal exercise is considered a normal functional response.[25–27]

LV volumes were determined by a nongeometric technique developed recently at our institution which is similar to methods used by others.[22–24] After background subtraction had been performed, a region of interest was constructed over the left ventricle at end-diastole and end-systole and the number of counts were determined. LV volumes were calculated from the radionuclide activity over the left ventricle normalized for the radionuclide activity per milliliter of peripheral venous blood, corrected for the acquisition time per frame, and decay of the radioisotope.[22,23] The following equation was used for scintigraphic volume calculations: (Background-corrected LV counts/[(percent cycle acquired/number of frames gated) T_{total}])/peripheral blood activity × $e^{-\lambda t}$. In this formula $e^{-\lambda t}$ is the general equation for isotope decay, $\lambda = 0.693/T^1/_2$, t = time in minutes from counting the peripheral blood sample to the midpoint of the gated study, and $T^1/_2$ for technetium-99m is 360 minutes. A decrease in LVESVI >5% with maximal exercise was considered a normal response.[13]

At our institution, LV volumes by radionuclide and contrast angiography have been shown to correlate closely.[22,23] However, in this study, we relied on the angiographic measurements of LV volumes to identify abnormalities in absolute values of LVESVI (at rest) (see Fig. 2 and 3) and have only used the scintigraphic determinations to identify exercise-induced alterations in LV volumes (Fig. 3). This was done to avoid concern about the influence of photon attenuation on the scintigraphic estimation of absolute LV volumes, which occurs especially in women with large breasts, or in patients who are extremely thin or particularly obese.

Echocardiographic technique for estimating ventricular dimensions: LV dimensions were determined at a level just below the mitral valve leaflets. The LV end-diastolic diameter (LVEDD) was measured as the vertical distance from the endocardium of the LV posterior wall to the endocardium of the ventricular septum at end-diastole measured at the time of the R wave of the electrocardiogram. Left ventricular end-systolic diameter (LVESD) was measured as the

vertical distance from the endocardium of the LV posterior wall at the peak of its anterior motion during systole to the endocardium of the ventricular septum at its maximal downward deflection during systole. The percent change in minor diameter or shortening fraction was calculated by the following equation: (LVEDD − LVESD)/LVEDD.

Results

The clinical and hemodynamic data in the 15 patients comprising this study are shown in Table I. Exercise radionuclide ventriculography identified 2 groups of patients (Fig. 1). Group 1 (5 patients) had a LVEF ≥0.50 and a normal LVEF response to peak exercise (that is, an increase in LVEF ≥0.05 units at peak exercise compared with the supine resting LVEF (0.63 ± 0.09 to 0.69 ± 0.07) (Fig. 1) and no change or a decrease in LVESVI with exercise (Fig. 2). Group 2 (10 patients) failed to have an increase in LVEF at peak exercise from the resting value (0.58 ± 0.11 to 0.50 ± 0.12); in 8 of the 10 patients LVEF decreased 10% from the resting LVEF value at peak exercise (Fig. 1). The degree of aortic regurgitation was similar in these 2 groups (regurgitant fraction 0.44 ± 0.11 versus 0.51 ± 0.16; p = NS [not significant]. Patients in Group 2 also demonstrated a marked increase in LVESVI at peak exercise (Fig. 3). LVESVI at rest (by contrast angiography) as well as the calculated absolute LVESVI at peak exercise (calculated by multiplying the absolute contrast angiographic values at rest by the percent change during exercise as determined scintigraphically) are shown for both groups in Figure 2. The relation between the percent increase in LVESVI at peak exercise (determined scintigraphically) and the LVESVI at rest (determined by contrast angiography) for patients in both groups is shown in Figure 4.

The heart rate, blood pressure, and work load data for both groups of patients are shown in Table II. Although the maximal heart rate, rate-pressure double product, and work load achieved were somewhat lower in patients in Group 2, this difference was not significant statistically.

Angiographic volumes: LVESVI at rest by contrast angiography is shown in Table I. One patient in Group 1 and 4 patients in Group 2 had an LVESVI ≥60 ml/m^2. Four of 5 patients with angiographic LVESVI ≥60

ml/m^2 had abnormal LV function responses to exercise. However, 6 of 10 patients with LVESVI ≤60 ml/m^2 also had abnormal LV responses to exercise.

M-mode echocardiography: The M-mode echocardiographic measurements are shown in Table I. All patients in Group 1 had normal LVESD (3.7 ± 0.2 cm). One patient in Group 2 had a LVESD ≥5.5 cm and 2 patients had LV shortening fractions ≤25.

Cardiothoracic ratios: The cardiothoracic ratio determined from standard posteroanterior chest roentgenograms are shown in Table I. The cardiothoracic ratios in both Groups 1 and 2 varied widely. Group 1 (normal response to exercise) had a range of 0.48 to 0.59 and a mean of 0.53 ± 0.06. Group 2 (abnormal response to exercise) had a range of 0.45 to 0.73 and a mean of 0.57 ± 0.09. Three patients in Group 2 (Patients 6, 7, and 10) had normal cardiothoracic ratios despite demonstrating global LV dysfunction with exercise, whereas 2 patients in Group 1 (Patients 2 and 4) demonstrating a normal response to exercise had an abnormal cardiothoracic ratio (>0.50).

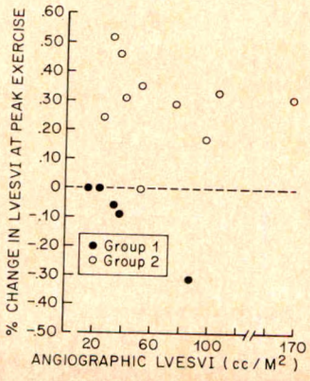

FIGURE 4. Percent change in left ventricular end-systolic volume index (LVESVI) versus the resting angiographic LVESVI for each patient.

Follow-up data: Eight patients underwent serial evaluation with rest and exercise radionuclide ventriculograms and M-mode echocardiograms during a mean follow-up period of 9.4 months (range 4 to 23 months) (Tables III and IV). All patients were asymptomatic at the time of the repeat studies. No major clinical event requiring a change in medication or hospitalization occurred in any of these patients during this period.

Three patients were in Group 1 and 5 were in Group 2. All 5 patients in Group 2 again demonstrated an abnormal response to exercise with a decrease in LVEF at peak exercise (0.64 ± 0.06 to 0.56 ± 0.07, mean ± SD), as well as an increase or no change in LVESVI (mean increase 28%) (Fig. 5). Two patients in Group 1 (Fig. 5) (Patients 1 and 4) who originally demonstrated a normal response to exercise demonstrated a marked decrease in LVEF at peak exercise (0.54 ± 0.07 to 0.44 ± 0.13) during the follow-up study. One patient (Patient 3) (Fig. 6) again showed a normal LVEF response to exercise. All 3 patients showed an abnormal LVESVI response to exercise.

The echocardiographic LVESD did not change significantly in patients in Group 2 from the original to the follow-up study (3.8 ± 0.7 to 3.6 ± 0.7) (Table III). The 2 patients in Group 1 who demonstrated an abnormal exercise LVEF response on repeat study both had an increase in LVESD (Table III), but no patient in either group who had an abnormal response to exercise during

the repeat evaluation had a LVESD ≥5.5 cm or an LV shortening fraction ≤25%.

Discussion

In patients with aortic regurgitation, it is generally agreed that valve replacement should be performed before irreversible LV dysfunction occurs.[28] In this condition, symptoms may not appear despite marked cardiac enlargement and the presence of LV dysfunction. However, once preoperative LV dysfunction is present, postoperative survival is reduced.[5] Therefore, various methods have been used to detect early LV dysfunction in patients with hemodynamically important aortic regurgitation who may be asymptomatic or only mildly symptomatic in an attempt at preempting the onset of irreversible LV dysfunction and its sequelae.

Earlier investigators have measured the pulmonary capillary wedge pressure, cardiac output, LV end-diastolic pressure, and LV end-diastolic volume in patients with aortic regurgitation. However, increases in the pulmonary capillary wedge pressure and decreases in the cardiac output occur relatively late in these patients.[29] In addition, the pulmonary capillary wedge pressure and cardiac output, LV end-diastolic pressure, and LV end-diastolic volume do not necessarily reflect LV contractile function directly, because they are dependent on LV compliance, the degree of valvular regurgitation, heart rate, and volume status.[30,31]

Forman et al[5] found that a preoperative LVEF <0.50 was associated with a poorer 3-year postoperative survival than a preoperative LVEF >0.50 (64 versus 93%). These findings have been corroborated by other investigators.[32,33]

However, the ejection fraction is preload-dependent, and variable alterations of blood pressure, venous return, heart rate, and circulating catecholamines combined with alterations in impedance to LV emptying

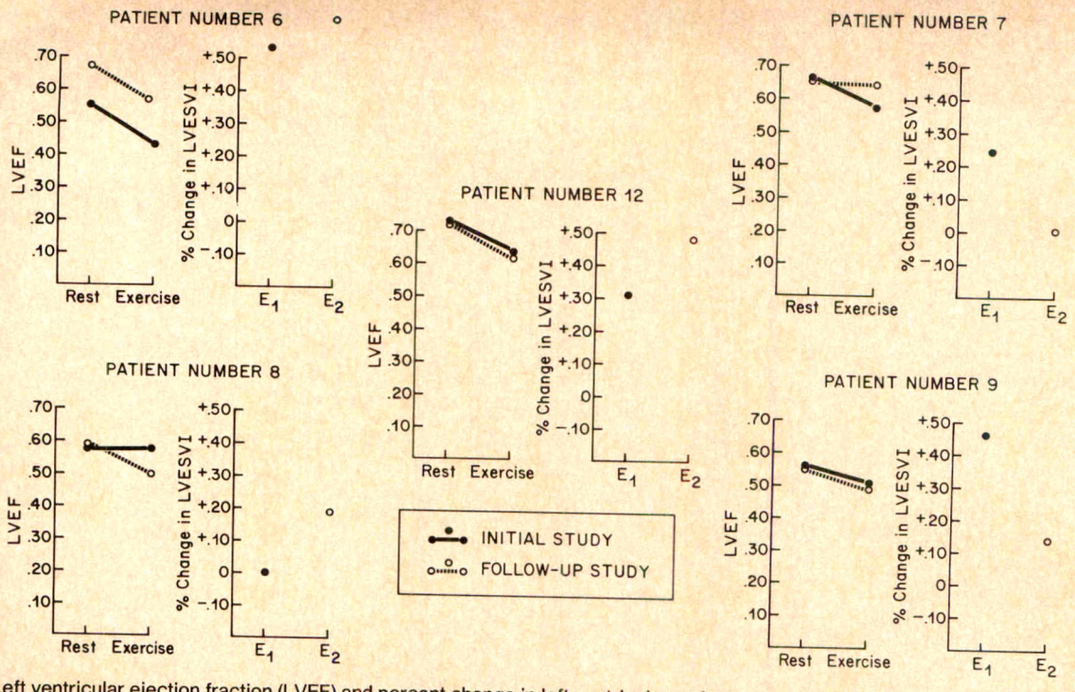

FIGURE 5. Left ventricular ejection fraction (LVEF) and percent change in left ventricular end-systolic volume index (LVESVI) at rest and exercise as determined scintigraphically in the 5 patients in Group 2 who underwent serial studies. **Solid lines** or **solid circles** indicate original study; **dotted lines** or **open circles** represent follow-up study. All 5 patients again demonstrated an abnormal response to exercise in the follow-up study. E_1 = original exercise response; E_2 = exercise response on follow-up study.

make LVEF a less than perfect means to characterize LV function at rest or exercise in patients with hemodynamically important aortic regurgitation.[13,34]

For example, if tachycardia predominates during exercise, a decrease in ejection fraction may be the result of a change in preload rather than deterioration in LV performance. An increase in arterial pressure may cause LV end-diastolic volume to increase, but ejection fraction to decrease or not change.

Data suggest that end-systolic fiber length closely reflects the contractile state of the ventricular myocardium and is preload-independent.[35–37] Because end-systolic volume is linearly related to the pressure at end-systole,[35] it would seem to provide a valuable assessment of myocardial function, and because it is relatively preload-independent, it should be especially helpful in patients with altered preload from LV volume overload.[10] Therefore, the end-systolic volume may provide a better assessment of LV performance than previously described variables including ejection fraction. Borow et al[10] found that an increased preoperative LVESVI ($\geq$60 ml/m^2) by contrast angiography correlated with postoperative LV dysfunction and increased perioperative mortality in these patients. However, serial contrast angiographic assessments of LV volumes cannot be performed easily, are invasive, and may be inaccurate when LV geometry is distorted. Radionuclide ventriculography provides an alternative method of assessing LV function because it is noninvasive, can be used serially, and can be applied during exercise. In addition, we and others have demonstrated that accurate LV volume determinations can be made independent of geometric assumptions concerning LV shape.[22–24]

Henry et al[11,12] emphasized that patients with an M-mode echocardiographically determined LVESD $\geq$5.5 cm or an LV shortening fraction $\leq$25% have a high operative and postoperative mortality. Thus, they recommended surgical intervention in asymptomatic subjects before the development of these alterations. However, echocardiographic assessment may be technically difficult, especially in patients with dilated left ventricles. In addition, errors in reproducibility are inherent in serial determinations and measurements.[7,38–41] Furthermore, it is not clear whether this degree of LV dilatation occurs before, concomitant with, or after other evidence of LV dysfunction.

Borer et al[25] and Dehmer et al[13] have shown that asymptomatic patients with chronic aortic regurgitation may have a "normal" LVEF at rest, but that it may decrease with exercise. Dehmer et al also demonstrated that some patients with aortic regurgitation have an abnormal increase in LVESVI with exercise, even though the LVEF is normal at rest.

In the present study, we found that 10 of 15 consecutive, asymptomatic (or mildly symptomatic) patients with aortic regurgitation demonstrated LV dysfunction, as evidenced by a failure to increase LVEF or decrease LVESVI with peak exercise. Despite scintigraphic evidence of LV dysfunction during exercise stress in these 10 patients, only 4 had angiographic LVESVI $\geq$60 ml/m^2, and only 1 had an echocardiographically determined LVESD $\geq$5.5 cm. Moreover, only 2 patients had an LV shortening fraction $\leq$25%. Lewis et al[42] also

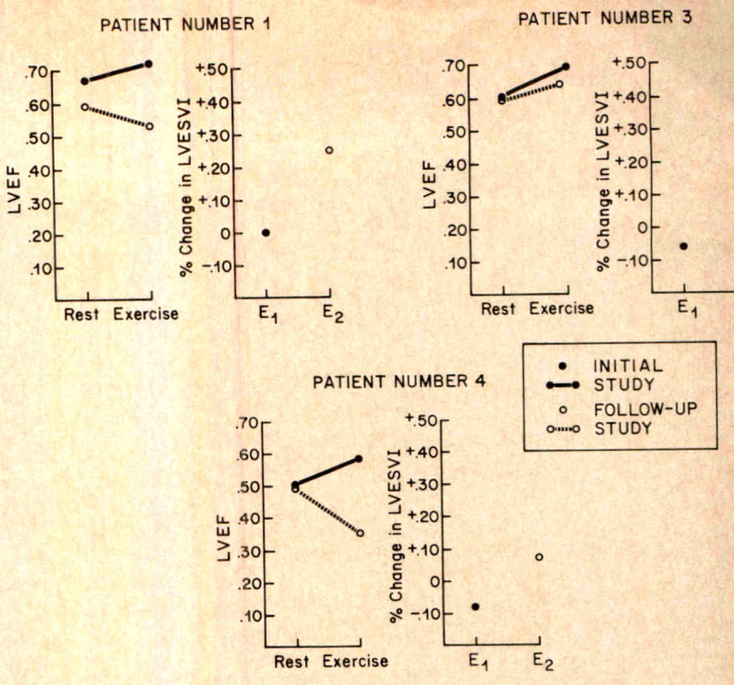

FIGURE 6. Left ventricular ejection fraction (LVEF) and percent change in left ventricular end-systolic volume index (LVESVI) at rest and exercise as determined scintigraphically in serial studies in 3 patients in Group 1. Two of 3 patients who originally demonstrated a normal response to exercise demonstrated a decrease in LVEF and an increase in LVESVI during the follow-up study. Abbreviations as in Figure 5.

found that a failure to increase or an absolute decrease in LVEF with exercise occurs before increases in LV end-systolic diameter determined echocardiographically in a study of 45 patients with chronic aortic regurgitation. However, in the study of Lewis et al, only 18 of 45 patients underwent cardiac catheterization and LV volumes were not measured scintigraphically. Because LVEF responses are dependent on preload and heart rate, the failure to analyze another (and probably better) variable to characterize LV systolic function, that is, the LVESVI at rest and exercise, leaves one uncertain as to whether LV dysfunction actually occurred. However, the study of Lewis et al and the present one taken together suggest that LV global dysfunction often exists before marked dilatation of the LV as detected by angiographic or echocardiographic measurement.

Recently, Schuler et al[43] studied 14 asymptomatic patients with isolated aortic regurgitation and found that the end-systolic pressure-volume relation identified 2 subsets of asymptomatic patients, 1 with impaired myocardial contractility and normal LV exercise reserve and a second with depressed myocardial contractility and LV dysfunction during exercise. In the present study, serial rest and exercise radionuclide ventriculograms demonstrated that the abnormal response to peak exercise was reproducible. In addition, we found evidence of LV dysfunction at peak exercise (as demonstrated by a decrease in LVEF and an increase in LVESVI at peak exercise) in 2 of 3 patients who showed a normal response to exercise originally. All patients who underwent serial analysis and demonstrated an abnormal response to exercise initially continued to have a normal LVESD on M-mode echocardiography.

Although the number of patients studied in the present evaluation is relatively small and validation of these results in a larger number of patients is necessary, our findings demonstrate (1) exercise radionuclide ventriculography identifies LV dysfunction earlier than previously described variables and before the onset of symptoms; (2) echocardiographic dilatation of the LVESD to ≥5.5 cm and LV fractional shortening ≤25% appear to be late, unusual occurrences; and (3) serial analysis with rest and exercise radionuclide ventriculography provides a valuable method of following up patients with chronic aortic regurgitation and for detecting early LV dysfunction.

Whether the ability to identify early LV dysfunction during exercise will influence the decision relative to when to intervene in asymptomatic patients with chronic aortic regurgitation is uncertain. However, this study should provide the basis for further prospective evaluations to assess the consequence of various forms of treatment of asymptomatic patients with chronic aortic regurgitation and exercise-induced LV dysfunction.

Acknowledgment: We thank Scott Lyons, John Hopkins, Randy Christian, Sarah Hawkins, and Beverly Erck for technical assistance in these studies, and Laurie Christian for typing the manuscript. The cooperation and assistance of medical house officers, cardiology fellows, and nurses at Parkland Memorial Hospital also is appreciated.

Effect of Elevating the Wrist on the Radial Pulse in Aortic Regurgitation: Corrigan Revisited

CAROLE A. WARNES, MB, BS, MRCP, PETER C. HARRIS, MD, PhD, and HARRY W. FRITTS, MD

Five patients with severe aortic regurgitation had their intraarterial radial pulse recorded simultaneously with the external radial artery deflection of the other wrist. Recordings were made with the arms horizontal and repeated after elevation of the wrists, until the arms were vertical. Elevating the arm of a patient with aortic regurgitation increased the pulsation recorded over the radial artery, lowered mean intraarterial pressure, and reduced the pulse pressure. The results suggest that elevation increases the compliance of the arterial wall, primarily by moving the artery to a lower position on its pressure-volume curve. The same changes occurred in 5 normal subjects but were less pronounced.

The increased pulsation of the radial artery that is felt in patients with aortic regurgitation (AR) becomes more noticeable when the wrist is raised. The effect was first described by Corrigan,[1] whose patient would "increase the pulsation of the brachial and palmar arteries to a most striking degree by elevating his arms to a perpendicular position above his head." Although this effect is accepted, the standard cardiologic and medical textbooks offer no satisfactory explanation. Corrigan believed that elevation makes the arteries "more flaccid" and "their visible pulsation of course more marked." Friedberg[2] thought elevation enhanced the pulse because "the radial artery is then in more direct line with the outflow stream from the aorta, and because gravity increases blood pressure changes at the wrist." This study records changes in arterial excursion and intraarterial pressure produced by elevation, and offers an explanation for the effect.

Methods

Subjects: Ten subjects were studied: (5 normal control subjects and 5 patients with at least grade 3/4 AR assessed angiographically). The age of the control subjects ranged from 26 to 60 years (mean 46) and of those with AR from 42 to 73 years (mean 55).

Address for reprints: Carole A. Warnes, MD, BS, MRCP, Building 10A, Room 3E30, National Institutes of Health, Bethesda, Maryland 20205.

The subjects were studied lying in the supine position. The pickup used to record the pulse over the radial artery was a flat cup (2 cm in diameter and 0.5 cm deep), which was held in position by adhesive tape and by a sprung clamp that applied pressure to the top of the cup and to the underside of the wrist only. The cup was connected by a 12 cm tube to a Cambridge piezoelectric pulse transducer taped to the forearm, and then to a Cambridge multichannel recorder. The recorder was set with the same sensitivity for each study, and the position of the cup adjusted before the start to obtain the maximum deflection possible.

To measure intraarterial pressure, a short 20G cannula was inserted into the other radial artery and connected to a Hewlett-Packard transducer and 7745B multichannel re-

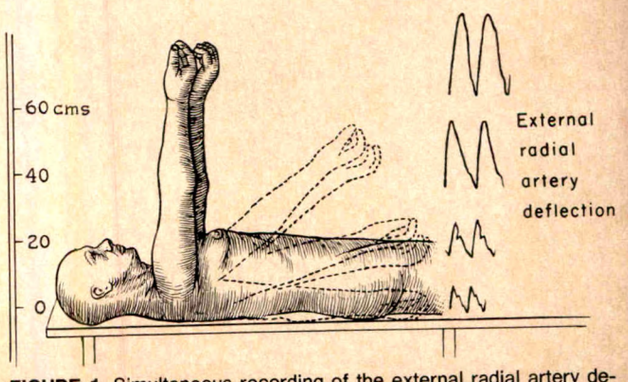

FIGURE 1. Simultaneous recording of the external radial artery deflection of 1 wrist and the intraarterial pressure of the other. Recordings were taken at rest (0), 20, 40, and 60 cm above 0. At 60 cm the arms were vertical. The deflections drawn are not actual size.

corder. Before each pressure measurement the gauge was set to the height of the wrist.

The subjects' arms were rested at their sides and the intraarterial pressure and the external pulse were recorded simultaneously, and marked position 0. With the arms kept extended, the wrists were then raised to 20, 40, and 60 cm above this level and recordings taken in each position (Fig. 1). The last position resulted in the arms being almost vertical. The subject was then asked to return the arms to the resting position when repeat recordings were taken.

BP = blood pressure; D = deflection (cm) of the radial artery pulse with the wrist elevated; D_0 = deflection (cm) of the radial artery pulse at rest or 0 position.

Results

The results are summarized in Table I. In every control subject and in every patient with AR, the radial arterial deflection increased with each elevation of the wrist, and reached a maximum when the arm was in a vertical position. In patients with AR, the increase in deflection with the wrist elevated was greater than in the normal subjects (Fig. 2). The increasing deflection was always associated with a decrease in mean blood pressure. In the normal subjects mean blood pressure decreased progressively from an average of 117 mm Hg with the wrist at rest to 71 mm Hg when the wrist was elevated to 60 cm. In those with AR, mean pressure decreased from an average of 100 mm Hg at rest to 54 mm Hg when vertical.

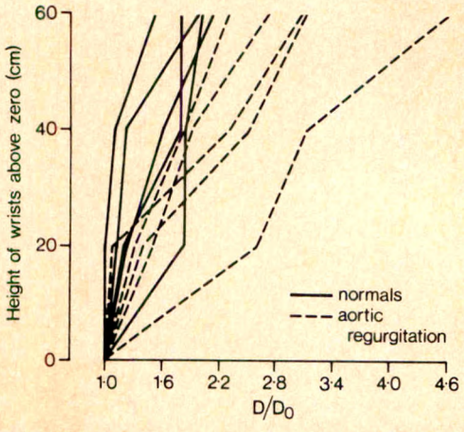

FIGURE 2. Effect of raising the arm on the pulsation of the radial artery. D = excursion of the pulse when the arm is raised; D_0 = excursion of the pulse when the arm is horizontal.

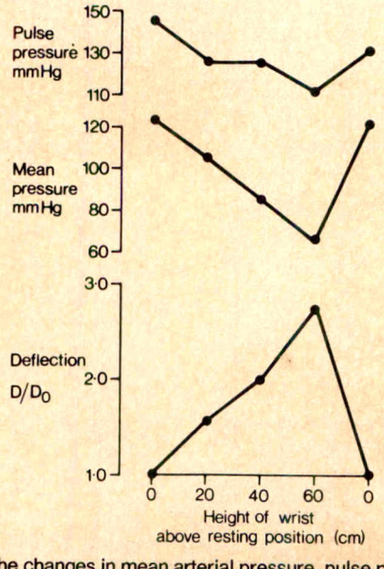

FIGURE 3. The changes in mean arterial pressure, pulse pressure, and arterial deflection of the radial artery that accompanied raising the arm in a patient with aortic incompetence. D = excursion of the pulse when the arm is raised; D_0 = excursion of the pulse when the arm is horizontal.

The pulse pressure also was reduced with elevation. In the normal subjects, pulse pressure decreased from an average of 70 mm Hg in the resting position to 61 mm Hg in the vertical position. In those with AR, it decreased from an average of 140 to 125 mm Hg. The changes in pressure and arterial deflection of 1 patient with AR (Case 6) are shown as an example in Figure 3.

Discussion

No attempt was made to compare the external pulse of 1 patient with that in another, because the pulse in each depends on the relative position of the cup and the artery. However, once the cup is clamped to the artery, the pulses recorded in the elevated position (D) may be compared with those at rest (D_0). Our results showed that D/D_0 increased with each elevation of the wrist.

A piezoelectric crystal may respond to rate of change rather than magnitude of the deforming signal, and the rate of change of blood pressure (dp/dt) increases when patients with AR stand erect.[3] The time constant of the crystal was 1.9 seconds, which suggested that its response to rate of change was minimal.[4] To be certain, we repeated 1 study, using an air-filled pickup with a strain gauge that measured only magnitude of arterial excursion. This produced identical tracings, and the pulse increased in exactly the same way when the wrist was elevated. Alterations in pulse rate also affect the dp/dt within the artery, but our control subjects showed only slight increase in pulse rate with elevation, and those with AR showed no change. Thus the changes produced by elevation were an increased external pulse, a lowered mean pressure, and a narrowed pulse pressure. The changes, taken together, suggest that elevation increases the compliance of the arterial wall. Previous studies have shown the pressure-volume relationship of arteries to be curvilinear.[5] It is because of this that in the presence of a lower mean pressure the vessel becomes more compliant, and therefore has a greater excursion (and hence deflection) with each pulse.

If this is true the same effect should be evident in other arteries. Corrigan noted that a bounding pulse in the leg became more noticeable when the foot was raised. One patient with AR also was studied using the dorsalis pedis artery. With the leg horizontal the arterial deflection was 3.1 cm and increased to 8.6 cm in the elevated position. Corresponding pressures were 220/65 mm Hg (mean 95) and 130/25 mm Hg (mean 50). Elevation, therefore, affects legs and arms in the same way.

Thus our observations agree with those of Corrigan, as does our interpretation. Elevation of the legs and arms increases the arterial compliance or, in his words, "makes the artery more flaccid."

Effects of Disopyramide on Left Ventricular Function: Assessment by Radionuclide Cineangiography

JOHN S. GOTTDIENER, MD, ROBERT DIBIANCO, MD, RICHARD BATES, MD, BERTRAM J. SAUERBRUNN, MD, and ROSS D. FLETCHER, MD,
With the technical assistance of ROD NOSS, BS and ANN RUSK, BA

To determine the effects of disopyramide on resting systolic left ventricular (LV) function and LV functional reserve, gated equilibrium radionuclide cineangiography was performed at rest and during maximal symptom-limited supine bicycle exercise in 12 patients after a single 300 mg oral loading dose of disopyramide, and in 22 patients (including the 12 patients just mentioned) after they received disopyramide 150 mg 4 times daily for 5 to 10 days (average 7). The oral loading dose (average serum level 3.6 ± 1.3 μg/ml [standard deviation]) produced decreases in ejection fraction in 9 of 12 patients with a decrease in average resting ejection fraction from 40 ± 15% to 33 ± 11% ($p < 0.005$). However, the lower, sustained dosage of disopyramide was associated with a lower average serum level of 2.5 ± 0.8 μg/ml and with smaller but significant decreases in ejection fraction in 3 of 22 patients during exercise only. At this dosage there was no significant decrease in average ejection fraction for the group at rest or during exercise. Adverse effects of disopyramide on ejection fraction occurred even in patients with previously normal LV function at rest. Hence, disopyramide may be associated with significant decreases in LV systolic function, particularly when given in high, oral "loading" doses. However, sustained therapy with lower dosages as well as lower drug levels is also associated with less depression of LV function.

Disopyramide phosphate (Norpace®) is a relatively recently introduced antiarrhythmic drug[1] with therapeutic efficacy[2–4] in the treatment of supraventricular and ventricular arrhythmias. The cardiac effects of disopyramide resemble those of quinidine in that both drugs reduce the rate of increase and amplitude of the cardiac muscle action potential and decrease automaticity. Unlike quinidine, depression of left ventricular (LV) function[5–9] has been considered a substantial difficulty. Although congestive heart failure was initially noted in patients with renal failure or previous cardiac decompensation or after large loading doses of a drug, a more recent clinical study suggests a high frequency of congestive heart failure even in patients with intact renal function.[9] To determine resting systolic LV function and LV functional reserve, gated equilibrium radionuclide cineangiography was performed at rest and during exercise before and after the administration of an oral loading dose, and during sustained therapy with disopyramide.

Methods

Patients: Patients with coronary artery disease and idiopathic dilated cardiomyopathy receiving antiarrhythmic drugs for suppression of ventricular ectopic beats were studied. The group consisted of 22 men with an average age of 60 years (range 44 to 80). Seventeen patients had coronary heart disease documented by coronary angiography (10 patients) or by previous documentation of acute myocardial infarction (7 patients). Five patients had idiopathic dilated cardiomyopathy; all were habitual alcoholics. In 3, coronary angiography disclosed <50% diameter reduction in any coronary artery; 2 patients had LV dysfunction without a previous history of acute myocardial infarction or angina pectoris. In addition, they did not have abnormal Q waves on electrocardiogram or

regional wall motion abnormality on radionuclide cineangiogram. Twelve patients were taking digitalis and 17 diuretics, although none had uncontrolled congestive heart failure at study.

Long-acting nitrates were discontinued at least 10 hours and quinidine or procainamide at least 1 week before study. Radionuclide angiography was performed at baseline and an average of 7 days (range 5 to 10) after beginning disopyramide 150 mg 4 times daily. On this sustained therapeutic regimen, radionuclide imaging was performed 2 to 3 hours after the last dose, at which time blood was drawn for measurement of the disopyramide level. In the first 12 patients studied, radionuclide cineangiography also was performed 2 hours after the ingestion of disopyramide administered as an acute oral loading dose of 300 mg, before beginning sustained therapy. Determination of ejection fraction at rest and during exercise in these 12 patients was performed at baseline just before the administration of disopyramide. Venous blood for measurement of serum levels of disopyramide was drawn 90 minutes after the 300 mg oral loading dose just before repeat imaging. Disopyramide levels were measured[10] by high-pressure liquid chromatography.

To exclude the possible effects of repeated exercise testing or other factors on multiple determinations of ejection fraction performed within a short time, an additional 10 patients (8 with coronary artery disease and 2 with aortic regurgitation) underwent 2 rest-exercise sequences, separated by 45 to 60 minutes, without intervening drug therapy.

Radionuclide cineangiography: Radionuclide cineangiography was performed with the subjects in a supine position at rest and during maximum symptom-limited supine bicycle exercise.[11] In vivo labeling of red blood cells with 25 mCi of technetium-99m was effected by injecting the isotope a half hour after the intravenous administration of stannous pyrophosphate. This dose of technetium coupled with a high sensitivity collimator results in 200,000 counts/frame in a 15 × 15 cm field surrounding the heart. After equilibration of the tracer in the blood pool, an Anger camera was oriented in the modified left anterior oblique position to isolate the left ventricle in the field of view.[12] Imaging was performed with a computer-based procedure gated to the electrocardiogram. LV ejection fraction could then be determined by computer-assisted analysis of LV time activity curves, using a commercially available system (General Electric, Med IV), and software (Medical Data Systems, MUGE). With this system, data were stored on a 12-sector disc and transferred to a minicomputer in real time. The initial 80% of the cardiac cycle, beginning at end-diastole, is divided into 14 equal frames, each with a spatial resolution of 64 × 64 pixels. At resting heart rates, ranging in our patients from 53 to 107 beats/min, this frame rate produced a temporal resolution of 0.06 second at the lowest resting heart rate observed and 0.03 second at the highest. Temporal resolution was 0.05 second or better in 52 of 56 studies performed at rest and in all 56 studies performed during exercise. Acquisition of data at rest over 5 to 8 minutes resulted in approximately 9,000 to 15,000 counts within the LV border at end-diastole. The LV border was determined by computer within a rectangle placed by the operator around the LV region of interest. The algorithm used identifies the LV border on a frame-by-frame basis, using both threshold and second derivative criteria. Each frame was reviewed by the operator. Appropriate changes in the count threshold were made as necessary, so that the final LV region of interest conformed to the visual image. Background was selected by the computer 5 pixel-widths from the inferolateral aspect of the LV border. The background-corrected LV time-activity curve was plotted on hard copy. Ejection fraction was determined automatically from the counts at the end-diastolic frame, determined at the peak of the curve, and from counts at the end-systolic frame, determined at the nadir of the curve. Excellent correspondence ($r = 0.90$, $p < 0.001$, $n = 32$) of radionuclide ejection fraction with those obtained by contrast angiography has previously been established in this laboratory. The ejection fraction in this comparison ranged from 10 to 87% (49 ± 29%, mean ± standard deviation [SD]) on contrast angiography and ranged from 13 to 69% (mean 40 ± 15%) on radionuclide cineangiography. The interstudy variability of ejection fraction in our laboratory, determined in 20 stable patients over several days, is 3 ± 2% (average ± SD ejection fraction units) with a range of 0 to 6%.

After images were obtained at rest, supine bicycle exercise was begun with 100 kpm-m increments in exercise load at 2-minute intervals. Exercise was continued until limitation by severe failure, chest pain, or severe dyspnea. Imaging was begun when the patient indicated severe fatigue and was continued an additional 2 or 3 minutes as required for acquisition of statistically sufficient data. Ejection fraction was calculated using the methods described herein. In all subjects, heart rate and blood pressure (measured using arm cuff sphygmomanometry) were recorded at 1- to 2-minute intervals during exercise.

Data are presented as the mean ± SD. Changes in ejection fraction are expressed as absolute values. A decrease in ejection fraction from 60 to 45% is a 15% change. A change in ejection fraction of >7% (interstudy variability mean ± 2 SD) was considered to represent a significant change in an individual patient. Comparisons of means between baseline ejection fractions and those determined after disopyramide were made using Student's t test for paired data. The criterion of significance was $p < 0.05$.

Results

An oral loading dose of disopyramide 300 mg (average serum level 3.6 ± 1.3 μg/ml, range 2.0 to 5.9) was associated with significant decreases (Fig. 1) in ejection fraction in 9 of 12 patients, either at rest only (3 patients), with exercise only (3 patients), or during both rest and exercise (3 patients). Decreases in ejection fraction from baseline values were as great as 18% at rest and during exercise. In addition, after disopyramide the average ejection fraction at rest for the group of 40 ±

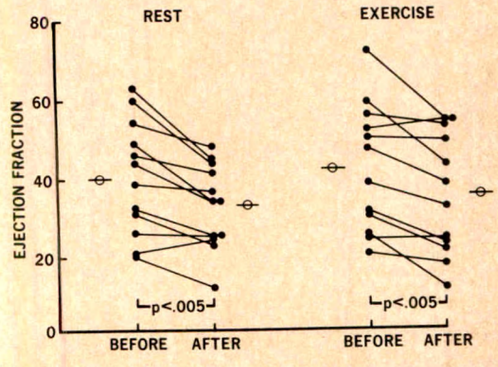

FIGURE 1. Response of resting (**left panel**) and exercise (**right panel**) ejection fraction to single 300 mg oral dose of disopyramide. Decreases of ejection fraction up to 18% at rest or during exercise, or both, are noted in most patients (9 of 12). The decrease in average ejection fraction at rest or with exercise is significant. Note that even 3 patients with previously normal ejection fractions (49, 60, and 63%) show decreases after disopyramide (**left panel**).

TABLE I Hemodynamic Effects of Disopyramide at Rest and During Exercise

	Ejection Fraction (%)		Heart Rate (beats/min)		Systolic Blood Pressure (mm Hg)		Double Product* (×10³)	
	Rest	Exercise	Rest	Exercise	Rest	Exercise	Rest	Exercise
Baseline (n = 22)	39 ± 14	42 ± 18	73 ± 14	116 ± 18	141 ± 14	171 ± 14	10.3 ± 2.3	20.0 ± 2.7
Maintenance† disopyramide (n = 22)	37 ± 9	41 ± 18	75 ± 14	115 ± 18	142 ± 18	176 ± 23	10.6 ± 1.8	20.2 ± 2.5
Disopyramide‡ load (n = 12)	33 ± 10§	35 ± 16§	78 ± 13¶	118 ± 20	140 ± 13	164 ± 13	10.8 ± 2.0	19.4 ± 3.3

* Double product = systolic blood pressure × heart rate/10³. Values expressed are the average of those determined for each patient.
† Disopyramide 150 mg every 6 hours postoperatively for 5 to 10 days (average 7).
‡ Disopyramide given as single 300 mg oral dose.
§ $p < 0.005$ in comparison with ejection fraction determined in these 12 patients before disopyramide.
¶ $p < 0.05$ in comparison with heart rate in these 12 patients before disopyramide.

15% decreased to 33 ± 11% ($p < 0.005$), and the average ejection fraction during exercise decreased from 42 ± 16% to 35 ± 16% ($p < 0.005$). The average systolic blood pressure and double product at rest or with exercise was not significantly changed by the oral disopyramide load, although there was a small increase in the average heart rate at rest (Table I). The correlation between plasma level of disopyramide and change in ejection fraction was not significant at rest ($r = 0.14$) or with exercise ($r = 0.37$). No patient evidenced congestive heart failure after disopyramide. Even 3 of 5 patients with normal resting ejection fraction (>45%) before disopyramide had decreases in ejection fraction after its administration.

Sustained disopyramide therapy: The average ejection fraction at rest (Fig. 2) in the 22 patients during sustained therapy with disopyramide (average serum level 2.5 ± 0.8 μg/ml, range 1.8 to 4.5) of 37 ± 13% was not significantly lower than the average ejection fraction before disopyramide of 39 ± 15%. With exercise, the average ejection fraction of 41 ± 18% on disopyramide also did not differ significantly from that determined at baseline of 41 ± 19%. The average heart rate, systolic blood pressure, and their double product were unchanged at rest or during exercise by disopyramide (Table I).

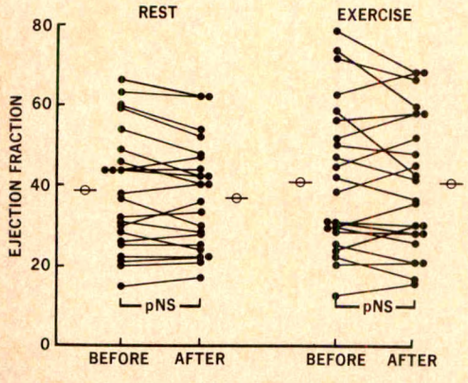

FIGURE 2. Ejection fraction at rest and during maximal supine bicycle exercise in 22 patients before and 5 to 10 days after beginning disopyramide in a maintenance dosage of 600 mg/day in 4 divided doses. The average ejection fraction at rest and during exercise was unchanged during disopyramide, although 3 patients had decreases in ejection fraction during exercise in excess of the test variability. NS = not significant.

Although this dosage of disopyramide was unassociated with a decrease in average ejection fraction for the group as a whole, 3 of 22 (14%) patients had decreases in ejection fraction during exercise in excess of the test variability of 7%. This decrease in ejection fraction during exercise from that obtained before disopyramide ranged from 10 to 16%.

Effects of repeat exercise on ejection fraction: Among the 10 additional control patients in whom rest and exercise studies were repeated without disopyramide 45 to 60 minutes after the first rest-exercise sequence, neither at rest nor with exercise did the second determination of ejection fraction differ significantly from the values obtained during the first sequence (rest 54 ± 4% versus 52 ± 4%, exercise 49 ± 5% versus 47 ± 5%). The interstudy variability for this test sequence was 3 ± 2% at rest and exercise.

Discussion

The results of this study indicate that a single 300 mg oral dose of disopyramide is associated with depression of LV function at rest and during exercise, even in patients with previously normal ejection fraction at rest in whom plasma drug levels did not exceed a therapeutic[1] range. Although depression of ejection fraction was apparent in 6 of 12 patients at rest, in 3 other patients depression of ejection fraction occurred during exercise only. In these 3 patients, the significance of decreases in LV functional reserve in the absence of depression of resting LV function is of uncertain significance. Rather than direct depression of LV systolic function, these changes may reflect myocardial ischemia, consequent to altered loading conditions, or decreased coronary blood flow. Alternatively, they may represent mild depression of the myocardium, unmasked only during exercise stress. Determination of ejection fraction during exercise also increases the sensitivity of radionuclide angiography in detecting LV functional abnormality associated with other noncoronary sources of LV dysfunction.[13–15] Although the single 300 mg dose produced depression of LV function in most patients studied as well as in the average ejec-

tion fraction at rest and during exercise for the group, maintenance dosages of disopyramide were unassociated with a significant decrease in average ejection fraction at rest or exercise. Three (14%) patients did have modest decreases in LV function during exercise only, in excess of study variability, even with this lower dosage. These patients did not have higher plasma drug levels than did the others.

Previous studies, with some exceptions, have indicated an adverse effect of disopyramide on LV function in both experimental animals and man. A decrease in peak-developed tension with disopyramide was documented[5] in guinea pig and rabbit trabecular muscle preparations as well as in human papillary muscle preparations. This decrease was associated with a dose-dependent decrease in superficially located calcium stores. Although depression of myocardial contractility in intact open-chest animals could not be documented by some investigators,[16] Walsh and Horwitz[17] noted myocardial depression and vasoconstriction in conscious, chronically instrumented dogs given disopyramide.

Studies of intravenously administered disopyramide on LV function in man also have been at variance. No adverse hemodynamic effects were noted in patients with normal LV function receiving 1.5 mg/kg of disopyramide intravenously or in individuals with depressed LV function, if heart rate was controlled by atrial pacing.[18] In contrast, Jensen et al[19,20] noted a 28% decline in cardiac index accompanied by an increase in right and LV end-diastolic pressure in patients with overt or subclinical heart failure, and others[21,22] also have described adverse hemodynamic effects after disopyramide 2 mg/kg given intravenously. Although resting LV function was depressed after an intravenous bolus of disopyramide, Thadani et al[23] found that hemodynamic variables during exercise were unaffected, possibly because of enhanced sympathoadrenergic activity. Of note, Kötter et al[24] found that in addition to adverse hemodynamic effects, intravenous disopyramide was also associated with peripheral and coronary arterial vasoconstriction which, in turn, might further compromise myocardial function in susceptible patients.

Although data on the effects of intravenously administered disopyramide have been plentiful, information on the effects of orally administered drug on cardiac performance has been less available. An echocardiographic study[25] documented small decreases in ejection fraction with disopyramide given as a single 200 mg oral dose as well as 4 times daily for 1 week to normal men; however, propranolol produced changes of similar magnitude. Conventional doses of disopyramide in normal subjects also have caused adverse effects on myocardial performance determined by systolic time intervals.[23]

Recently, the onset of clinical manifestations of congestive heart failure was described[9] in 13 of 38 patients receiving long-term oral disopyramide in doses of 300 to 800 mg/day (average serum level 3.4 μg/ml, range 2.2 to 5.6). Objective tests of LV function were not reported in these patients, precluding assessment of the relation between LV ejection fraction and clinical effects. Although no patient had congestive heart failure, our data are consistent with these observations in that most (75%) of our patients receiving a single 300 mg oral dose, in association with an average serum drug level of 3.6 μg/ml, comparable to that just reported, had significant decreases in LV ejection fraction at rest and during exercise. Conceivably, if these higher serum drug levels had been maintained for longer durations, adverse clinical effects may have occurred. Although average ejection fractions at rest or with exercise did not decrease in our patients on "maintenance" disopyramide for 5 to 10 days, and only 4 of these patients had modest decreases in ejection fraction, these patients had substantially lower serum drug levels (average 2.5 μg/ml) than did those just reported on herein. In addition, prolonged exposure to disopyramide may be necessary before cardiotoxic effects are manifested. In our study, LV function was evaluated within a relatively short time (5 to 10 days) after beginning disopyramide therapy. In contrast, some patients described by Podrid et al[9] had the onset of congestive heart failure only after several months of disopyramide therapy. However, 2 of their patients evidenced congestive heart failure within 48 hours of beginning a daily divided disopyramide dose of 600 mg, 8 patients had congestive symptoms during the first 3 weeks, and 1 patient had them 3 hour after a single 300 mg dose. In addition, with the single 300 mg dose, we were able to document a rapid adverse effect on LV function. Hence, both clinical and laboratory manifestations of depressed LV function can be documented within a short time of beginning disopyramide. Concerning the clinical manifestations of congestive heart failure after disopyramide, patients with chronic impairment of LV function are likely to have recurrent pulmonary edema when observed over long intervals, often related to factors other than toxic drug effects. Clinical improvement on drug withdrawal in addition to other therapy for congestive heart failure would not be sufficient to document the drug as the cause of cardiac decompensation. Careful case-controlled studies would be required to identify the contribution of disopyramide or other concurrent medication to such episodes. Also, in patients with poor LV function, large increases in left ventricular filling pressure, and hence pulmonary congestion, may occur in the absence of marked decreases in LV systolic performance. Therefore, although our study shows that ejection fraction may decrease transiently without the onset of pulmonary edema, the absence of a measurable decrease in ejection fraction during sustained disopyramide may not exclude the possibility of a toxic drug effect on cardiac performance.

Septal Ischemia as a Mechanism of Complete Atrioventricular Block: Demonstration by Thallium Scintigraphy

Avraham Theodore Weiss, MD
Yonathan Hasin, MD
Mervyn Samuel Gotsman, MD

Complete atrioventricular block in anterior myocardial infarction usually indicates extensive involvement of the ventricular septum with widespread damage to the conduction system, usually below the undivided bundle of His.[1] The mortality is high.[1–3] Herein we describe a patient with transient complete atrioventricular block caused by transient septal ischemia demonstrated by thallium-201 scintigraphy.

A 65-year-old man with a 5-year history of effort-induced angina pectoris and a 3-year history of repeated syncopal attacks after episodes of chest pain was hospitalized with severe retrosternal pain and recurrent syncope. He was pale and sweating; the pulse was 30 beats/min and blood pressure 170/90 mm Hg. The electrocardiogram showed complete heart block with a slow idioventricular rhythm and a wide QRS complex and right bundle branch block. After a temporary transvenous pacemaker electrode was inserted, he reverted spontaneously to normal sinus rhythm with a normal P-R interval and a pattern of left bundle branch block identical to a tracing taken 6 months previously (Fig. 1). The patient refused to undergo coronary angiography. Another spontaneous ischemic episode associated with sweating occurred the following day, and the atrioventricular block reappeared and was controlled by the pacemaker. A thallium scintiscan (2 mCi of thallium-201) made immediately showed septal ischemia with a 20% decrease in septal perfusion (Fig. 2, left). The remainder of the myocardial uptake of thallium was normal. The pain subsided after 30 minutes and normal atrioventricular conduction returned. A redistribution scan including the area of the septum performed 4 hours later showed normal myocardial uptake (Fig. 2, right). The patient refused further investigation, and a permanent endocardial demand ventricular pacemaker was inserted. He has been well for 6 months, and despite recurrent episodes of chest pain he has not fainted again.

Thallium-201 enters and labels normal nonischemic myocardial cells and is an excellent method of demonstrating regional myocardial perfusion.[4] Ischemia which is induced by stress[5] or develops spontaneously during an episode of pain[6,7] can be demonstrated by scintigraphy; it causes a transient filling defect which disappears during a subsequent redistribution scan.

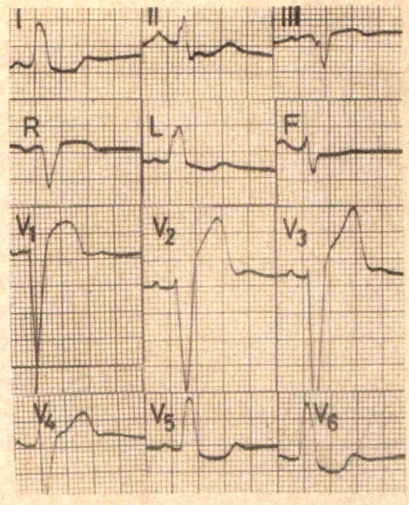

FIGURE 1. Resting electrocardiogram shows a P-R interval of 0.18 seconds, a mean frontal QRS axis of −10°, and complete left bundle branch block.

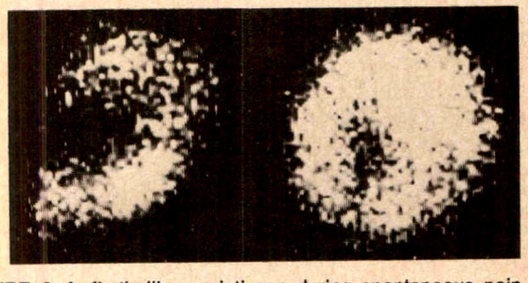

FIGURE 2. Left, thallium scintiscan during spontaneous pain and complete atrioventricular block. Left anterior oblique position. Significant decrease in septal perfusion. **Right,** redistribution scan 4 hours after the episode of complete heart block. Normal septal perfusion.

Left bundle branch block usually masks the diagnosis and the site of myocardial infarction and ischemia. The proximal perforating branches of the left anterior descending artery supply the proximal ventricular septum and the right bundle branch. Septal ischemia, diagnosed with the thallium scintiscan, implied a high lesion of the left anterior descending artery.

This case shows the value of thallium scintigraphy in the intensive care unit to demonstrate the site and nature of transient ischemia of the septum in analyzing the significance and genesis of complete heart block. It established the diagnosis in a patient who refused further investigation and justified the implantation of a ventricular pacemaker.

Atrial Septostomy as Palliative Therapy for Refractory Primary Pulmonary Hypertension

Stuart Rich, MD
Wilfred Lam, MD

Primary pulmonary hypertension (PPH) is an inexorably progressive illness that invariably leads to death. We describe a patient with PPH that was refractory to multiple trials with different vasodilator drugs. A right-to-left shunt using an atrial septostomy catheter was created.

A 22-year-old black woman first presented in 1978 with hemoptysis and dyspnea. Catheterization showed marked pulmonary arterial hypertension with normal cardiac output (Table I). Attempts to lower pulmonary arterial pressure with oral vasodilators including tolazoline, hydralazine, prazosin, captopril, minoxidil, and nifedipine were unsuccessful. Several subsequent catheterizations were performed (Table I). With little else to offer, a right-to-left shunt through an atrial septostomy was created.[1] *A transatrial septal puncture was performed with a Brockenbrough catheter passed through an 8Fr. Mullens sheath. The catheter was then removed and a Park blade septostomy catheter was placed through the sheath into the left atrium. Three successive passages of the catheter were made with the blade open at 30°, 45°, and 90°, respectively. The blade septostomy catheter was then removed and several passages were made with a Rashkind balloon septostomy catheter to further enlarge the newly created atrial septal defect. The effects of the procedure are summarized in Table II. The septostomy caused equalization of pressure between the atria, which resulted in a large right-to-left shunt. Despite the high pulmonary vascular resistance and elevated right-sided pressure, pulmonary blood flow did not decrease after septostomy.*

The patient tolerated the procedure well. The following morning she attempted to get out of bed and sit in a chair but became lightheaded and dyspneic. However, blood gases were unchanged. Later that evening she became more agitated and dyspneic. Repeat blood gases revealed the same partial pressure of oxygen, but the pH was 7.32. Over the next 2 hours, she became more dyspneic and acidotic, developed systemic hypotension, and died.

Necropsy disclosed a 9 mm longitudinal opening in the fossa ovalis and marked right ventricular hypertrophy. In

m = mean; O_2 = oxygen; s/d = peak systolic/end-diastolic.

addition, the left side of her heart was markedly dilated and marked pulmonary venous congestion was present.

Patients with PPH usually develop symptoms from reduced cardiac output,[2] and on initial presentation are often difficult to distinguish from patients with Eisenmenger's physiology from congenital heart disease. However, patients with severe pulmonary hypertension from an atrial septal defect do better than do patients with PPH,[3] possibly because the right side of the heart is able to decompress itself during periods of stress through the right-to-left shunt.[4]

Some patients with PPH have a patent foramen ovale and thus are able to decompress the right side of the heart. Although it has not been clearly demonstrated that these patients do better, a recent retrospective study on patient survival with PPH suggested that this may be the case.[5] We created a right-to-left shunt in our patient because her condition was refractory to medicines and because it was clear that she would die soon. The procedure increased the systemic blood flow without compromising pulmonary blood flow despite the marked right-to-left shunting and the increase in left atrial pressure. That this was beneficial to the patient acutely was confirmed by the fact that she survived initially without other medical support.

The cause of her sudden death is not understood. The findings of acute left ventricular volume overload at necropsy implies that the left ventricle was no longer able to handle a normal preload, as it had 3 years earlier. Although the patient had no clinical signs of left ventricular dysfunction, perhaps left ventricular function is compromised when right ventricular pressure overload develops.[6]

A theoretical basis exists for creating an atrial septal defect in a patient with refractory pulmonary hypertension. Further studies will determine if the creation of an atrial septal defect in patients with PPH will provide long-term benefit.

Fatal Small Bowel Obstruction After Pacemaker Generator Implantation in the Abdominal Wall

Meir Mazuz, MD
Natesa G. Pandian, MD
Richard E. Kerber, MD

Major complications due to pacemaker implantation are unusual and most often associated with implantation of an epicardial electrode by thoracotomy under general anesthesia. Fatal complications remote from the time of implantation are rare and almost always due to pacemaker malfunction. A case is reported of fatal intestinal obstruction caused by a pacemaker generator which was implanted in the abdominal wall 7 years earlier.

A 69-year-old man was admitted because of abdominal pain, nausea, and vomiting. Nine years earlier a transvenous ventricular demand pacemaker had been implanted because of 2 episodes of syncope associated with left anterior hemiblock on electrocardiogram. Because of pacemaker malfunction, it was replaced 1 year later; because of continued intermittent capture, 1 year later it was replaced again, this time with an epicardial pacing electrode with the generator placed subcutaneously in the left upper quadrant of the abdominal wall. The generator was replaced a fourth time because of abdominal wall pacing thought to be due to a current leak. Thereafter, the patient's condition remained stable for 30 months, when abdominal pain prompted readmission. During his outpatient clinic visits, electrocardiograms and 24-hour Holter monitoring always showed normal sinus rhythm with frequent ventricular premature

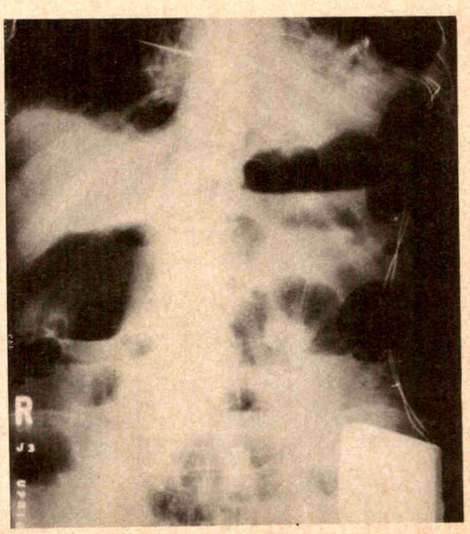

FIGURE 1. Upright abdominal roentgenogram showing multiple dilated loops of small bowel with air-fluid levels. The pacemaker generator implanted in the left lower abdominal wall is visible.

contraction, left anterior hemiblock, and intermittent P-R interval prolongation. Pacemaker rhythm was seen infrequently.

On admission, he had sinus tachycardia (110 beats/min) with occasional ventricular premature contractions. The abdomen was tender, with maximum tenderness over the pacemaker pouch. Bowel sounds were active. The leukocyte count was 13,700 cells/mm^3. The abdominal radiograph (Fig. 1) had a pattern of small bowel obstruction. Initial conservative management of partial intestinal obstruction included nasogastric suction and fluid replacement. After 5 days, laparotomy was performed which revealed a "knuckle" of bowel that was adherent to a suture that had been placed through the peritoneum at the time of generator implantation. This segment of bowel was necrotic and ruptured during surgery. Postoperatively, septic peritonitis, wound dehiscence and evisceration, septic shock, and death occurred (19 days later).

We describe a previously unreported complication from pacemakers: intestinal obstruction related to an intraperitoneal suture placed during generator implantation in the abdominal wall. A related complication has been described.[1] Excessively deep suturing at the time of pacemaker generator implantation should be avoided. Pacemaker-related adhesions may exist in patients who present with evidence of bowel obstruction or other abdominal disease and who have abdominal wall pacemaker generators. A long symptom-free interval since pacemaker implantation does not exclude this possibility.

Five Coronary Ostia: Duplicate Left Anterior Descending and Right Conus Coronary Arteries

Bruce F. Waller, MD

Multiple aortic coronary ostia are occasionally observed at necropsy. Duplication of an entire major epicardial coronary artery producing an extraaortic ostium, however, has not previously been reported. Recently, I examined the heart of a 57-year-old man who never had symptoms of cardiac dysfunction and died of lymphoma. At necropsy, 5 separate coronary ostia were present (Fig. 1). A right coronary artery and 2 conus arteries arose from the right aortic sinus of Valsalva, and a typical left main artery (with left anterior descending [LAD] and left circumflex divisions) and a duplicate LAD coronary artery arose from the area of the left sinus. Both LAD arteries descended in parallel fashion over the anterior ventricular surface to the cardiac apex.

Five aortic coronary ostia have previously been reported in at least 9 subjects at necropsy,[1,2] but in each the multiple ostia resulted from triplicate conus arteries. Advantages of multiple separate coronary arteries include extra sources of myocardial blood and potential use as collateral arteries. Disadvantages relate to difficulties in recognition and cannulation during coronary angiography or cardiopulmonary bypass procedures.

From the Departments of Pathology and Medicine, Indiana University School of Medicine, and The Krannert Institute of Cardiology, Indianapolis, Indiana. Manuscript received December 14, 1982; revised manuscript received January 10, 1983, accepted January 21, 1983.

Left Atrial Mass: Diagnostic Value of Transesophageal 2-Dimensional Echocardiography and Indium-111 Platelet Scintigraphy

Michael D. Ezekowitz, MD, PhD
Eileen O. Smith, BS
Robert Rankin, MD
Lynn H. Harrison, Jr., MD
Henry F. Krous, MD

Although cardiac myxomas are rare, accurate recognition is essential because excision is usually associated with complete cure. This report demonstrates that although the recognition of this condition by transthoracic, 2-dimensional (2-D) echocardiography is well established,[1] technical difficulties related to obtaining an adequate acoustic window may impair the quality of the image and preclude a definitive diagnosis.[2] These difficulties are minimized by using a transesophageal approach which eliminates the need to transmit the ultrasound through the anterior chest wall and air-filled lungs.[3] This report also demonstrates that myxomas may be mistaken for thrombi by indium-111 platelet scintigraphy, a technique heretofore believed to be specific for thrombosis.[4,5]

A 46-year-old woman with no evidence of preexisting cardiovascular disease presented with a 2-month history of malaise and nonspecific muscle aches. On examination, the only abnormality was an intermittent mid-diastolic rumble heard best at the cardiac apex. Resting electrocardiogram and chest radiograph were within normal limits. Routine M-mode and 2-D echocardiograms were of suboptimal technical quality (Fig. 1). The parasternal long-axis image was suspicious for a left atrial (LA) mass. The apical 4-chamber views were foreshortened, and a definitive demonstration of the mass was not possible. Further investigation was performed by transesophageal 2-D echocardiography and indium-111 platelet scintigraphy.

Before performing the transesophageal 2-D echocardiographic study, the posterior pharynx was anesthetized with a topical benzocaine anesthetic and intravenous diazepam was administered until drowsiness ensued. A modified fiberoptic gastroscope (Fig. 2) was passed through the pharynx into the esophagus and images were obtained (Fig. 3). The method of labelling and imaging platelets has been described previously.[5] Images were obtained in multiple views (Fig. 4).

At surgery, a single LA myxoma 9.0 cm in diameter was successfully removed. The patient recovered uneventfully. By light and electron microscopy, the tumor was characteristic of myxoma. No thrombus was seen on the tumor surface, and scanning electron microscopy failed to disclose platelets adhering to the tumor surface.

From the Departments of Medicine, Surgery, and Pathology, the University of Oklahoma Health Sciences Center. This study was supported by Grant PPG 2 P01 HL 17812-07 from the National Institutes of Health, Bethesda, Maryland, and Veterans Administration Merit Review Grant, Oklahoma City, Oklahoma. Manuscript received December 14, 1982; revised manuscript received January 7, 1983, accepted January 10, 1983.

The interest in this case is twofold. First, we believe that this patient is the first to have LA myxoma demonstrated by transesophageal 2-D echocardiography. Although this form of echocardiographic exami-

nation is associated with more discomfort than the traditional transthoracic approach, the patient was successfully managed without recourse to an invasive procedure. This technique is a viable alternative to cardiac angiography when a definitive diagnosis of LA myxoma cannot be made by regular echocardiographic techniques. Second, this case also is the first demonstration of a nonthrombus presenting as a positive cardiac indium-111 platelet scintiphoto. Platelet scintigraphy is thought to be specific for thrombosis.[4,5] The appearance of myxoma as a positive study demonstrates that cardiac tumors may accumulate platelets on their surface and be mistaken for intracavitary thrombi. An important point of differentiation may be the observation that these images were maximally positive at 24 to 48 hours after injection of the platelet suspension. Thrombi are typically positive at 72 to 96 hours. This difference may suggest transient adherence of platelets to the tumor rather than permanent incorporation as occurs in a thrombus.

The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

Rheumatology

A Primary Care Approach

Written by:

Bruce M. Rothschild, MD

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8 430 pp., illus., November 1982, $39.50

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Rheumatology: A Primary Care Approach is Not

- a research monograph filled with esoteric information of little use to the practicing primary care physician
- a difficult to follow, badly organized reference tool requiring a thorough knowledge of the subject matter before it can be used effectively
- a massive and verbose dissertation more useful as a door stop than a clinical reference

We know of no other book on rheumatic disease which covers the subject as exhaustively in terms of diagnosis and treatment while avoiding wasting the busy practitioner's time by including information of little interest to the primary care physician. This book emphasizes that information necessary to recognize basic disease processes and their natural history. It provides the reader with the information necessary for making a diagnosis and initiating a plan of treatment. Information on differential diagnosis from the point of view of characteristics which would not fit with a given diagnosis is also provided. It is especially strong on the interpretation of rheumatologic radiology and in its approach to joint examination and assessment of lab results. Rheumatic disease cannot be cured but proper intervention can reduce and sometimes eliminate the attendant disability. This book provides you with the means to diagnose, assess and decide for yourself the necessary intervention.

From the Preface:

"More than 15 million individuals in the United States suffer from arthritis, and there are only 3,000 physicians practicing rheumatology. It is evident that the majority of patients receive continuing care from the nonrheumatologist, i.e., the internist, family practitioner, pediatrician and other disciplines in medicine. Therefore, we require concise and authoritative clinical guidelines for the primary care physician. With this as motivation Dr. Bruce Rothschild has skillfully structured a text geared to the particular and immediate needs of the practitioner... This text... is an important contribution to continuing medical education of the clinician. It will be of immediate interest and value to clinicians in a wide variety of specialties and should be of great assistance to the faculties and student bodies of our medical schools. We have long needed this type of approach to primary care of patients with musculoskeletal diseases and we are indebted to the author for his accomplishments."

The next breakthrough in cardiac imaging

Full-Spectrum Doppler®:
Because 2-D imaging alone is like watching a silent movie

Just as a silent movie can't tell it all, a silent 2-D image can't convey everything that's happening inside the heart

Now, the newest dimension in echocardiography only from Irex…2-D imaging, M-mode, plus FULL-SPECTRUM DOPPLER® for the noninvasive assessment of both hemodynamics and anatomy… a technique you can learn easily and quickly, with full training support from Irex.

In the unique Irex System, the Doppler audio signal is the key to getting the proper information from the Doppler examination…because it alone guides you to the optimum angle to flow for the most accurate measurement.

Once oriented correctly, pulsed Doppler provides the resolution needed for precise localization and selective sampling. CW Doppler is essential to detect the high flow velocities of most cardiac lesions and to assess the degree of obstruction. Only the Irex Phased Array Imaging System gives you *both* modes for the *complete* simultaneous 2-D/Doppler examination… plus a full-spectrum audio signal to *verify* results.

Hear FULL-SPECTRUM DOPPLER for yourself. Send for your audiocassette. Complete and return the coupon to hear the sound of a sound diagnosis.

DISCRIMINANT FUNCTION ANALYSIS USING THALLIUM-201 SCINTISCANS AND EXERCISE STRESS VARIABLES TO PREDICT CORONARY HEART DISEASE

McCarthy et al[1] constructed discriminant functions from 72 Fourier coefficients of a thallium-201 scan and from treadmill stress test information characterized by 17 variables along with 3 clinical variables. For the population from which they are derived, these functions detect persons with coronary artery disease (CAD) with 92% accuracy and distinguish among persons with no disease, single-vessel disease, and multiple-vessel disease with 78% accuracy. From the information in that report, we believe that these figures are overly optimistic and not reproducible.

The authors developed a discriminant function based on 141 observations and 92 variables which were selected from an even larger group since the use of variables from all 3 views was "not sufficiently more accurate in predicting the presence of CAD than using the Fourier coefficients from the 30 degree left anterior oblique view alone." Their use of a partial F of 8 for variable selection shows that they are aware of the difficulties with multiple comparisons, especially with a limited number of observations. Use of this conservative F value will help prevent spurious factors from being declared significant. The sheer number of candidate variables examined would still be expected to cause problems of reliability and stability of the model.

Although the jackknife procedure eliminates bias in the estimation-classification process based on a single, prechosen statistical model, it does not eliminate the bias caused by variable selection. The estimate of accuracy may be higher than what one would observe when the final model is used to predict CAD in an entirely new patient sample.

A technique preferable to allowing so many variables to be candidates is to develop summary indexes based on clinical intuition and to let such summary indexes be used in a modeling procedure such as the authors have used. As Marquardt and Snee[2] have noted, "It is better to use a little bit of all the variables than all of some variables and none of the remaining ones." Better predictive models which are more interpretable can be obtained by imposing more structure on the problem (even by using subjective evaluations of the scintiscans) than by requiring each of the Fourier coefficients or treadmill measurements to be considered independently.

Finally, it is difficult to know the clinical importance of the discriminant functions because the clinical characterization of the patients is incomplete. Knowing only the sex of the patient, one can correctly classify presence of disease 84% of the time in this population, compared with a 92% accuracy based on the much more complicated data. Other clinically important factors such as type of angina and patient risk factors would improve on this 84%. Thus, when describing the benefits of new technology, it is important to compare the new procedures with results that can be obtained using routinely available information. The true incremental yield of a new test can then be qualified and properly evaluated.[3]

Ray McKinnis, PhD

Durham, North Carolina

1. **McCarthy DM, Sciacca RR, Blood DK, Cannon PJ.** Discriminant function analysis using thallium-201 scintiscans and exercise stress test variables to predict the presence and extent of coronary artery disease. Am J Cardiol 1982;49(June):1917–1926.
2. **Marquardt DW, Snee RD.** Ridge regression in practice. Am Stat 1975;29:4.
3. **Harrell FE Jr, Califf RM, Pryor DB, Lee KL, Rosati RA.** Evaluating the yield of medical tests. JAMA 1982;247:2543–2546.

REPLY: McKinnis, Harrell, and Lee express concern that the statistical model employed in our recent study may have yielded unrealistic results regarding the ability to classify patients suspected of having CAD. We agree that stepwise procedures are susceptible to problems.[1]

One problem is that when considering a large number of candidate variables, there is an increased chance of falsely declaring a variable to be a significant addition to the model. The Bonferroni-type approach[2] of using a cutoff partial F value of 8 was an attempt to deal with this problem; the smallest partial F value actually observed (13.05) corresponds to a p value of 0.05 for 92 independent variables considered jointly. Thus, we are fairly confident that the variables selected have some predictive power.

A second consideration regarding reliability arises when variables which comprise the model are not statistically independent. Attempts to circumvent this problem have led to consideration of biased estimators with smaller variances than the classic least-square estimates.[3] For the model in our study, the square of the largest multiple correlation coefficient between any one of the predictor variables and the rest of the predictor variables was only 0.3, indicating that the predictor variables are not highly intercorrelated.

The suggestion that summary indexes based on clinical intuition be developed for modeling purposes is interesting but difficult to apply. As noted in our report, candidate variables from the electrocardiographic stress test were selected on the basis of previous reports of their utility in predicting the presence or extent of CAD. For the Fourier amplitude coefficients, no previous experience was available other than the theoretical consideration that low-frequency components of the transform contain more useful information than high-frequency components. Visual scan interpretations were specifically excluded from consideration because we were seeking to develop an *objective* method as an alternative to subjective evaluation, which has significant interobserver disagreement.[4]

To determine the accuracy of the discriminant function, we employed the jackknife procedure.[5] While a stepwise analysis will introduce an additional degree of bias to the jackknife procedure, the amount of this additional bias may not be large. Also, as noted, it is important to consider prior information in evaluating the utility of any classification rule. The observation that coronary artery disease could have been predicted with 84% accuracy on the basis of classifying all males as having CAD and all females as normal is true but misleading. The more relevant observation is that the discriminant function was significantly predictive of CAD for both the male and female subpopulations with vastly different prevalence of CAD (the predictive accuracy was 93% for males and 88% for females).

Although statistical methods can be helpful in determining the validity of a model of this type, the best evaluation is by application to a different group of patients. To this end, we are currently testing the discriminant functions in a prospective study of an additional 100 patients undergoing thallium scintigraphy and coronary arteriography. Preliminary results show that the discriminant function employing just Fourier amplitude coefficients, which had an estimated accuracy of 89% in our original report, results in an accuracy of 85%. Employing prior estimates of the probability of CAD based upon age, sex, and anginal pattern,[6] the predictive accuracy is 88%. Although this increase in overall predictive accuracy is small, 48% of the CAD patients are predicted to have disease with a probability exceeding 99%. Thus, while incorporation of prior information can be demonstrated to enhance the certainty of the predictions, these preliminary results suggest that the model is reliable for detecting CAD.

GLUCOSE-INSULIN-POTASSIUM INFUSION IN ACUTE MYOCARDIAL INFARCTION

Whitlow et al[1] presented data for 28 (66%) of 42 patients, originally randomized with a diagnosis of suspected myocardial infarction (MI), to either a control group or a group treated with a glucose-insulin-potassium (GIK) infusion. Ten randomized patients were excluded from the analysis because they did not have a diagnostic increase in plasma CK-MB, and in some of these treatment may have prevented MI. Four other randomized patients were excluded because radionuclide scans were not performed.

We would be interested in seeing analysis of the hemodynamic, cardiac catheterization, radionuclide data, and mortality on *all* randomized patients, where these data are available. This would show the effect of GIK treatment on an "intention-to-treat" basis and would remove any biases introduced by excluding patients from the final analysis. In addition, it would be possible to see whether GIK infusion can reduce the probability of MI developing in patients with threatened MI, as has been shown by early intervention studies of intravenous beta-blockers.[2]

2. **Yusuf S, Peto R, Bennett D, Ramsdale D, Furse L, Bray C, Sleight P.** Early intravenous atenolol treatment in suspected acute myocardial infarction. Lancet 1980; 2:273–276.

REPLY: We certainly appreciate the inquiry of Collins and Yusuf. Much of the data they request appears in abstract form[1] for the entire group of patients studied in our institution. To summarize, 190 patients admitted within 12 hours of chest pain were randomized to glucose-insulin-potassium (GIK) infusion (95 patients) or control infusion (95 patients). Acute myocardial infarction was confirmed enzymatically in 64% (61 of 95) of GIK patients versus 77% (73 of 95) of controls ($p < 0.06$). The group of patients without confirmed myocardial infarction were urged to undergo cardiac catheterization within 1 week after randomization. Many of these patients were treated surgically, and therefore the 2-week postrandomization data are not comparable to the group of patients treated medically. In the subgroup of patients originally randomized the referred to by Collins and Yusuf, hospital mortality was 0% in both groups. The hemodynamic, cardiac catheterization, radionuclide, and mortality data on all randomized patients is the subject of a planned report.

FOLLOW-UP OF PATIENTS HAVING EITHER TRANSVENOUS CATHETER ABLATION OF THE ATRIOVENTRICULAR JUNCTION OR DIRECT SURGICAL HIS BUNDLE DISRUPTION

A new technique for transvenous catheter ablation of the atrioventricular junction was recently described.[1,2] At a recent meeting of investigators using this technique, it was estimated that approximately 70 patients throughout the world underwent this procedure. To assess the efficacy and safety of this procedure, we need follow-up data for these patients. We have, therefore, instituted a registry to allow accumulation and analyses of these data. In addition, to compare the newer technique with standard cardiac-surgical techniques for His bundle ablation, we plan to accumulate similar data for these patients who have undergone direct surgical attempts at His bundle disruption. If you, or colleagues at your institution, have been involved in any of these procedures, please contact *Melvin Scheinman, MD, Room 573, Moffitt Hospital, University of California, San Francisco, California 94143*, telephone (415) 666-1035.

The appropriate forms will be sent to you directly to allow entrance of your data in the registry. Individual patient and institution confidentiality of this data will be strictly enforced. We plan to furnish you with biannual follow-up data from the registry.

CATHETER DEFIBRILLATION

The current surge of interest in catheter defibrillation makes it particularly important that those who are now entering the field be thoroughly acquainted with the historical background of the technique. I am referring especially to a report by Yee et al,[1] suggesting that the authors may not be aware of the early work. In contrast to the information provided, the concept of a single intravascular catheter defibrillating system originated with Mirowski et al,[2] who also implemented and applied it to the clinical setting.[3,4]

COMPARISON OF VERAPAMIL AND NIFEDIPINE IN CHRONIC STABLE ANGINA PECTORIS

We wish to draw your readers' attention to certain aspects of a recent report in your Journal by Bala Subramanian et al.[1] As far as we are aware, it is neither normal nor recommended clinical practice to commence the prescription of nifedipine at 20 mg 3 times a day, particularly when many patients have not had any previous antianginal therapy. Such doses might be applicable if control was inadequate with a beta-blocking drug, but Fox et al[2] previously suggested careful titration of nifedipine dosage since individual responses vary.

It is stated that 32 patients commenced the study and 3 were withdrawn from the nifedipine group before the fortnightly review. It is then stated that a further 4 patients were withdrawn at this review because of dose-related chest pain associated with tachycardia and S-T depression. The fate of the fourth patient who was withdrawn is not apparent, and the penultimate paragraph of the report states that 7 patients had aggravation of angina while taking nifedipine. It is not at all clear whether the analysis involves 25 patients receiving nifedipine, but certainly 28 could not have completed the study as stated.

The experience of these investigators is very different from the report of Dawson et al[3] from Hillingdon Hospital, who wisely introduced nifedipine in a 10 mg 3 times a day dosage for the first 3 days before increasing to 20 mg 3 times a day. In that study, the 2 drugs employed in identical dosage to the Northwick Park regime were equipotent in terms of efficacy, though side effects were less frequent on verapamil. With a more cautious approach no patient developed aggravation of angina from nifedipine. Moreover, the lack of effect of nifedipine on S-T depression during Holter monitoring is in sharp contrast to the effects described by Lynch et al.[4]

The investigators are aware of our concern about the placebo they used, for it is hard to accept that orange capsules bought commercially and filled with water are indistinguishable from the characteristic peppermint taste and smell of nifedipine and matching placebo available from Bayer.

4. **Lynch P, Dargie H, Krikler S, Krikler D.** Objective assessment of antianginal treatment: a double-blind comparison of propranolol, nifedipine and their combination. Br Med J 1980;1:184–187.

REPLY: Thirty-two patients initially were included in the trial; 4 were withdrawn before completing any evaluation on any active

drug. One was withdrawn in the placebo phase due to hypochromic anemia, and 3 developed side effects to nifedipine. Four more developed side effects to nifedipine therapy and did not want to continue beyond 2 weeks; all objective assessments had been completed at 2 weeks and therefore data were included for analysis.

It is difficult to compare the results of the current study with those of the Dawson or the Lynch study. The study of Dawson et al included 16 patients who were chosen because they did not respond to beta-adrenergic blocking drugs and nitrates. They used Bruce's protocol in contrast to our modified Balke's protocol and did not specify the actual treadmill exercise time required to produce angina but used calculated maximal VO_2. Their data show clear differences between verapamil and nifedipine which did not reach statistical significance, perhaps due to the small number of patients. The number of anginal attacks was reduced from 11 on placebo to 3 on verapamil ($p < 0.01$) and 6 on nifedipine ($p < 0.05$). Similarly, the glyceryl trinitrate consumption was reduced from 9 on placebo to 3 on verapamil and 5 on nifedipine. The predicted VO_2 max was 23 ± 1.5 ml/kg/min on placebo and increased to 26 ± 1.4 ml/kg/min on verapamil ($p < 0.001$). Nifedipine increased the value to 25 ± 1.5 ml/kg/min ($p = 0.05$). The improvement in exercise time noted in our trial on nifedipine was 39%, which is similar to the results published by the American multicenter double-blind trial on nifedipine.[1] That report showed a 38% improvement on a mean dose of 51 mg/day, in contrast to the Dawson study, which showed an increase in VO_2 max of 11%. Even the decision of Dawson et al to increase the dose of nifedipine gradually did not prevent a frequency of palpitations of 38% (6 of 16) compared with 25% in our group. The English data sheet on nifedipine (Adalat) does not specify the need for dose titration and informs that the recommended dose is 10 mg 3 times daily but that, if necessary, up to 2 capsules 3 times daily may be taken.[2]

In their study Lynch et al used an Oxford medilog direct recording AM tape system which is unreliable for measuring S-T segment changes.[3,4] Bragg-Remschel et al[4] state that "with the exception of the Oxford AM system which introduces so much additional S-T depression that using it for S-T segment studies would seem unwise, probably all of the manufacturers evaluated could be considered acceptable for grossly reproducing S-T segment depression." Lynch et al used visual methods of S-T segment analysis which are neither accurate nor free from observer variations. It is unreasonable to compare such a study with the current one, which used frequency modulated tape recording and precise computerized digital analysis of S-T segments and heart rate.

The placebo capsules were identical in appearance to the active drug. It is unreasonable to expect that a placebo should taste and smell identical to the active drug. Further, the contention has no relevance because the patients were specifically asked to swallow all drugs with water and never chewed them, a procedure which kept the characteristic nifedipine taste within the capsules. It makes one wonder whether Bayer UK may demand the use of a placebo that produces the characteristic facial flush as nifedipine does, which can be claimed to be a factor influencing all double-blind trials using nifedipine.

ATRIOVENTRICULAR NODAL REENTRY

Scheinman et al[1] reported a case of atrioventricular nodal reentry in which they purport to show that the atrium is not an integral part of the tachycardia reentry circuit. This conclusion is based on the following observations. First, burst pacing of the high right atrium at a cycle length shorter than that of the tachycardia captured the right atrium and atrium in the region of the His bundle catheter without altering the tachycardia cycle length (Figure 2 of their report). Examination of their figure, however, indicates that the tachycardia cycle length was not constant. We have taken their figure, enlarged it, and added a ladder diagram (our Fig. 1). Our caliper measurements indicate that the R-R intervals during the tachycardia progressively shorten by up to 25 ms. Our measurements are calculated from the time scale provided by the authors. We note, however, that in the figure in question, the intervals between the heavy vertical lines (presumably time interval markers) are not constant and vary by 25 ms, suggesting that the paper recorder speed may not have been constant. If this were so it would obviously invalidate the findings of the authors.

We believe an alternative explanation is possible. Atrial pacing could have resulted in capture of the ventricles by the slow atrioventricular nodal pathway with a Wenckebach sequence (see ladder diagram). Since during atrioventricular nodal reentry tachycardia the atrioventricular node is operating close to its functional refractory period, invasion of the tachycardia circuit could be expected to produce only slight advancement of each QRS complex. It should be noted that to obtain our measurements we had to assume a constant paper recording speed.

The second observation, that a premature atrial depolarization in the high right atrium advanced the septal atrial electrogram without affecting the tachycardia (Figure 3 of their report), also bears critical examination. According to our measurements, the fourth QRS complex in Figure 3 is 5 to 10 ms earlier than expected, indicating that the slow pathway of the tachycardia circuit may have been invaded by the premature atrial stimulus leading to premature His bundle and ventricular depolarization.

Essential to the correct interpretation of any electrophysiologic study is the accurate measurement of data. From the published information we cannot agree with the authors' conclusions that in this patient the atrium was not part of the reentry circuit. The perplexing question of whether the atrium is a necessary part of the reentry circuit in atrioventricular reentrant tachycardia remains, in our view, unanswered.

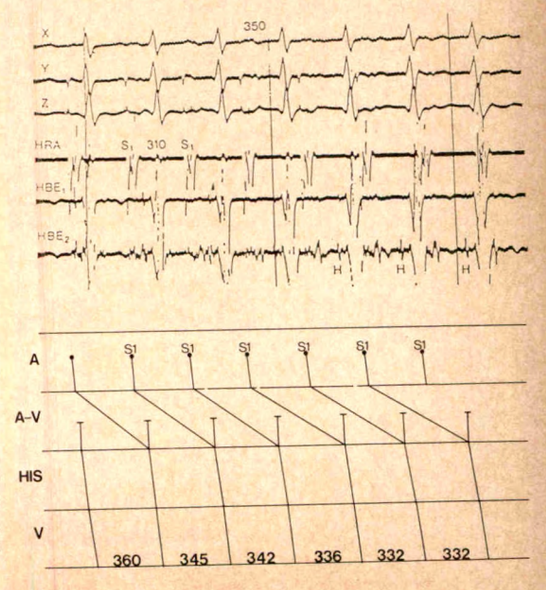

FIGURE 1. Ladder diagram illustrating our explanation for Figure 2 in the report of Scheinman et al.[1] A = atrium; A-V = A-V node; His = His bundle; V - ventricle. Measurements of the intervals between each QRS complex are in milliseconds.

REPLY: Your measurements are accurate, and on review of the study we found that during rapid atrial pacing, clear-cut shortening of the cycle length uniformly occurred just before tachycardia termination. I therefore agree that a Wenckebach sequence is likely. However, during initiation of atrial pacing, 1 or more atrial complexes were clearly dissociated from the tachycardia. Dissociation of the recorded atrial electrograms has been previously described in patients with atrioventricular nodal reentrant tachycardia. However, neither these studies nor our own observations during electrophysiologic studies conclusively exclude the possibility of a small atrial link in the tachycardia circuit. The careful histologic studies by Lev and Bharati are important in that a distinct atrionodal or atrial-His pathway was not found. These observations support the thesis that the atrium is not a necessary link in the tachycardia circuit.

VENTRICULAR FUNCTION BEFORE AND AFTER REPAIR OF TETRALOGY OF FALLOT

In their report on ventricular function in pre- and postoperative tetralogy of Fallot, Lange et al[1] separate their patient groups on the basis of a total right ventricular volume load. This volume is calculated on the basis of combined pulmonic regurgitant volume plus left-to-right ventricular septal defect (VSD) flow, and the separate contributions of each are not reported. They justify this on the basis that the end-diastolic volume (EDV) bears a similar relation to the quantity of additional flow through the right ventricle, whether that flow is derived from pulmonic regurgitation or VSD. However, these patients also are considered to have right ventricular dysfunction, which means that a normal ventricular function curve cannot be assumed, and hence EDV is not determined solely by the degree of volume loading.[2] Although some diastolic VSD flow can at times be noted, there is predominantly a systolic right ventricular volume load in contrast to the purely diastolic volume load of pulmonic regurgitation. The significance of an elevated EDV is therefore quite different in the 2 situations and would hardly justify pooling the data.

By combining these patients, the authors also render it difficult to interpret the right ventricular ejection fraction (EF) results. The systolic loading through a residual VSD will augment right ventricular ejection impedance. Because EF is inversely related to afterload, EF would be expected to decrease.[3] The volume load of pulmonic regurgitation results in enhanced preload without afterload augmentation, producing an increase in EF.[3] Clearly, a reduced EF in this situation has far different significance than a reduced EF with residual VSD. Separate reporting of these data would have facilitated these interpretations.

Finally, the authors interpret a reduced left ventricular EF in the preoperative patient with tetralogy of Fallot as indicative of impaired myocardial function. In the patient with unrepaired tetralogy of Fallot, the flow from right to left through the VSD results in reduced pulmonary blood flow. This results in a decrease in left ventricular preload, which would result in a reduced EF.[4] In contrast to the statement by Lange et al,[1] the VSD in the patient with unrepaired tetralogy of Fallot would *not* reduce ejection impedance. With the right-to-left systolic shunt, a net increase in ventricular afterload would be predicted, thereby reducing EF. In the presence of preload and afterload changes that could reduce EF, it is unwarranted to conclude that the observed reduction in EF is due to an abnormal contractile state. The primary issue to be settled here is whether there is any underlying abnormality of contractile function in tetralogy of Fallot and whether deterioration of myocardial function occurs with time. EF is a nonspecific index and cannot settle this issue. Other techniques are necessary to differentiate myocardial dysfunction from altered loading conditions.[5]

Steven Colan, MD
Boston, Massachusetts

5. **Borow KM, Neumann A, Wynne J.** Sensitivity of end-systolic pressure-dimension and pressure volume relations to the inotropic state in humans. Circulation 1982;65:988–997.

REPLY: Colan's comments should further stimulate the discussion on the applicability of experimentally derived concepts to clinical medicine. He doubts that in patients with tetralogy of Fallot postsurgical repair chronic volume overloading of the right ventricle during systole secondary to a residual ventricular septal defect (VSD) and during diastole secondary to pulmonic regurgitation may have similar effects on size and function of the right ventricle. We certainly evaluated carefully our data with respect to this question and thought we discussed this point sufficiently in our report. Colan is right, that end-diastolic volume (EDV) is not solely determined by the degree of volume load. Preload is important, especially when acutely altered as has been shown in animal studies of the left ventricle.[1] In our patients with chronic volume loading of the right ventricle after surgical repair of tetralogy of Fallot, we assumed a comparable stable basal state during the cardiac catheterization procedure under light sedation. In this state the observed depressed ejection fraction (EF) indicates a maximally utilized preload reserve according to the concept of Ross.[1] Thus, we assume that EDV is mainly determined by the degree of chronic volume loading, justifying pooling of the data.

Colan's statement that chronic systolic loading through a residual VSD augments ejection impedance of the right ventricle, thereby reducing EF, is unproven. In pure systolic loading in children with a classic singular VSD without pulmonary hypertension, EF is normal in the presence of an elevated EDV.[2,3] This indicates that dilatation of the right ventricle can be due to chronic systolic volume overloading. If ejection impedance is chronically increased, as in valvular pulmonic stenosis, one would expect in children a normal EDV and an EF at the upper limit of normal.[3]

Colan's statement that reduced pulmonary flow in unrepaired tetralogy of Fallot results in a decrease in left ventricle preload, which would result in a reduced EF, is speculative. As proof he cites the work of Parker and Case.[4] These authors developed a concept of normal left ventricle function in man we fully agree with.[5] They state that for the normal left ventricle, significant preload dependency exists only for end-diastolic filling pressures <10 mm Hg. In experimental dogs, acute decrease of preload resulted indeed in a reduction of ejection phase indexes.[1] In our patients with unrepaired tetralogy of Fallot, however, end-diastolic pressures were normal and it can be expected that the left ventricle has adapted its size to the chronically reduced preload secondary to the reduced pulmonary flow. In fact, pulmonary flow has always been diminished, even during the developmental phase.

We cannot agree with the statement of Colan that the right-to-left shunt would increase afterload of the left ventricle, thereby reducing EF. During the period of ejection into the aorta, pressure in the aorta and thus afterload is normal. During the preejection phase with respect to aortic ejection there is a left-to-right shunt through the VSD, which probably causes a reduction of impedance compared with a normal hemodynamic situation.[6] In contrast to Colan, we would not expect to find an increased impedance. In children with chronic pressure overload, as in valvular aortic stenosis, EF tends to be elevated,[7] which is contrary to the reduction of EF found after acute increase of afterload in experimental animals. Therefore, we maintain that the reduced left ventricular EF in unrepaired tetralogy of Fallot suggests impaired global myocardial function.

We agree with Colan that a pressure stress in patients after repair of tetralogy of Fallot would be helpful in assessing myocardial function of the left ventricle, especially if EF is normal. Adopting the concept of Ross,[1] our patients with a reduced EF during the cardiac catheterization procedure under light sedation would be in a "depressed basal state." The preload reserve is expected to be practically utilized. Any further afterload increase of even moderate degree would result in a further reduction of EF. Accordingly, myocardial function of the left ventricle after surgical repair of tetralogy of Fallot did remain depressed.

In general, it is difficult to apply concepts based mainly on acute loading experiments

of the left ventricle in open-chest animals or isolated heart preparations to the chronically overloaded right ventricle of children with surgically repaired congenital heart diseases.

DEGENERATION OF ANTIDROMIC TACHYCARDIA INTO ATRIAL FIBRILLATION IN THE WOLFF-PARKINSON-WHITE SYNDROME

Cosio et al[1] recently highlighted the possibility of transition of an antidromic reciprocating tachycardia to atrial fibrillation (AF) with a rapid ventricular response. We also observed similar features in a patient.

A 41-year-old woman had in the last 5 years frequent attacks of AF with a fast ventricular response and large QRS complexes. During attacks she was hypotensive and prostrated. With sinus rhythm, signs of intermittent Wolff-Parkinson-White syndrome type A were found, which were rate-dependent and present only at heart rates >100 beats/min. At the onset of electrophysiologic study, the A-H interval was 95 ms and the H-V interval 35 ms (Fig. 1A). During the study, orthodromic and antidromic tachycardias were easily provoked by programmed atrial pacing (Fig. 1, B and C). Orthodromic tachycardia exhibited a curious alternation from a normal conduction pattern to incomplete right bundle branch block with associated alternation of cycle length duration (Fig. 1B). Antidromic tachycardia spontaneously degenerated into AF with a minimal R-R interval of 185 ms (Fig. 1D). After application of Ethmozin, a short-lasting transition of AF to atrial flutter was seen (Fig. 1E). Atrioventricular conduction was 2:1. AF was not self-limiting, and after attempts of conversion with injections of ajmaline (50 mg) and aminodarone (300 mg) had failed, a direct-current shock of 150 J terminated the arrhythmia. Programmed atrial stimulation revealed an anterograde effective refractory period of the accessory pathway of 200 ms.

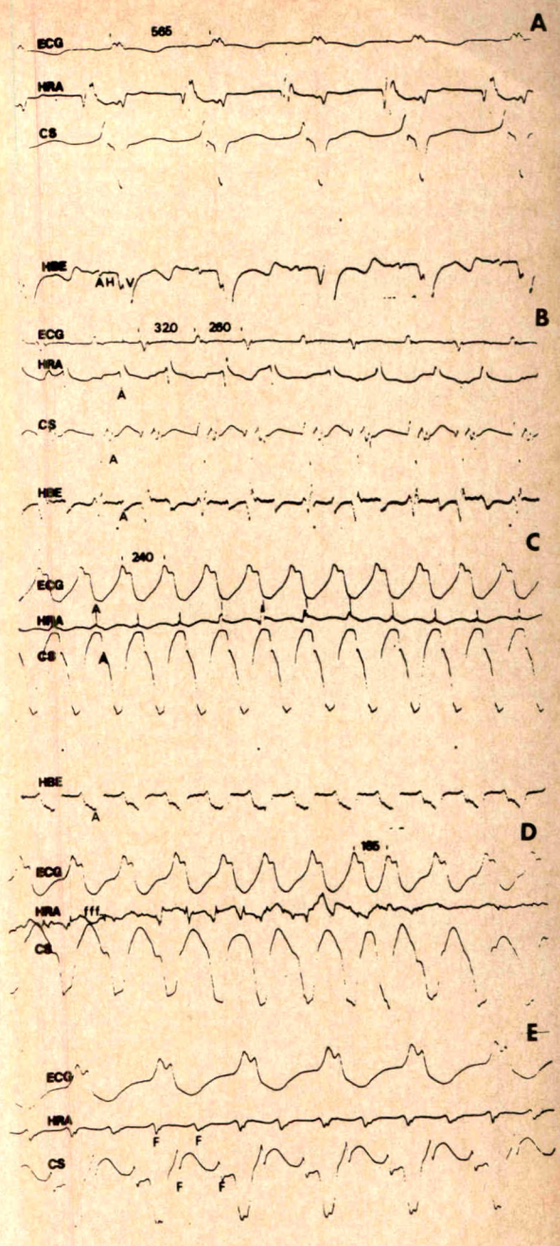

FIGURE 1. A, recordings during sinus rhythm. **B,** orthodromic tachycardia with alternating cycles of 320 and 260 ms. Note the asymmetric retrograde atrial activation sequence, suggesting a left-sided accessory pathway. **C,** antidromic tachycardia with a cycle length of 240 ms. **D,** atrial fibrillation with a fast ventricular response; the minimal R-R distance is 185 ms. **E,** atrial flutter with 2:1 atrioventricular conduction. CS = left atrial electrogram from the coronary sinus; ECG = electrocardiographic lead V_1; HBE = His bundle electrogram; HRA = high right atrial electrogram.

Chronic electrophysiologic study on subsequent days found that antidromic tachycardia was still inducible after medication with sotalol and orthodromic tachycardia after application of disopyramide and propafenone. The tachycardias could be controlled by aprindine, 100 mg daily. This drug increased the effective refractory period of the accessory pathway to 240 ms.

Although right bundle branch block in patients with Wolff-Parkinson-White syndrome has been described,[2] we cannot explain the alternation of normal conduction and incomplete right bundle branch block in our patient. The work of Cosio et al[1] and our experience suggest that a transition of antidromic tachycardia into AF is possible and probably not exceptional. AF in patients with short effective refractory periods of the accessory pathway (as found in our case), or with shortening of this period under influence of catecholamines (as described in the case of Cosio et al[1]), is life-threatening.

IMPORT OF EXERCISE-INDUCED VENTRICULAR ARRHYTHMIA IN MALIGNANT VENTRICULAR ARRHYTHMIA

Weaver et al[1] detail an experience with survivors of out-of-hospital cardiac arrest undergoing exercise testing. The landmark work by this group in defining this complex patient population remains unparalleled. There is a fundamental methodologic flaw, however, in these current data which limit conclusions regarding the import of exertionally induced ventricular arrhythmia (VA). The exercise testing protocol did not include *continuous recording* of all rhythm to allow true quantification of the density or complexity of ventricular premature beats (VPB). Rather, rhythm was "monitored continuously by the oscilloscope and recorded each minute." Several years ago we addressed the issue of continuous recording of rhythm versus intermittent sampling and found an 18% increase in coded VPB during continuous recordings but, more importantly, a 6-fold increase in the disclosure of complex and repetitive VPB (56 versus 9 episodes).[2] Second, the indication for termination of exercise by Weaver et al was increasing VA. Thus, the prognostic weight of those forms of VPB (repetitive or salvos) now considered to carry highest risk[3] cannot be assessed in the current report.

Our experience with a similar population is considerably different. The indications for terminating exercise in our laboratory is provocation of salvos of ventricular tachycardia (VT). Thus, 65% of our patients with a history of malignant VA exhibit VT salvos and 91%, ventricular couplets.[4] Patients with malignant VA who continue to exhibit VT salvos during exercise despite control of arrhythmia during extended electrocardiographic recordings remain at extreme risk for sudden death or recurrence. Abolition of these forms of VPB with antiarrhythmic drugs, however, results in enhanced long-term survival.[4]

3. **Bigger JT, Weld FM, Rolnitzky LM.** Prevalence, characteristics and significance of ventricular tachycardia detected with ambulatory electrocardiographic recording in the late hospital phase of acute myocardial infarction. Am J Cardiol 1981;48:815–823.
4. **Graboys TB, Lown B, Podrid PJ, DeSilva R.** Long-term survival of patients with malignant ventricular arrhythmia treated with antiarrhythmic drugs. Am J Cardiol 1982; 50:437–443.

REPLY: We agree that the qualitative and quantitative assessment of complex VA during exercise testing can be enhanced by continuous monitoring during the test. Although we did not report the results, continuous recording of the electrocardiogram on magnetic tape during and after exercise was accomplished in all but 3 of the 90 patients in our report. With continuous monitoring we detected only 5 additional (6%) patients (total 49%) with any complex VA. In 10% of patients, the physician missed repetitive forms present on the magnetic tapes. The forms of arrhythmias documented by either the physician or by the continuous recordings were not of prognostic value in subsequent determinations of survival. Therefore, in assessing outcome in this group of patients, only exercise-evoked angina or failure to augment systolic blood pressure were of prognostic importance. Exercise testing was most often patient-limited because of complaints of fatigue and not because of arrhythmias.

Graboy's patients and ours have both experienced recurrent serious arrhythmias. We believe that the patients followed by our group, that is, survivors of out-of-hospital ventricular fibrillation, may differ from patients referred for management of recurrent symptomatic VT. Few of our patients exhibit paroxysms of symptomatic VT during follow-up. We do not know if sustained VT preceded the episodes of cardiac arrest in patients treated by our emergency care system; however, we suspect that was not usual. Sustained VT has rarely been recorded at the time these patients are initially assessed by the paramedical personnel, and most patients had no apparent symptoms immediately before collapse. It is, of course, quite likely that ventricular fibrillation was preceded by a few beats of rapid VT. In survivors of out-of-hospital ventricular fibrillation, VT is relatively uncommon during exercise testing as well as 24-hour ambulatory electrocardiographic recording.[1] On the other hand, rates of 65 to 90% have been repeated in patients with malignant symptomatic arrhythmias.[2,3] The former group more commonly stops exercise with symptoms of left ventricular dysfunction, while the latter stops because of arrhythmias. Because of the infrequent occurrence of VT during ambulatory monitoring (10%) and exercise testing (8%), these tests appear to be of limited use and offer guidelines to treatment in only a few of our previously resuscitated patients.

Although both groups of patients share many common characteristics, differences in ambient arrhythmias, in the syndromes associated with arrhythmias, and perhaps also in the arrhythmias immediately preceding VF all suggest that one should be cautious in lumping the syndromes of symptomatic VT and out-of-hospital ventricular fibrillation—treatment strategies and efficacy may differ for the groups.

APICAL HYPERTROPHIC CARDIOMYOPATHY

We read with interest the article by Maron et al,[1] and wish to point out certain additional differences between their cases and the Japanese form of apical hypertrophic cardiomyopathy (HC).[2–4] The latter is found predominantly in males and the prognosis seems to be better than in the usual HC. In addition to the mentioned differences in the degree of T-wave negativity, the QRS axis lies between 0° and +90°.[2,3] Septal Q waves are often lacking, as found in 83% of Yamaguchi's patients and in the 2 cases reported outside Japan.[3,4] Neither QRS axis nor septal Q waves was commented on by the authors.[1] Spatial vectorcardiograms in our case and in those reported from Japan disclosed a QRS loop oriented to the left and inferiorly with characteristically elongated T-loops oriented to the right and posteriorly.[2,3] Are these additional electrocardiographic and vectorcardiographic findings available for comparison? The spade-like angiographic appearance is very different from that seen in Maron's cases, and we suggest that the term "apical hypertrophic cardiomyopathy" should be reserved for the Japanese form[2–4] which shows marked concentric apical hypertrophy rather than the apical distribution of septal hypertrophy with mid-ventricular constriction.[1]

4. **Steingo L, Dansky R, Pockock WA, Barlow JB.** Apical hypertrophic nonobstructive cardiomyopathy. Am Heart J 1982;104:635–637.

REPLY: Abinader raises an important consideration related to the morphology and nomenclature of HC. The application of 2-dimensional echocardiography to the study of patients with HC has demonstrated that a diverse spectrum of patterns of left ventricular (LV) hypertrophy may occur.[1,2] One pattern is characterized by disproportionate hypertrophy in the LV apical region (see References 1 to 4 in Abinader's letter). This morphologic form of HC appears quite common in Japan (see Reference 2 in Abinader's letter), where it is associated with a distinctive electrocardiographic pattern ("giant T-wave inversion") and a "spade-like" LV angiographic appearance. In our report, we described a subgroup of patients with HC who had a distribution of LV hypertrophy which was similar (but perhaps not identical) to that described by the Japanese investigators. Our patients also differed somewhat with regard to the LV angiographic appearance and electrocardiographic pattern.

From a morphologic point of view, however, the differences in distribution of LV hypertrophy exhibited by those patients with "apical hypertrophic cardiomyopathy" reported from several centers (including those in Japan) appear to constitute relatively minor anatomic variations. Differences in the LV angiographic appearance probably only reflect the variations in distribution of hypertrophy. In each patient with apical HC, the common morphologic denominator was hypertrophy confined to, or located primarily in, the LV apical region.

Because a great number of patterns of LV hypertrophy and morphologic subsets may be identified in HC (many of which have different clinical or electrocardiographic features[3]), I would not favor applying a different official name or label to each of these individual variations. Perhaps it would be preferable to refer to the subset of patients reported from Japan as "apical hypertrophic cardiomyopathy of the Japanese type" and other closely related variants simply as "apical hypertrophic cardiomyopathy" or, alternatively, "hypertrophic cardiomyopathy with distally located LV hypertrophy."

VENTRICULAR ACTIVATION TIME WITH LEFT VENTRICULAR HYPERTROPHY

Toyoshima et al[1] demonstrated a significant correlation between transmural conduction index and ventricular septal (VS) thickness, and that the transmural conduction index was significantly greater in the group with than in the group without left ventricular (LV) hypertrophy. There was no significant difference, however, between mean ventricular activation time in lead V_5 in these 2 groups. According to the authors' findings, LV activation time is not related to VS thickness.

In a recent study[2] performed by us, we obtained results which differ from those of Toyoshima et al on the latter point. We studied the correlation between electrocardiographic, vectorcardiographic, and echocardiographic parameters in 92 patients with and without LV hypertrophy. The ventricular activation time, which was taken in lead V_5 and orthogonal Franks' leads X, Y, and Z, was significantly ($p < 0.01$) greater in the presence of LV hypertrophy. There was a statistically significant correlation between ventricular activation time in lead V_5 and posterior wall thickness ($r = 0.41$, $p < 0.03$) in the group with concentric LV hypertrophy. In this group, posterior wall thickness (mean 12 ± 3 mm) also correlated well with the ventricular activation time in lead Z ($r = 0.84$, $p < 0.01$), while the correlation coefficient between VS thickness and ventricular activation time in lead Z was 0.53 ($p < 0.05$).

In the group with eccentric hypertrophy (aortic regurgitation), we found no correlation between ventricular activation time in lead V_5 and posterior wall or septal thickness, while there was a very good correlation between posterior wall thickness and ventricular activation time in lead Y ($r = 0.92$, $p < 0.004$).

Our observations on ventricular activation time in LV hypertrophy, especially when orthogonal leads are used, thus contradict the findings of Toyoshima et al[1] that ventricular activation time is not related to LV thickness, and are partly in agreement with data reported by Carter and Estes.[3]

In spite of technical limitations in measuring ventricular activation time in lead V_5 (which was recorded at a speed of 25 mm/s while the orthogonal leads were recorded at 100 or 250 mm/s), we believed that ventricular activation time increased in patients with LV hypertrophy and that there is a linear correlation between ventricular thickness and ventricular activation time.

2. **Ovsyshcher I, Gueron M, Wanderman K, Gussarsky Y.** The relationship between echocardiographic parameters and the magnitude of cardiac electrical potentials. IX World Congress of Cardiology, Moscow, 1982;1:713.
3. **Carter WA, Estes EH Jr.** Electrocardiographic manifestations of ventricular hypertrophy: a computer study of ECG-anatomic correlations in 319 cases. Am Heart J 1964;68:173–182.

REPLY: I appreciate the interest of Ovsyshcher et al in our article on LV hypertrophy and conduction velocity. Although they state that their observations on ventricular activation time in LV hypertrophy contradict ours, we disagree.

The beginning of the intrinsicoid deflection or so-called ventricular activation time is originally applied to the semidirect unipolar lead electrocardiogram, such as precordial lead one, and has been considered to closely approximate the time when the activation front arrives at the ventricular subepicardial site beneath the electrode in problem. Debates remain as to its exact timing and accuracy.[1,2] In the indirect bipolar lead electrocardiograms, such as the standard bipolar limb lead and orthogonal lead, however, there should be no time phase equivalent to ventricular activation time in precordial lead 1 in terms of arrival of activation front at the specific site. Thus, I have no comment on their observations as to "ventricular activation time in the orthogonal lead electrocardiograms" versus ventricular hypertrophy.

Ovsyshcher et al found low but significant correlation ($r = 0.41$, $p < 0.03$) between ventricular activation time in lead V_5 and posterior wall thickness in the group with concentric LV hypertrophy, while we found no statistically significant difference in the mean ventricular activation time in lead V_5 in the groups with and without LV hypertrophy. This apparent contradiction may be due to selection of materials, their technical inadequacy in recording and measuring electrocardiograms, or both. In our study[3] of 47 patients with systemic hypertension, aortic valvular disease, or dilated cardiomyopathy without any apparent conduction disturbance, we have found no significant difference in the mean ventricular activation time in lead V_5 in the groups with and without LV hypertrophy and no significant correlation between VS thickness and ventricular activation time in the total group of hearts, similar to the findings in our previous report. When patients who had congestive heart failure (usually from dilated cardiomyopathy) were excluded, a low but significant ($r = 0.42$, $p < 0.025$, $n = 40$) linear correlation between the 2 variables was observed, as in the letter by Ovsyshcher et al. However, the difference in mean ventricular activation time was still insignificant in the groups with and without LV hypertrophy (45.93 ± 6.52 ms versus 42.89 ± 6.76, $p > 0.10$). Thus, the selection of patients seems to be a key point that yielded different results.

As long as LV hypertrophy is defined by only ventricular wall thickness, we are of the opinion that there is no correlation with ventricular activation time, because any heart with any pathologic condition should be included in both control and hypertrophied groups for analysis.

POLYMORPHOUS VENTRICULAR TACHYCARDIA

In a recent report Soffer et al[1] discussed torsade de pointes arrhythmias. In their Table I they listed "conditions in which torsade de pointes in association with Q-T interval prolongation has been described." In this table the authors mentioned that mitral valve prolapse might be a cause of torsade de pointes. Recently, Bennet[2] described the first well-documented case of torsade de pointes

in a patient with mitral valve prolapse. We observed a similar case.

A 54-year-old woman was admitted when an electrocardiogram (ECG) disclosed multiple premature ventricular beats and several runs of ventricular tachycardia (Fig. 1). The Q-T interval was 0.52 to 0.56 second (upper limit 0.40 second), and bizarre, inverted T waves in all leads were found (Fig. 1). Three days of therapy, which included lidocaine, propranolol, and atropine, failed to prevent recurrences of the arrhythmia (>60 episodes of torsade de pointes). Ventricular arrhythmia disappeared after infusion of isoproterenol (2 mg/500 ml of 5% glucose). After 48 hours, the ECG returned to normal. Physical examination revealed an apical grade 2/6 late systolic murmur and an echocardiogram showed mitral valve prolapse.

Several drugs, poisons, and diseases should also be added to their Table I: ajmaline,[3] lidocaine,[4] haloperidol,[4] suxamethonium,[5] arsenic[6] and strychnine intoxication (our unpublished data), scorpion venom,[7] cardiomyopathy,[8] myotonic dystrophy,[9] osteogenic sarcoma,[10] carcinoma of the lung (our unpublished data), and hypothermia.[11]

ABNORMAL ELECTROCARDIOGRAMS IN HIGHLY TRAINED ATHLETES

The report by Oakley and Oakley[1] raises a question concerning the specific criteria for abnormal septal hypertrophy, particularly in the context of an athletic individual. Athlete 4, for example, had both electrocardiographic evidence of left ventricular hypertrophy with strain and an echocardiographic septal-free wall ratio of 1.9:1. It is unclear how the diagnosis of nonobstructive cardiomyopathy was excluded in this patient. The authors appear to emphasize a normal exercise response as an important differential point. Normalization of electrocardiographic abnormalities with increasing heart rates has been reported in hypertrophic cardiomyopathy.[2] Good exercise capacity is not inconsistent with the diagnosis of hypertrophic cardiomyopathy. The specificity and sensitivity of the commonly used features of asymmetric septal hypertrophy are still debated.[3] Three questions remain: (1) How was hypertrophic cardiomyopathy excluded in patient 4? (2) Can physiologic exercise induce extreme septal hypertrophy, and to what degree? (3) Does exercise-induced hypertrophy predispose to the complications seen in familial hypertrophic cardiomyopathy?

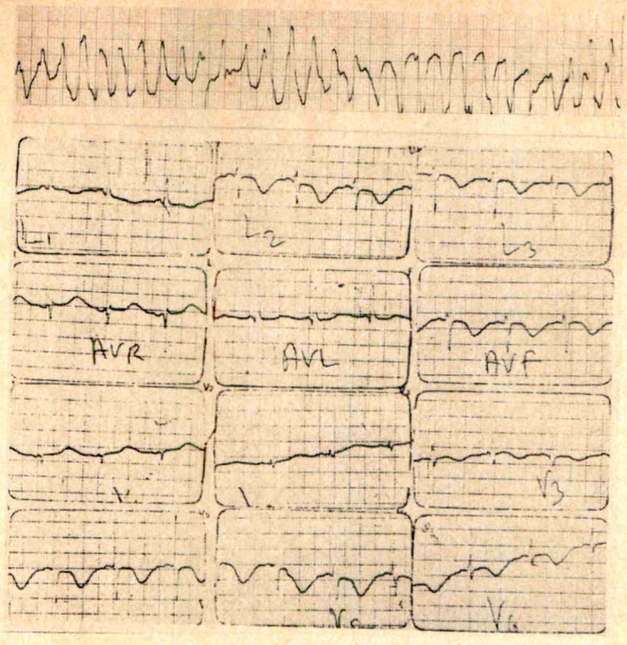

FIGURE 1. Top, a continuous strip recorded in monitoring lead, showing a sustained episode of ventricular tachycardia characteristic of torsade de pointes. **Bottom,** 12-lead electrocardiogram: sinus rhythm of 75 beats/min, broad, inverted T waves in leads I, II, III, aVR, aVF, V_3-V_6, and a markedly prolonged Q-T interval (0.52 to 0.56 second) can be seen.

REPLY: We are grateful to Goldman and Dunn for highlighting some important issues raised in our report. They correctly identified the 1 patient (patient 4) who gave rise to the most diagnostic difficulties.

With regard to the exercise test results, they quote Cosio et al. These investigators did not exercise patients with hypertrophic cardiomyopathy; they used atrial pacing and atrial extrastimulus testing during a supine electrophysiologic study—a completely different stress! We accept that normalization of the exercise electrocardiogram does not exclude disease, but we are unaware of any report showing such normalization of ST-T wave abnormalities in patients with hypertrophic cardiomyopathy during exercise. Our own studies have never shown this.

Coming to the 3 questions, number 1 should read "How could hypertrophic cardiomyopathy in patient 4 be *proven*?" It is surely up to the physician to prove that his patient is sick rather than the patient to prove that he is not. This is especially relevant when the patient's way of life depends upon supreme physical fitness. The answer to question 2 is unknown. Only a longitudinal study documenting the appearance of asymmetric hypertrophy as training progresses could establish whether it can be training-induced, and such a study would not distinguish between physiologic adaptation and exercise-induced disease in predisposed subjects. If such changes are adaptive, then a degree of resolution might be expected if training is stopped. We quoted a patient in whom this was so. Question 3 will only be answered by following up these patients who have been given the real benefit of any doubt that some still feel. So far all our patients are well, in training, and asymptomatic.

Cardiac Bioprostheses

Proceedings of the Second International Symposium
Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

NITROSTAT®
(nitroglycerin tablets, USP)

Before prescribing, please see full prescribing information. A Brief Summary follows:

INDICATIONS
Nitroglycerin is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain):
N 0071-0568-24—Bottle of 100 tablets;
N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain):
N 0071-0569-24—Bottle of 100 tablets;
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain):
N 0071-0570-24—Bottle of 100 tablets;
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain):
N 0071-0571-24—Bottle of 100 tablets;
N 0071-0571-13—Convenience Package.

NATURE
HAS A WAY
OF PROTECTING
ITS OWN.

So does NITROSTAT®
(nitroglycerin tablets, USP)

Just by the way it's made, NITROSTAT, too, has built-in protection—protection against loss of nitroglycerin. In fact, NITROSTAT is more stable than conventional nitroglycerin tablets under all conditions of temperature and humidity tested.

But that's not all. Average assay still shows better than 100% of label claim for at least 60 months after manufacture of NITROSTAT. Because of this stability NITROSTAT has a five-year expiration date.*

What's more, only NITROSTAT Tablets are available in convenient packages of 4 x 25 tablets. So emergency angina relief can be ready when needed in four different locations. "Because of its rapid action, long-established efficacy and low cost, nitroglycerin is the most useful drug among the organic nitrates that can be given sublingually."[1] NITROSTAT...useful alone or as concomitant therapy with long-acting nitrates or propranolol.

*Five-year expiration date when stored at recommended storage conditions in an unopened bottle. Data on file, Medical Affairs Dept, Parke-Davis.

ANGINA
PROTECTION
AND MORE
INDERAL represents core therapy for angina... unlike calcium antagonists and other beta blockers, only INDERAL is indicated for angina prophylaxis, a wide range of supraventricular arrhythmias and hypertension.
INDERAL, used early, reduces myocardial oxygen demand and protects against ischemia. INDERAL slows heart rate, decreases contractility, and lowers elevated blood pressure. Use INDERAL early in the treatment of angina to prevent ischemia-induced pains and to protect the heart against coexisting arrhythmias...and their consequences.
INDERAL®
(PROPRANOLOL HCl)
COMPREHENSIVE
CARDIOVASCULAR PROTECTION
Please see next page for brief summary of prescribing information.

INDERAL®
(PROPRANOLOL HCl)

CORE THERAPY FOR ANGINA.

TM

The appearance of these tablets is a trademark of Ayerst Laboratories.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

Propranolol hydrochloride is contraindicated in 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. Propranolol acts selectively without abolishing the inotropic action of digitalis on the heart muscle (i.e., that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by propranolol's negative inotropic effect. The effects of propranolol and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during propranolol therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of propranolol therapy. Therefore, when discontinuance of propranolol is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when propranolol is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If propranolol therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute propranolol therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long-term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since propranolol is a competitive inhibitor of beta-receptor agonists, its effects can be reversed by administration of such agents, e.g., isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), propranolol should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of propranolol in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if propranolol is administered. The added catecholamine-blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of propranolol may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

INDERAL (propranolol hydrochloride)

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains **10 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains **20 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains **40 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

—Each hexagonal-shaped, pink, scored tablet is embossed with an "I" and imprinted with "INDERAL 60," contains **60 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0426-81) and 1,000 (NDC 0046-0426-91). Also in unit dose package of 100 (NDC 0046-0426-99).

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains **80 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

In Cardiac Edema*...

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Dyazide® is a trademark of SK&F Co.

When You Need to Conserve K^+

SK&F CO.
a SmithKline company
Carolina, P.R. 00630

Serum K^+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, Dyazide should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on Dyazide when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with Dyazide. The following may occur: transient elevated BUN or creatinine or both; hyperglycemia and glycosuria (diabetic insulin requirements may be altered); hyperuricemia and gout; digitalis intoxication (in hypokalemia); decreasing alkali reserve with possible metabolic acidosis. Dyazide interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with Dyazide, but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and Dyazide should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Dyazide should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth, anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions, nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances, postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on Dyazide, although a causal relationship has not been established.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

Once

Now...

Once-a-day antihypertensive efficacy confirmed worldwide

Studies done in the U.S.A., England, Scandinavia and other parts of Europe and Asia have shown that once-a-day dosage of metoprolol significantly reduced both systolic and diastolic pressure.[1-11]

-a-day

cardioselective*

Lopressor®

metoprolol tartrate

New dosage schedule: To start, 100 mg once-a-day, or in divided doses.

Lower doses (especially 100 mg) may not maintain full effect at end of 24-hour period. Measure BP near end of dosing interval, adjust to larger or more frequent dosage if needed.

*exerts a relative preference for beta-one receptors; this preference is not absolute.

Contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure.

Please turn page for brief Prescribing Information.

Geigy

536-5761-A

Now more convenient than ever in once-a-day dosage

Lopressor®
metoprolol tartrate

An antihypertensive beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Prescribing Information

Brief Summary of Prescribing Information.

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

Changes in The AJC Since June 1982

This piece will describe certain visible and nonvisible changes in the AJC during the first 12 months (since June 1982) of the present editorship.

1. Alteration of the *Instructions-to-Authors* page came first. This page is an extremely important one and I encourage all authors submitting manuscripts to the AJC to read these Instructions carefully before the final typing of their manuscripts. I include a reprint of the Instructions page when returning a manuscript to an author requesting revision of his or her manuscript. In addition to the required stylistic changes delineated in the Instructions, authors are encouraged, as stated in this page, to suggest 1 or more nonlocal potentially objective reviewers and also potentially biased reviewers for their manuscripts. These suggestions have been quite useful to me, and, I hope, to the authors. I generally send a manuscript to 1 reviewer suggested by the authors and to 1 reviewer of my choosing. I never send a manuscript to a potentially biased reviewer if so requested by an author. The Instructions page also describes the method of having a manuscript reviewed blindly. This method of review is available to the submitting authors on request and this request is always honored by the editor.

2. The next change made was on the *Editorial Board* page. The board members were separated according to subspeciality.

3. The format of the *Title Page* was changed in October 1982 to make the content of this page more compact and the layout more attractive. Initially, both the title and authors' names were "flush left" but now each is centered.

4. The style and type size of the *References* was changed in October 1982. Although all authors as well as inclusive pages are now listed, the space occupied by each reference is considerably less than previously.

5. The *Table of Contents* page was changed in January 1982. The articles are now grouped by the various disease categories—Coronary, Valvular, Myocardial, Congenital, Arrhythmias and Conduction Disturbances, Systemic Hypertension, Congestive Heart Failure, etc. Exceptions to these categories include Methods, Cardiac Pharmacology, Experimental Studies, Brief Reports, Editorials, Point of View, Historical Studies, Letters, and The AJC 25 Years Ago.

6. The bottom half of the *Cover* was changed in January 1983 to include the general categories of the table of contents.

7. The Letters to the Editor were retitled simply *Letters* and in March 1983 they were laid out in 3-column rather than 2-column format to add variation. The layout of this section was made more compact, and a request was inserted on the initial "letter page" of each issue indicating that a letter concerning an article published in the AJC must be received from USA readers within 2 months of the article's publication.

8. A *Brief Report* section was added in September 1982. These are primarily single case reports and they now average about 1.4 printed pages apiece, including figures.

9. The *Point-of-View* section was added in March 1983. This section is intended to provide a medium for brief presentation of a concept or idea. The idea may or may not be provable and references are not required. The section may be considered in the category of a "capsule editorial." The editorial, in contrast, is a well-developed thesis.

10. *Quotations*, inserted on empty spaces of pages at the end of individual articles, began appearing in February 1983. These will focus primarily, but not entirely, on scientific matters. I would be pleased to receive quotations from any reader and if the quotation appears, appropriate credit will be given to the submitter.

Continued on page A10

11. The *From-the-Editor* page began in July 1982, initially to emphasize some items described in the Instructions to Authors page, and has continued with discussions of the manuscript review process, relations between authors, editors, reviewers, publishers, and advertisers, and viewpoints on various portions of a manuscript. It is my intent to continue these columns for awhile.

12. A new section entitled "The AJC 25 Years Ago" was added in May 1983 and will be a monthly feature hereafter.

As the foregoing changes were being implemented, a number of other changes also were taking place. A strenuous attempt has been made to make each manuscript more compact so that there is more content per page for the reader without an increase in the *Journal*'s size or price. During this first year, the average content per page has increased by slightly over 20%. The means by which this increased content per page was made possible are the following: (1) The title page is more compact. (2) The references are smaller than previously, and in recent months, fewer in number. (3) More figures and tables occupy only a half column rather than portions of 2 columns. (4) Less space is now (last 2 months only) retained between figures and/or tables and the text. (5) An additional line in each column was acquired by deleting the Journal's title at the bottom of each page. (6) The use of abbreviations, numbers (<10 as well as >10) and symbols has saved many lines per page. I prefer no more than 3 abbreviations per manuscript and that they be limited to commonly recognized cardiologic terms, preferably those appearing in the article's title. The symbols for percent (%), less than (<) and greater than (>) save space and decrease reading time. It takes 36 spaces to spell out the first 9 numbers (1 to 9), but only 9 spaces are utilized when numbers are used, a 4-fold savings of space.

Moreover, the publisher is providing more pages per issue than a year ago. Comparison of 4 items in the last 2 months of the previous editorship (May to June 1982) with the 2 latest months (before this piece went to press) under the present editorship is illustrated in the table. The number of articles published between these 2 periods increased 52% while the number of pages published increased only 8%. The average number of pages per article decreased 29%. Although the number of lines per page (2 columns per page) increased by nearly 2%, the utilization of a single additional line per page potentially provides 4 additional full pages per issue and 48 additional pages per year.

COMPARISON OF MAY-JUNE 1982 AJC TO FEBRUARY-MARCH 1, 1983 AJC

	Combined 5/82 + 6/82	Combined 2/83 + 3/83	Percent Change
Number of papers	64	97	+52
Average number of pages per paper	7.5	5.3	−29
Number of pages	480	519	+ 8
Number of lines per column	61	62	+ 2

In addition to the visible changes made in the *Journal* in the past 12 months, several visible changes have been made in the processing of manuscripts: (1) The *reviewer forms* have been changed so that 1 entire page is for "confidential comments to the editor" and another for "comments to the authors." The editor has requested all reviewers to answer the following question on the "confidential" page: "Would you grant the editor permission to make the authors aware of who reviewed their manuscript?" (2) All manuscripts now are sent to reviewers in thick blue-and-white *container folders* which help in the organization of the text, figures, tables, and review forms. (3) New blue-and-white *mailing envelopes* have been provided. (4) *Personal letters* from the editor now accompany all manuscripts returned to authors and to nonboard reviewers when requesting a review.

The intent of most of these changes in the *Journal* is to increase content per page and this translates into increased content per issue. Suggestions for further improvements to the *Journal* are always welcomed by the editor.

William C. Roberts, MD
Editor-in-Chief

*"Simplifying drug regimens is one method of improving patient compliance."**

SEARLE Aldactazide®

(spironolactone 50 mg/hydrochlorothiazide 50 mg)

50/50 q.d.

Uncomplicated, once-a-day dosage
Increased convenience for increased compliance.

Fewer tablets to swallow
A compliance advantage for patients presently on Aldactazide 25/25 therapy—especially when they are taking several medications.

Film-coated tablets
Easy to swallow with no unpleasant taste.

Helps regulate potassium
Ordinarily no need for potassium supplements—another compliance-encouraging benefit.

Now available—a single-tablet once-a-day dosage to encourage patient compliance

Established efficacy
Aldactazide is a recognized antihypertensive agent for effective, long-term control of hypertension when other measures are considered inadequate or inappropriate.

Limitations to consider
Spironolactone has been shown to be a tumorigen in chronic toxicity studies in rats. Thus, Aldactazide should be prescribed only when other measures are considered inadequate or inappropriate. (See boxed warning and *Warnings* section of Aldactazide prescribing information.)

Please see next page for a brief summary of prescribing information.

*Fischer, R.G., Compliance-Oriented Prescribing: Simplifying Drug Regimens, J. Fam. Pract. *10*:427-435 (March) 1980.

Aldactazide®

(spironolactone 50 mg/hydrochlorothiazide 50 mg)

WARNING:
Spironolactone, an ingredient of Aldactazide, has been shown to be a tumorigen in chronic toxicity studies in rats (see *Warnings*). Aldactazide should be used only in those conditions described in the *Indications* section of the complete prescribing information. Unnecessary use of this drug should be avoided. Fixed-dose combination drugs are not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Anuria, acute renal insufficiency, significant impairment of renal function, hyperkalemia or acute or severe hepatic failure. Allergy to thiazide diuretics or to other sulfonamide-derived drugs.

Warnings: Excessive potassium intake may cause hyperkalemia. Potassium supplements should not be given with Aldactazide. Do not administer concurrently with other potassium-sparing diuretics. Sulfonamide derivatives including thiazides have been reported to exacerbate or activate systemic lupus erythematosus. Spironolactone has been shown to be a tumorigen in chronic toxicity studies in rats. In one study using 25, 75 and 250 times the usual daily human dose (2 mg/kg) there was a statistically significant dose-related increase in benign adenomas of the thyroid and testes. In female rats there was a statistically significant increase in malignant mammary tumors at the mid-dose only. In male rats there was a dose-related increase in proliferative changes in the liver. At the highest dosage level (500 mg/kg) the range of effects included hepatocytomegaly, hyperplastic nodules and hepatocellular carcinoma; the last was not statistically significant.

Precautions: Patients should be carefully evaluated for possible disturbances of fluid and electrolyte balance. Hyperkalemia may occur in patients with impaired renal function or excessive potassium intake and can cause cardiac irregularities which may be fatal. Hypokalemia may develop as a result of profound diuresis, particularly when Aldactazide is used concomitantly with loop diuretics, glucocorticoids or ACTH. Transient elevation of BUN may occur. Reversible hyperchloremic metabolic acidosis may occur in some patients with decompensated hepatic cirrhosis. Dilutional hyponatremia or rarely low-salt syndrome may develop. Gynecomastia may develop and in rare instances some breast enlargement may persist. Thiazides may alter the metabolism of uric acid and carbohydrates with possible hyperuricemia, gout and decreased glucose tolerance. Vascular responsiveness to norepinephrine is reduced. Thiazides may also increase the responsiveness to tubocurarine. The antihypertensive effects of hydrochlorothiazide may be enhanced in sympathectomized patients. Thiazides may decrease serum PBI levels and prolonged therapy may induce hypercalcemia and hypophosphatemia. Spironolactone may and hydrochlorothiazide does cross the placental barrier. Use in pregnant women requires that the anticipated benefit be weighed against possible hazards to the fetus. Breast feeding should be discontinued when Aldactazide is being used.

Adverse Reactions: *Associated with spironolactone*: Gynecomastia is observed not infrequently. Gastrointestinal symptoms including cramping and diarrhea, drowsiness, lethargy, headache, maculopapular or erythematous cutaneous eruptions, urticaria, mental confusion, drug fever, ataxia, inability to achieve or maintain erection, irregular menses or amenorrhea, postmenopausal bleeding, hirsutism and deepening of the voice. Carcinoma of the breast has been reported but a cause-and-effect relationship has not been established. *Associated with thiazides*: Gastrointestinal symptoms (anorexia, nausea, vomiting, diarrhea, abdominal cramps), purpura, thrombocytopenia, leukopenia, agranulocytosis, dermatologic symptoms (cutaneous eruptions, pruritus, erythema multiforme), paresthesia, acute pancreatitis, jaundice, dizziness, vertigo, headache, xanthopsia, photosensitivity, necrotizing angiitis, aplastic anemia, orthostatic hypotension, muscle spasm, weakness and restlessness. Adverse reactions are usually reversible upon discontinuation of Aldactazide.

CONTENTS IN BRIEF

JUNE 1983 • VOLUME 51 • NUMBER 10

A note from the Editor-in-Chief, William C. Roberts, MD, appears on pages A9 and A10 of this issue.

CORONARY HEART DISEASE

1573 **Intracoronary Thrombolysis in Acute Myocardial Infarction: An Attempt to Quantitate Its Effect by Comparison of Enzymatic Estimate of Myocardial Necrosis With Left Ventricular Ejection Fraction.** Franz Schwarz, Andreas Faure, Hugo Katus, Klaus Von Olshausen, Manfred Hofmann, Gerhard Schuler, Joachim Manthey, and Wolfgang Kübler

1579 **Dynamic Evaluation of Prognosis from Time-Dependent Variables in Acute Myocardial Infarction.** Erling Birk Madsen, Philip Hougaard, and Elizabeth Gilpin

1584 **Prevalence and Prognosis After a First Nontransmural Myocardial Infarction.** Santiago Coll, Angel Castañer, Gines Sanz, Eulalia Roig, Jorge Magriña, Francisco Navarro-Lopez, and Amadeo Betriu

1589 **Symptomatic, Electrocardiographic, Metabolic, and Hemodynamic Alterations During Pacing-Induced Myocardial Ischemia.** Roy V. Markham, Jr., Michael D. Winniford, Brian G. Firth, Pascal Nicod, Gregory J. Dehmer, Samuel E. Lewis, and L. David Hillis

1595 **Effect of Oral Sustained-Release Nitroglycerin on Exercise Capacity in Angina Pectoris: Dose-Response Relation and Duration of Action During Double-Blind Crossover Randomized Acute Therapy.** Serge G. Degré, Gisèle M. Strappart, John C. Sobolski, Guy M. Berkenboom, Eric E. Stoupel, and Pol P. Vandermoten

1599 **Prolonged Angina Pectoris and Persistent Negative T Waves in the Precordial Leads: Response to Atrial Pacing and to Methoxamine-Induced Hypertension.** Jaime Figueras, Juan Cinca, Luis Gutierrez, Rosa Segura, and Jorge Rius

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

1608 **Clinical Evaluation of the Internal Automatic Cardioverter-Defibrillator in Survivors of Sudden Cardiac Death.** Philip R. Reid, M. Mirowski, Morton M. Mower, Edward V. Platia, Lawrence S. C. Griffith, Levi Watkins, Jr., Stanley M. Bach, Jr., Mir Imran, and Andra Thomas

1614 **Efficacy of Verapamil in Chronic, Recurrent Ventricular Tachycardia.** Jay W. Mason, Charles D. Swerdlow, and Brent Mitchell

1618 **Electrophysiologic Effects of Lorcainide on the Accessory Pathway in the Wolff-Parkinson-White Syndrome.** Wolfgang Kasper, Norbert Treese, Thomas Meinertz, Eberhard Jähnchen, and Tiberius Pop

1623 **Electrophysiologic Testing in the Management of Patients With the Wolff-Parkinson-White Syndrome and Atrial Fibrillation.** Fred Morady, Carlos Sledge, Edward Shen, Ruey J. Sung, Rolando Gonzales, and Melvin M. Scheinman

1629 **Long-Term Recording of Monophasic Action Potentials From Human Endocardium.** Michael R. Franz

CONGESTIVE HEART FAILURE

1635 **Association of Hyponatremia With Increased Renin Activity in Chronic Congestive Heart Failure: Impact of Diuretic Therapy.** Gary L. Schaer, Andrew B. Covit, John H. Laragh, and Robert J. Cody

1639 **Respiratory Gas Analysis During Exercise as a Noninvasive Measure of Lactate Concentration in Chronic Congestive Heart Failure.** John R. Wilson, Nancy Ferraro, and Karl T. Weber

VALVULAR HEART DISEASE

1644 **Conduction Disturbances Related to the Site and Severity of Mitral Anular Calcification: A 2-Dimensional Echocardiographic and Electrocardiographic Correlative Study.** Toshihiko Takamoto and Richard L. Popp

1650 **Analysis of Surgical Versus Medical Therapy in Active Complicated Native Valve Infective Endocarditis.** Charles H. Croft, Wayne Woodward, Alan Elliott, Patrick J. Commerford, Christiaan N. Barnard, and Walter Beck

1656 **BOOKS RECEIVED**

MISCELLANEOUS TOPICS

1657 **Coronary Dilatory Capacity in Idiopathic Dilated Cardiomyopathy: Analysis of 16 Patients.** Dieter Opherk, Franz Schwarz, Gerhard Mall, Joachim Manthey, Detlev Baller, and Wolfgang Kübler

1663 **Prevalence and Significance of an Abnormal S-T Segment Response to Exercise in a Young Athletic Population.** Paolo Spirito, Barry J. Maron, Robert O. Bonow, and Stephen E. Epstein

1667 **Heterogeneity of Left Ventricular Segmental Wall Thickening and Excursion in 2-Dimensional Echocardiograms of Normal Human Subjects.** Natesa G. Pandian, David J. Skorton, Steve M. Collins, Herman L. Falsetti, Edmund R. Burke, and Richard E. Kerber

1674 **Cardiac Function in Sickle Cell Anemia.** Barry S. Denenberg, Gerard Criner, Richard Jones, and James F. Spann

1679 **Cardiac Disease After Radiation Therapy for Hodgkin's Disease: Analysis of 48 Patients.** Mark M. Applefeld and Peter H. Wiernik

1682 **Contrasting Acute Effects of Vasodilators (Nitroglycerin, Nitroprusside, and Hydralazine) on Right Ventricular Performance in Patients With Chronic Obstructive Pulmonary Disease and Pulmonary Hypertension: A Combined Radionuclide-Hemodynamic Study.** Bruce N. Brent, Harvey J. Berger, Richard A. Matthay, Donald Mahler, Linda Pytlik, and Barry L. Zaret

CONGENITAL HEART DISEASE

1690 **Reoperation for Isthmic Coarctation of the Aorta: Follow-Up of 26 Patients.** Phyllis Pollack, Michael D. Freed, Aldo R. Castaneda, and William I. Norwood

1695 **Subxyphoid 2-Dimensional Echocardiographic Identification of Left Ventricular Papillary Muscle Anomalies in Complete Common Atrioventricular Canal.** Alvin J. Chin, Fredrick, Bierman, Stephen P. Sanders, Roberta G. Williams, William I. Norwood, and Aldo R. Castaneda

1701 **Anatomic Obstruction of the Right Ventricular Outflow Tract in Transposition of the Great Arteries.** Rudolf J. Moene, Arentje Oppenheimer-Dekker, and Margot M. Bartelings

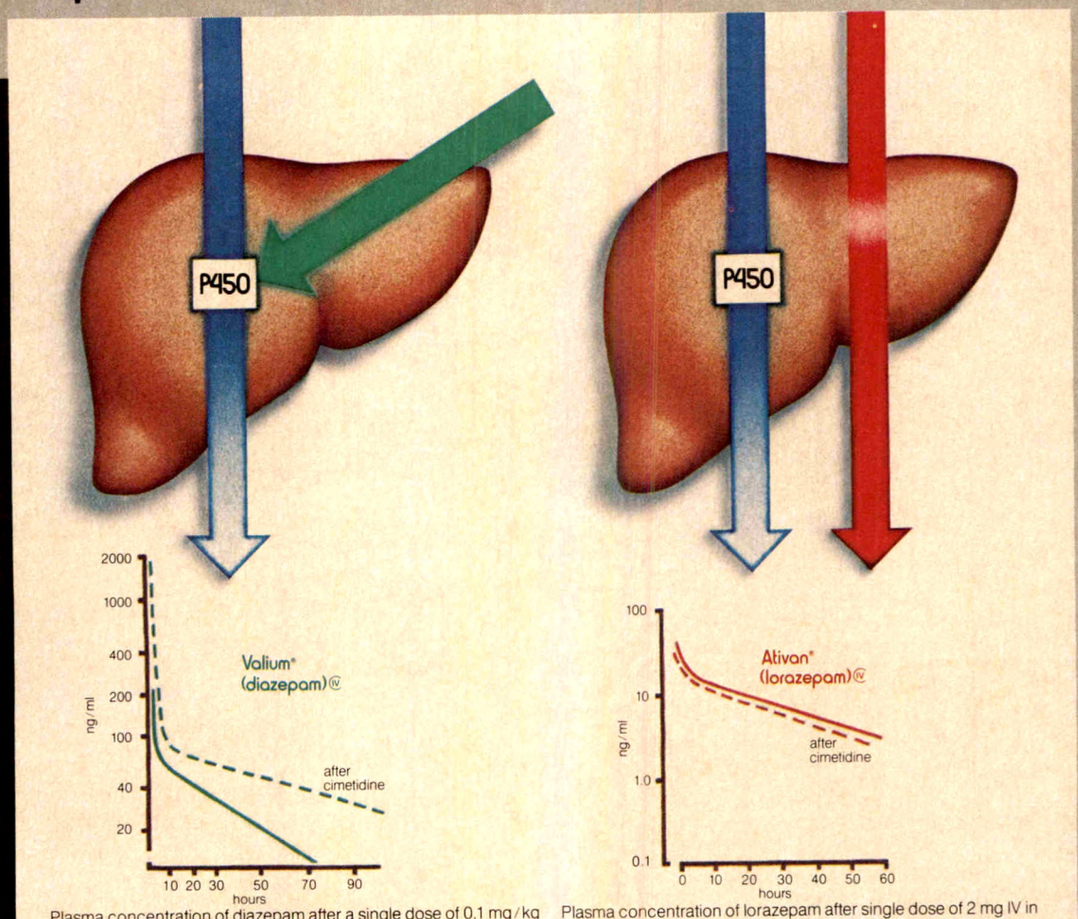
Ativan®: Agent of Change
(lorazepam)



Plasma concentration of diazepam after a single dose of 0.1 mg/kg IV to a single subject administered before (—) and after (---) pretreatment with cimetidine—5 X 200 mg orally q6h. (Adapted from Klotz U, Reimann I: N Engl J Med *302*:1012-1014, 1980.)

Plasma concentration of lorazepam after single dose of 2 mg IV in 8 normal subjects before (—) and after (---) 7 days of treatment with cimetidine, 300 mg orally qid. (Adapted from Patwardhan RV, Yarborough GW, Desmond PV, et al: Gastroenterology *79*:912-916, 1980.)

because it doesn't utilize the P450 system

All drugs inactivated by oxidative metabolism, including cimetidine and most benzodiazepines, utilize the cytochrome P450 oxidase enzyme system and, therefore, compete for it when given concomitantly. Patients on cimetidine, for example, are apt to experience excessive drowsiness when taking a benzodiazepine dependent on this system—because benzodiazepine clearance is delayed and plasma levels increase.

Ativan® (lorazepam) is inactivated by simple, one-step glucuronidation and is not subject to N-dealkylation or hydroxylation by the P450 system—unlike diazepam, chlordiazepoxide, clorazepate and prazepam, all CIV.

And, since Ativan does not compete for the P450 system, its elimination is not appreciably affected by concomitant use of cimetidine... one more reason why Ativan is becoming the anxiolytic of choice for an increasing number of physicians.

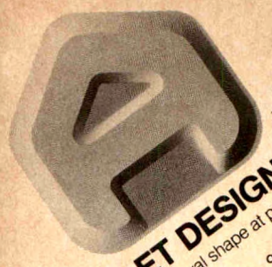
for (lorazepam)ⓥ
Anxiety



The appearance of these tablets is a trademark of Wyeth Laboratories.

NEW TABLET DESIGN 0.5 mg and 1 mg

(2 mg tablet retains original oval shape at present)

Brief Summary of Prescribing Information.

Indications and Usage: Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® (IV) **for** (lorazepam) **Anxiety**

DOSAGE: Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.

HOW SUPPLIED: 0.5, 1.0 and 2.0mg tablets.

CORONARY HEART DISEASE

1573 Intracoronary Thrombolysis in Acute Myocardial Infarction: An Attempt to Quantitate Its Effect by Comparison of Enzymatic Estimate of Myocardial Necrosis With Left Ventricular Ejection Fraction

FRANZ SCHWARZ, ANDREAS FAURE, HUGO KATUS, KLAUS VON OLSHAUSEN, MANFRED HOFMANN, GERHARD SCHULER, JOACHIM MANTHEY, and WOLFGANG KÜBLER

The quantity of myocardium that can be salvaged by reperfusion of acute transmural myocardial infarction (MI) was estimated. Serial analysis of serum creatine kinase activity was carried out in 41 consecutive patients with acute MI who underwent intracoronary thrombolysis. Left ventricular ejection fraction 4 weeks after successful thrombolysis correlated closely with enzymatic estimate of MI size. Patients with reperfusion within 4 hours after onset of symptoms were assembled in group A, patients with successful reperfusion after 4 hours in group A_2, and patients without reperfusion in group B. MI size was significantly reduced to one third in group A_1 but was not reduced in group A_2 when compared with group B. It is concluded that MI size may be significantly reduced by early reperfusion in acute MI.

1579 Dynamic Evaluation of Prognosis from Time-Dependent Variables in Acute Myocardial Infarction

ERLING BIRK MADSEN, PHILIP HOUGAARD, and ELIZABETH GILPIN

To evaluate the prognostic importance of time-dependent variables for endpoints other than death, a competing risk variant of the multivariate Cox model was utilized to predict the risk of 3 endpoints (death, cardiac arrest, or cardiogenic shock) up to 44 days after admission for acute myocardial infarction in 1,140 patients. The important variables were ventricular fibrillation, age, congestive heart failure, and asystole (death); congestive heart failure, ventricular premature beats, supraventricular tachycardia, extension of infarction, and age (cardiac arrest); cardiac arrest, age, congestive heart failure, previous infarction, and nodal rhythm (cardiogenic shock). With use of the regression coefficients and hazard functions for each endpoint, the model can be directly utilized to assess risk.

1584 Prevalence and Prognosis After a First Nontransmural Myocardial Infarction

SANTIAGO COLL, ANGEL CASTAÑER, GINES SANZ, EULALIA ROIG, JORGE MAGRIÑA, FRANCISCO NAVARRO-LOPEZ, and AMADEO BETRIU

Prevalence, prognosis, and coronary anatomy associated with nontransmural myocardial infarction were prospectively assessed in a series of 458 consecutive men. Cardiac catheterization was performed in 402 of the 436 survivors. The 28 patients presenting with nontransmural myocardial infarction were younger, showed lower peak creatine kinase values, higher ejection fraction, and lower prevalence of total or subtotal occlusion of the involved coronary artery than their counterparts. Long-term survival at 4 years and occurrence of nonfatal new coronary events was similar in both groups. Thus, a more aggressive management to improve survival does not appear warranted after nontransmural myocardial infarction.

1589 Symptomatic, Electocardiographic, Metabolic, and Hemodynamic Alterations During Pacing-Induced Myocardial Ischemia

ROY V. MARKHAM, Jr., MICHAEL D. WINNIFORD, BRIAN G. FIRTH, PASCAL NICOD, GREGORY J. DEHMER, SAMUEL E. LEWIS, and L. DAVID HILLIS

Although several variables have served as markers of pacing-induced myocardial ischemia, their specificities and sensitivities are unknown. In 28 patients, atrial pacing was performed. Of the 28, 10 had no coronary artery disease. In this group, the left ventricular ejection fraction increased with pacing. Left ventricular end-diastolic pressure did not increase substantially in any of the 10, and none had myocardial lactate production. Two (20%) had transient S-T segment depression, and 4 had their usual chest pain. In the other 18 patients with coronary artery disease, atrial pacing induced a decrease in the ejection fraction and new segmental wall motion abnormalities in all. However, only 8 (44%) had an increase in end-diastolic pressure; 9 (50%) had lactate production; 10 (56%) had S-T segment depression; and 12 (67%) had their usual chest pain. Thus, the electrocardiographic, metabolic, and hemodynamic alterations that may occur during pacing-induced ischemia are specific but relatively insensitive markers of ischemia. Chest pain during pacing is a nonspecific occurrence.

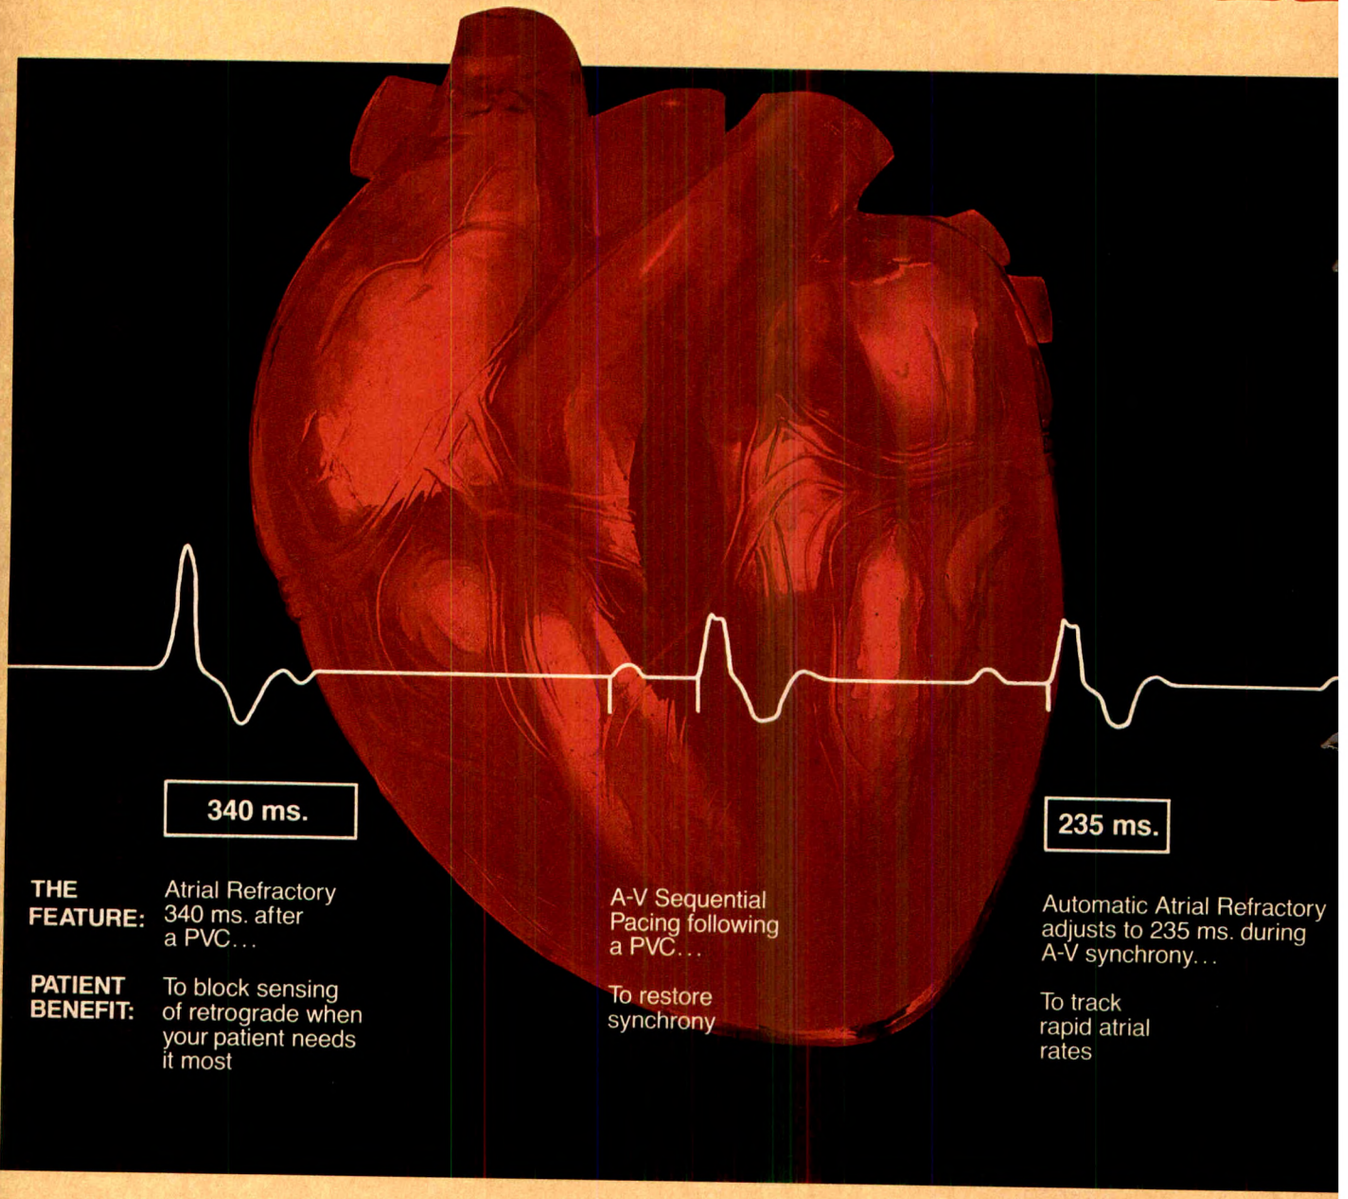
New VERSATRAX II



THE FEATURE: Atrial Refractory 340 ms. after a PVC...

PATIENT BENEFIT: To block sensing of retrograde when your patient needs it most

A-V Sequential Pacing following a PVC...

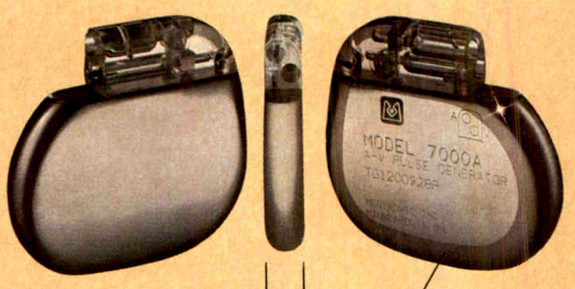
To restore synchrony

Automatic Atrial Refractory adjusts to 235 ms. during A-V synchrony...

To track rapid atrial rates

Keeps a heart beating like a heart.

The most physiologic pacemaker.



52 grams 10mm Anti-muscle-stimulation coating

New Versatrax II Model 7000A is:

- **Automatic Atrial Refractory**
  The advanced physiological method of tracking the atrium and discriminating retrograde
- **Smallest**
  The most physiological size and shape available
- **Superior Sensing Performance**
  Medtronic's exclusive patented circuitry rejects most myopotentials
- **Plus... uniquely from Medtronic**
  - A-V Pacing System Analyzer—Model 5311
  - Endocardial screw-in leads—Models 6957/6957J
  - Follow-up choices—Cardiocare™/Teletrace™
  - Educational programs
  - Service options
  - Proven reliability

Versatrax™ II Model 7000A Universal A-V Pacemaker

Intended Use

The Model 7000A universal A-V pulse generator has a wide range of application in patients requiring permanent cardiac pacing where restoration of A-V synchrony and/or sinus modulated rate variability is indicated to improve cardiac output or to protect against arrhythmias related to the sequence of cardiac impulse propagation.

With the Model 7000A programmed in the A-V universal (DDD) mode, indications may include:

- Some of the sick sinus syndrome conditions such as intermittent sinus bradycardia, sinus arrest or SA block.
- Intermittent or complete atrioventricular block with normal sinus activity.
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V interval settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

In the A-V sequential (DVI) mode, the Model 7000A may have application in the following:

- Sick Sinus Syndrome (sinus bradycardia, sinus arrest, SA block, and the brady-tachy syndrome).
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V delay settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

At any time, the Model 7000A can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry (e.g., atrial lead malfunction).

NOTE: The Medtronic® Model 7000A universal A-V pulse generator is under clinical investigation in the U.S. The procedures for using this pulse generator, as well as its safety and efficacy, will be evaluated during this investigational study according to the Clinical Investigation Protocol. Therefore, the "Intended Uses" section is based on Medtronic's experience with other physiologic pulse generators. No claims for safety and efficacy can be made for the Model 7000A pulse generator during its clinical investigation. Patients should be advised that the Model 7000A pulse generator is under clinical investigation.

Contraindications

General: There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician.

DDD Mode: The DDD mode is contraindicated in the presence of atrial fibrillation, atrial flutter and rapid atrial rhythms or slow retrograde conduction.

DVI Mode: In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation or flutter.

Warnings

Diathermy: Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site.

Electrosurgical Units: Electrosurgical units should never be used in the vicinity of unipolar pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead.

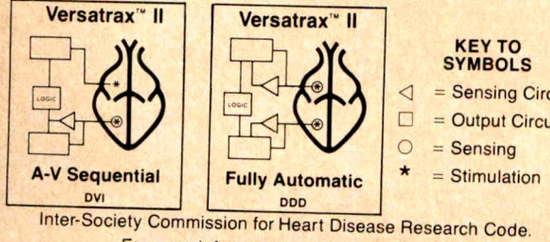
Defibrillation: Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. Positioning a magnet or the programming head over the pulse generator makes it subject to programming. A nominal vertical magnetic field strength of 90 Gauss (in a field measured 1½ inches from the magnet's surface) from a magnet at 1¼ inches from the reed switch is required to initiate asynchronous pacing. Do not use electrocautery, diathermy, or any other source of electromagnetic interference in the vicinity of the patient once a magnet or programming head has been positioned over the pulse generator. If an electrocautery unit is used, the physician may prefer to program the pacemaker to asynchronous pacing prior to the procedure.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.



Inter-Society Commission for Heart Disease Research Code.

1595 Effect of Oral Sustained-Release Nitroglycerin on Exercise Capacity in Angina Pectoris: Dose-Response Relation and Duration of Action During Double-Blind Crossover Randomized Acute Therapy

SERGE G. DEGRÉ, GISÈLE M. STRAPPART, JOHN C. SOBOLSKI, GUY M. BERKENBOOM, ERIC E. STOUPEL, and POL P. VANDERMOTEN

This double-blind crossover study compares the effect of 2 oral doses (2.5 and 6.5 mg) of sustained-release nitroglycerin (SRNG) on the symptom-limited exercise capacity of patients with stable exertional angina. While 2.5 mg of SRNG only increased the symptom-limited working capacity at 1 hour (+9%; $p < 0.01$), 6.5 mg SRNG was more effective at 1 hour (+25%; $p < 0.001$) and was still active at 5 hours (+27%; $p < 0.001$). Angina occurred at a higher heart rate (+5 to +8%; difference not significant and $p < 0.01$); S-T segment depression at the onset of angina was unchanged. It is concluded that 6.5 mg of orally administered SRNG is effective during at least 5 hours and that the magnitude of the benefit and its duration are dose-related.

1599 Prolonged Angina Pectoris and Persistent Negative T Waves in the Precordial Leads: Response to Atrial Pacing and to Methoxamine-Induced Hypertension

JAIME FIGUERAS, JUAN CINCA, LUIS GUTIERREZ, ROSA SEGURA, and JORGE RIUS

In 18 patients prolonged angina and persistent negative T waves in the precordial leads was associated with in-hospital spontaneous angina in 78% and myocardial infarction in 22%. Severe proximal stenosis of the left anterior descending coronary artery (LAD) was present in 14 of 16 patients with coronary arteriography. None had triple vessel disease and very few had collateral vessels. Arterial hypertension by methoxamine in 14 patients caused reversal of negative T waves without significant S-T segment shifts or lactate extraction abnormalities. Thus, prolonged angina with negative T waves in the precordial leads is almost always associated with severe LAD obstruction, 1 or 2 vessel disease, and poor collateral vessels. The nonischemic response to pacing in 55% of patients suggests that these negative T waves do not commonly represent active ischemia. Furthermore, their transient positivization may not be related to ischemia when associated with acute hypertension.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

1608 Clinical Evaluation of the Internal Automatic Cardioverter-Defibrillator in Survivors of Sudden Cardiac Death

PHILIP R. REID, M. MIROWSKI, MORTON M. MOWER, EDWARD V. PLATIA, LAWRENCE S. C. GRIFFITH, LEVI WATKINS, Jr., STANLEY M. BACH, Jr., MIR IMRAN, and ANDRA THOMAS

An internal automatic cardioverter-defibrillator (IACD) was clinically evaluated in 12 patients (average age 60.6 years) who had survived an average of 3 previous cardiac arrests. Severe heart failure (NYHA class III or IV) was present in 6 patients, and the average ejection fraction was 35%. Postoperatively 1 patient had spontaneous ventricular tachycardia which was automatically converted by the IACD. Ten patients had ventricular tachycardia and 1 had ventricular fibrillation induced in the electrophysiology laboratory; there was effective conversion in all by the IACD in an average of 17.9 ± 4.2 seconds. This study suggests that (1) ventricular tachycardia, not ventricular fibrillation, is the predominant rhythm induced during programmed ventricular stimulation in these high-risk patients, and (2) the IACD effectively functions over a wide rate range of ventricular tachycardia, as well as ventricular fibrillation. The IACD appears to offer an effective method of management in a group of patients for whom no satisfactory therapy was previously available.

1614 Efficacy of Verapamil in Chronic, Recurrent Ventricular Tachycardia

JAY W. MASON, CHARLES D. SWERDLOW, and L. BRENT MITCHELL

Verapamil was administered intravenously at electrophysiologic study in 24 patients who had spontaneously recurrent and inducible ventricular tachycardia. In 7 of these patients (29%) verapamil prevented reinduction of tachycardia (5 patients) or converted sustained ventricular tachycardia to tachycardia of <5 seconds' duration (2 patients). Responders were younger and had better left ventricular function than did nonresponders. Long-term therapy with verapamil was attempted in 5 patients and was effective in 3. When not contraindicated, verapamil should be given a trial in patients whose ventricular tachycardia is unresponsive to other drugs.

1618 Electrophysiologic Effects of Lorcainide on the Accessory Pathway in the Wolff-Parkinson-White Syndrome

WOLFGANG KASPER, NORBERT TREESE, THOMAS MEINERTZ, EBERHARD JÄHNCHEN, and TIBERIUS POP

The electrophysiologic effects of the new antiarrhythmic agent lorcainide were studied in 20 patients with the Wolff-Parkinson-White syndrome. After intravenous administration of lorcainide, atrioventricular (AH), intraventricular (HV), and intramyocardial (QRS) conduction increased. Conduction over the accessory pathway was

for many post-MI patients...

Cardio-protective.

Cardioprotective is a word you won't find in standard medical dictionaries.

But you will find it appearing in the medical literature. And you will be hearing it in medical discussions. Until dictionaries recognize the term, MSD invites you to use this as a working definition of *cardioprotective:*

"reduction of the risk of reinfarction and cardiac mortality for many stabilized post-MI patients."

We at MSD feel it is appropriate to bring you this definition of cardioprotective since it was MSD that brought you the impressive clinical data[1] that documented the cardioprotective benefits of BLOCADREN® (Timolol Maleate, MSD) for many stabilized patients who have survived the acute phase of a myocardial infarction.

[1]The Norwegian Multicenter Study Group: Timolol-induced reduction in mortality and reinfarction in patients surviving acute myocardial infarction, N. Engl. J. Med. 304(14):801-807, April 2, 1981.

BLOCADREN is contraindicated in patients with bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated.

In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy, exacerbation of angina and, in some cases, myocardial infarction have occurred after **abrupt** discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart

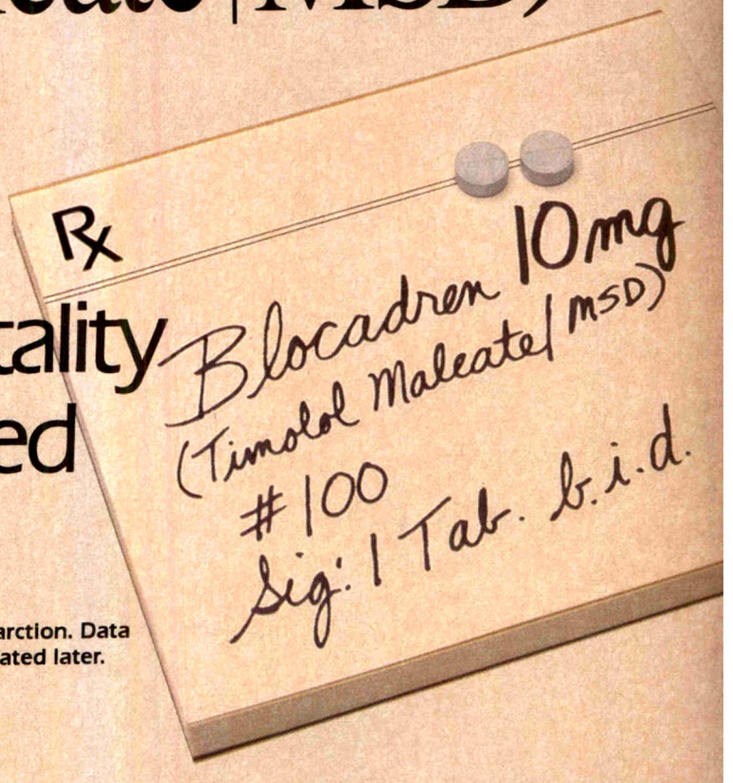
Blocadren®
(Timolol Maleate | MSD)

reduces the risk of reinfarction and cardiac mortality for many stabilized post-MI patients

Treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if initiated later.



disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

MSD
MERCK SHARP & DOHME

For a Brief Summary of Prescribing Information, please see next page of this advertisement.

BLOCADREN®
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: *Impaired Hepatic or Renal Function*: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n=176) %	Placebo (n=168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction†		Withdrawal‡	
	Timolol (n=945) %	Placebo (n=939) %	Timolol (n=945) %	Placebo (n=939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure—Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema—Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1
AV Block 2nd or 3rd degree	<1	<1	<1	<1
Sinoatrial Block	<1	<1	<1	<1
Cold Hands and Feet	8	<1	<1	0
Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

†When an adverse reaction recurred in a patient, it is listed only once.

‡Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

MSD
MERCK SHARP & DOHME

For more detailed information, consult your MSD Representative and the Prescribing Information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, PA 19486.

blocked in 5 of 18 patients in a retrograde direction, and in 6 of 17 patients in an anterograde direction. Circus movement tachycardia could be induced in 14 patients before and in 10 patients after the drug. The cycle length of the tachycardia increased from 326 ± 40 to 364 ± 67 ms. In 15 patients atrial fibrillation was induced. In 5 patients anterograde conduction was blocked, in the other patients the shortest R-R interval over the accessory pathway increased from 228 ± 35 to 304 ± 103 ms. Thus, lorcainide excerted a pronounced negative dromotropic effect on the conduction properties of the accessory pathway.

1623 Electrophysiologic Testing in the Management of Patients With the Wolff-Parkinson-White Syndrome and Atrial Fibrillation

FRED MORADY, CARLOS SLEDGE, EDWARD SHEN, RUEY J. SUNG, ROLANDO GONZALES, and MELVIN M. SCHEINMAN

Twenty patients with the Wolff-Parkinson-White syndrome and symptomatic atrial fibrillation underwent electrophysiologic testing. Six patients underwent surgical bypass tract ablation and 14 were treated medically, based on the results of electropharmacologic testing. Over a mean follow-up period of 35 months, only 1 patient treated medically had a recurrence of atrial fibrillation. Successful medical therapy was predicted by the inability to induce atrial fibrillation and atrioventricular reciprocating tachycardia during drug testing or with the induction of atrial fibrillation with a ratio <200 beats/min and a shortest preexcited R-R interval of >250 ms. Electrophysiologic testing can identify patients with Wolff-Parkinson-White syndrome and atrial fibrillation in whom medical therapy is a suitable alternative to bypass tract ablation.

1629 Long-Term Recording of Monophasic Action Potentials From Human Endocardium

MICHAEL R. FRANZ

In this study of 36 patients, a new "contact electrode" catheter technique was used to record monophasic action potentials from atrial and ventricular endocardium without the application of suction. Continuous recordings were of stable amplitude and, at a constant paced frequency, highly reproducible for test periods of 1 hour, permitting direct evaluation of the effect of cycle length alterations on local myocardial repolarization. Duration and configuration of the monophasic action potential were similar to those previously described in intracellular recordings from excised ventricular muscle and showed appropriate changes in response to abrupt and sustained cycle length alterations. Monophasic action potentials could not be recorded from areas of scar, indicating that local viable myocardium is a prerequisite for the generation of the monophasic signal. This technique may provide important information concerning cellular electrical events in man.

CONGESTIVE HEART FAILURE

1635 Association of Hyponatremia With Increased Renin Activity in Chronic Congestive Heart Failure: Impact of Diuretic Therapy

GARY L. SCHAER, ANDREW B. COVIT, JOHN H. LARAGH, and ROBERT J. CODY

The interrelation of serum sodium, prerenal azotemia, and plasma renin activity (PRA) was evaluated in 44 patients with chronic stable heart failure while diuretic therapy was maintained and in 12 similarly ill heart failure patients placed on sodium balance diets (10 and 100 mEq/day) after diuretic therapy was discontinued. The diuretic group showed inverse correlations between serum sodium and PRA ($r = -0.389$, $p < 0.02$) and blood urea nitrogen (BUN)/creatinine ratio ($r = -0.332$, $p < 0.025$). A positive correlation between BUN/creatinine ratio and PRA was noted ($r = 0.365$, $p < 0.025$), with all 3 parameters interrelated by multiple regression analysis ($p < 0.01$). The sodium balance nondiuretic group revealed no statistically significant sodium, BUN/creatinine ratio, or PRA relationship on either balance diet. These results suggest that the prediction of high PRA and angiotensin mediated vasoconstriction, based on the presence of hyponatremia, is highly variable and significantly influenced by diuretic therapy. Although some clinical value may be derived from such associations, the serum sodium-PRA correlation should not be used to draw major inferences regarding the severity of heart failure or the pathophysiology of water balance in patients with heart failure.

1639 Respiratory Gas Analysis During Exercise as a Noninvasive Measure of Lactate Concentration in Chronic Congestive Heart Failure

JOHN R. WILSON, NANCY FERRARO, and KARL T. WEBER

During exercise, bicarbonate buffering of lactate produces carbon dioxide (CO_2) in excess of that resulting from oxidative metabolism. To determine whether calculation of this excess CO_2 production from respiratory gas analysis provides a useful index of blood lactate in patients with heart failure, 22 patients with depressed left ventricular function were studied during progressive maximal upright bicycle exercise. Exercise increased $\dot{V}O_2$, O_2, lactate, and the cardiac index. The increase in lactate at each work load was linearly related to excess production of CO_2 ($r = 0.92$, $p < 0.01$). Exercise was repeated in 10 patients; measurement of excess CO_2 was highly reproducible ($r = 0.98$, $p < 0.01$). Excess CO_2 also correlated with the decrease in bicarbonate produced

Continued on page A26

by exercise (r = 0.81), supporting the hypothesis that excess CO_2 is produced by
tate. Thus, calculation of excess CO_2 provides a reliable and reproducible method

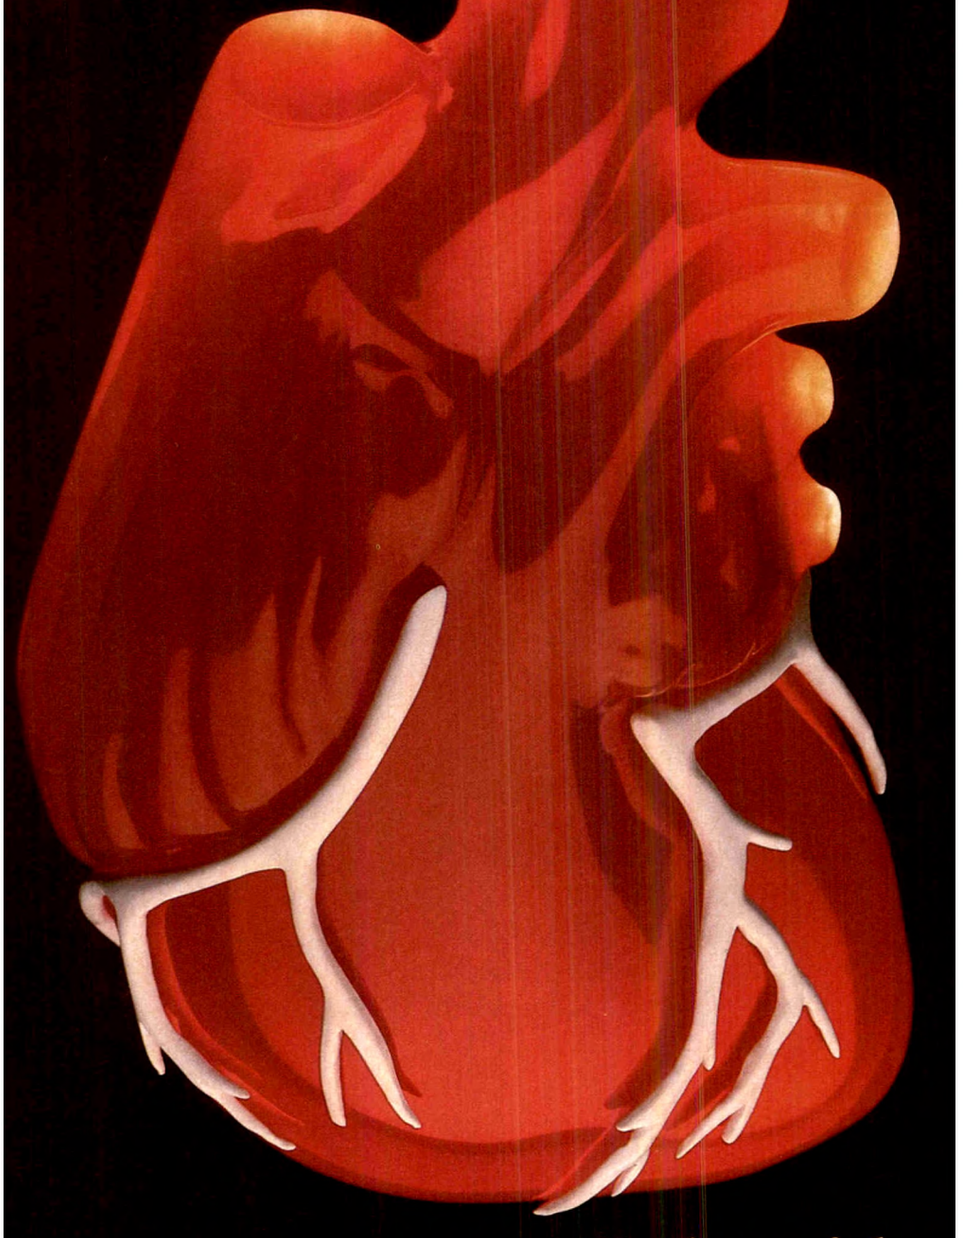
in cardiovascular therapy

New CARDIZEM™ (diltiazem HCl)

CALCIUM CHANNEL BLOCKADE
from Marion Laboratories



Potent coronary vasodilation with a distinctive hemodynamic profile

Please see full prescribing information on last f

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

INCREASES EXERCISE TOLERANCE, REDUCES ANGINAL FREQUENCY WITH A LOW INCIDENCE OF SIDE EFFECTS

CARDIZEM™ (diltiazem HCl) produces changes in cardiovascular hemodynamics and coronary blood flow that are of benefit in myocardial ischemia.

These changes provide effective therapy with a low incidence of side effects.

Indications

(1) Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm.

(2) Cardizem is indicated in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

ANTIANGINAL MECHANISM OF ACTION

- Produces relaxation of coronary vascular smooth muscle
- Dilates both large and small coronary arteries at drug levels that cause little or no negative inotropic effect
- Produces dose-dependent decreases in peripheral resistance
- Resting heart rate is usually unchanged or slightly reduced

Reduces the pressure/rate product for any given work load in patients with effort-associated angina

© 1983, Marion Laboratories, Inc.

CARDIZEM™ (diltiazem HCl) offers a distinctive profile of effects

(1) Vascular smooth-muscle relaxation with a potent effect on the coronary arteries.[1]

(2) Mild effect on afterload reduction.

(3) In normotensive patients at rest, recommended dosage levels producing coronary vasodilation result in only a mild reduction in diastolic blood pressure and no change in heart rate.

(4) At submaximal exercise, it causes a reduction in heart rate and mean blood pressure compared with placebo, thus reducing myocardial oxygen demand and permitting patients to exercise significantly longer.

(5) Increases coronary blood flow.

(6) Little or no negative inotropic effect at recommended doses while providing a powerful inhibition of coronary artery spasm.

(7) A positive effect on left ventricular function in patients with reduced left ventricular ejection fraction.[2]

(8) Increases ejection fraction at both submaximal and maximal exercise. Exercise ejection fraction is especially increased in patients with poor ventricular function.[3]

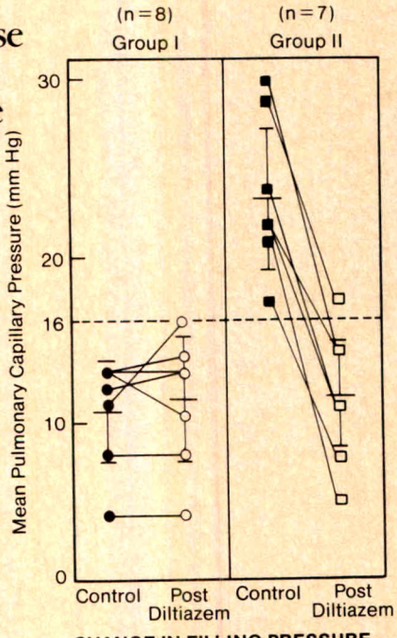
While Cardizem tends to prolong AV conduction,* only rarely has there been an increase in PR intervals outside of normal limits.

*See Contraindications and Warnings.

CARDIZEM™ (diltiazem HCl) tends to normalize stress-induced increases in pulmonary capillary pressure (PCP)

The effect of a single 120-mg† dose of Cardizem was evaluated on symptom-limited upright exercise in 15 patients with effort angina.[4]

†It should be noted that this study employed a single 120-mg dose of diltiazem for hemodynamic measurement purposes. The approved maximum dose for Cardizem is 240 mg given in divided doses, three to four times daily.



CHANGE IN FILLING PRESSURE AT MAXIMAL EXERCISE[4]

Patients with control PCPs in normal range at maximal exercise showed little change in these values following diltiazem (Group I). Patients with markedly elevated control PCPs at maximal exercise (>16 mm Hg) showed dramatic reductions in these values following diltiazem (Group II).

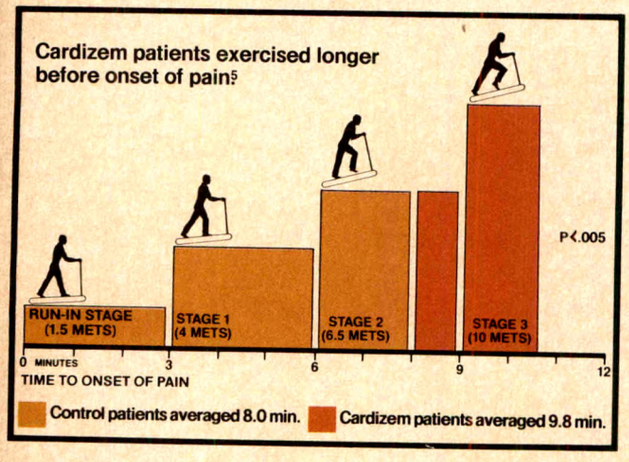
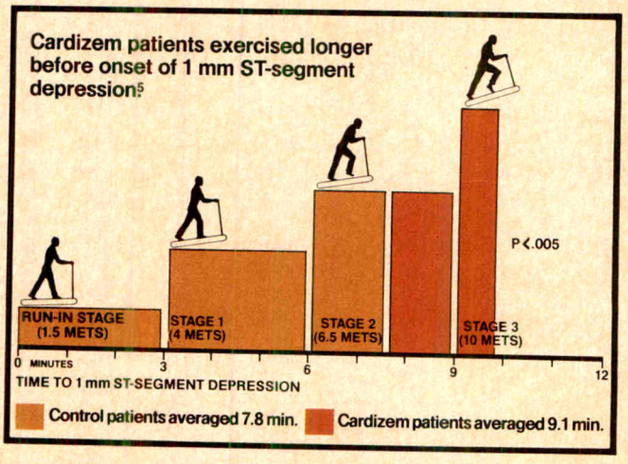
EXCELLENT CLINICAL RESPONSE TO CARDIZEM™ (diltiazem HCl) IN THE MANAGEMENT OF CLASSIC EFFORT ANGINA

CARDIZEM™ (diltiazem HCl) allows angina patients to significantly prolong exercise tolerance, even in demanding Bruce protocol exercise tests[5] (n=15)*





Protocol:

A Bruce protocol with a run-in stage was used. Each stage lasts three minutes.

Succeeding stages represent such an increase in speed and slant of the treadmill that each minute spent in a succeeding stage represents a highly significant increase in metabolic equivalents (METS). For example, METS expenditure in run-in stage of the protocol (0 to 3 min) is 1.5. METS expenditure of stage 1 (3 to 6 min) is 4.0. Stage 2 (6 to 9 min) expenditure is 6.5, and stage 3 (9 to 12 min) is 10.

The study[5,6] was double-blind, randomized, triple cross-over comparing diltiazem with placebo, lasting 7 weeks.

5. Pool PE, Seagren SC, Bonanno JA, et al: The treatment of exercise-inducible chronic stable angina with diltiazem: Effect on treadmill exercise. *Chest* 78(July suppl): 234-238, 1980.

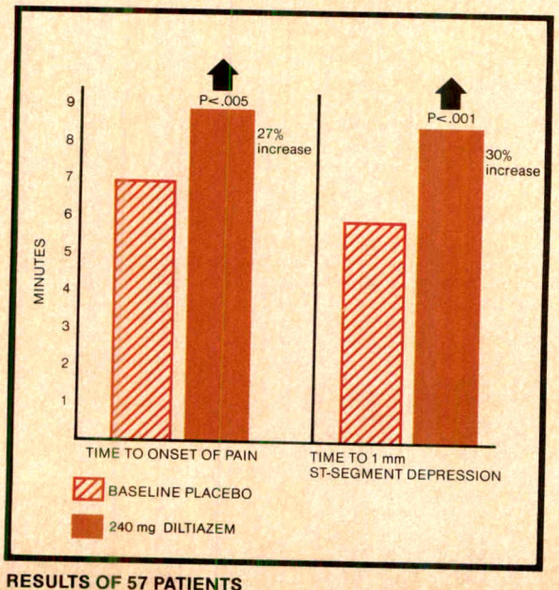
*This study is a report from one center in a multicenter study.

CARDIZEM™ (diltiazem HCl) produced marked angina improvement in multicenter study[6]

- 27% increase in time to onset of pain
- 30% increase in time to ST-segment depression



RESULTS OF 57 PATIENTS EVALUATED IN A MULTICENTER STUDY[6]

CARDIZEM™ (diltiazem HCl) PRODUCED SIGNIFICANT DECREASE IN EFFORT ANGINA ATTACKS COMPARED WITH PLACEBO IN 63-PATIENT DIARY STUDY[7]

Cardizem therapy resulted in a mean reduction of 5.3 attacks per week during weeks 7 and 8, compared with a mean reduction with placebo of 2.0 attacks per week.

During weeks 9 and 10, Cardizem therapy resulted in a mean reduction of approximately 5.9 attacks per week compared with a mean reduction of 2.5 attacks per week with placebo.

41% TO 68% REDUCTION IN FREQUENCY OF PRINZMETAL'S VARIANT ANGINA ATTACKS WITH CARDIZEM™ (diltiazem HCl)[8]

Mean attack rate during 120-mg/day dosage period was reduced 41% from baseline period. In 240-mg/day phase, decrease with Cardizem was 68%. This shows a positive dose-related response.

75% reduction in attack rate reported in 13-patient, cross-over, placebo-controlled study[1]

71% reduction in attack rate reported in 11-patient, cross-over, placebo-controlled study[9]

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

LOW INCIDENCE OF SIDE EFFECTS WITH CARDIZEM™ (diltiazem HCl)

In placebo-controlled trials conducted in the United States, the incidence of adverse reactions reported during Cardizem therapy was not greater than that reported during placebo therapy.

Those adverse reactions reported most frequently with CARDIZEM™ (diltiazem HCl) have been:

- Nausea 2.7%
- Swelling/edema 2.4%
- Arrhythmia 2.0%
- Headache 2.0%
- Rash 1.8%
- Fatigue 1.1%

In many cases, the relationship to Cardizem has not been established.

Other reactions infrequently reported (<1.0%) during supervised trials were:

- Cardiovascular: Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart
- Central Nervous System: Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations
- Gastrointestinal: Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis
- Dermatologic: Pruritus, petechiae, urticaria
- Other: Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain

Of those adverse reactions reported, the most severe were:
A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of Cardizem.

Experience in 959 patients taking oral doses of Cardizem resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during Cardizem therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

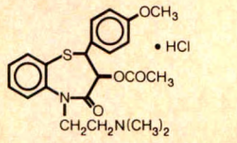
PROFESSIONAL INFORMATION

cardizem™ (diltiazem HCl)

30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanism of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in controlling anginal symptoms, including documented ECG changes, in patients presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

   No other similar liver injury has been reported in clinical trials, but marketing experience in Europe has resulted in a rechallenge-confirmed instance of hepatocellular injury. However, it should be noted that there have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that the relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminase elevation have been reported in Europe, but their relationship to drug is uncertain.

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers or digitalis is currently being investigated in well-controlled studies.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

Cardiovascular:	Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart.
Central Nervous System:	Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations.
Gastrointestinal:	Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis.
Dermatologic:	Pruritus, petechiae, urticaria.
Other:	Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents.

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

studied by M-mode echocardiography and exercise electrocardiography. Ventricular septal and posterior free wall thicknesses and calculated LV mass were significantly greater in athletes than in control subjects. An abnormal S-T segment response to exercise was present in 7 (9%) of the 75 athletes, all of whom had LV mass >275 g, and in 5 the LV mass was above the 95th percentile of that of the control subjects. An abnormal treadmill exercise test also was present in 3 (6%) of 48 controls. Abnormal results on exercise tests occur commonly in both athletes and nonathletes. The fact that almost 10% of isometrically trained athletes have "false-positive" exercise electrocardiograms suggests that this test has major limitations in screening athletes for underlying cardiovascular disease.

1667 Heterogeneity of Left Ventricular Segmental Wall Thickening and Excursion in 2-Dimensional Echocardiograms of Normal Human Subjects

NATESA G. PANDIAN, DAVID J. SKORTON, STEVE M. COLLINS, HERMAN L. FALSETTI, EDMUND R. BURKE, and RICHARD E. KERBER

Two-dimensional (2-D) echocardiograms from 12 normal men were analyzed to determine the normal range of segmental left ventricular (LV) contraction using echocardiography. Short-axis images at mitral valve, chordal, papillary muscle, and apical levels were obtained at end-diastole and end-systole, and each image was divided by computer into 12 cavity and wall segments. The overall range of cavity segment area change was 0 to 100%, and of segmental wall thickening 0 to 150%. Significant differences were found between adjacent segments and between subjects. We conclude that considerable intersegmental and intersubject variability of left ventricular contraction occurs in normals as exhibited on 2-D echocardiograms. Because significant differences in segmental wall thickening and endocardial excursion may be exhibited in echos of normal subjects, such differences alone may not indicate cardiac disease.

1674 Cardiac Function in Sickle Cell Anemia

BARRY S. DENENBERG, GERARD CRINER, RICHARD JONES, and JAMES F. SPANN

Although ventricular dysfunction is suspected to underlie congestive heart failure in sickle cell anemia (SCA), ejection indexes of left ventricular (LV) pump function are normal. Increased preload and decreased afterload of SCA increase the ejection indexes and might obscure LV dysfunction. Therefore, the preload and afterload independent stress-volume index was compared in 11 patients with SCA and 11 normal subjects. Systemic vascular resistance (afterload) was decreased in SCA. End-diastolic volume index (preload) was increased in SCA. Ejection fractions were similar in the 2 groups. In patients with SCA, the resting end-systolic stress-volume index was decreased and the slope of the end-systolic stress versus end-systolic volume index relation was also decreased, suggesting LV dysfunction in those patients. Thus, the intrinsic muscle contractile performance is depressed in SCA. Increased preload and decreased afterload compensate for LV dysfunction and maintain a normal ejection fraction and high cardiac output.

1679 Cardiac Disease After Radiation Therapy for Hodgkin's Disease: Analysis of 48 Patients

MARK M. APPLEFELD and PETER H. WIERNIK

Delayed cardiac disease as a consequence of previous thoracic radiation therapy for Hodgkin's disease may be more common than previously believed. This hypothesis was tested by performing detailed cardiac evaluations in 48 patients 37 to 172 (mean 97) months after radiotherapy. Evaluation identified cardiac disease in 46 of 48 (96%) of these patients. The disorders most often identified were chronic pericarditis (24 patients), an abnormal hemodynamic response to fluid challenge (14 patients), and coronary artery disease (6 patients). Excluding patients with coronary artery disease, left ventricular systolic function as assessed by gated radionuclide ventriculography was normal at rest and during exercise. Six patients underwent pericardiectomy for constrictive pericarditis: 3 had a good operative result; 2 have persistent symptoms postoperatively, presumably caused by visceral pericardial constriction; and a third patient died from progressive Hodgkin's disease. Three other patients had coronary artery bypass surgery for occlusive coronary artery disease. Surgery was successful in 2 patients; 1 patient died after operation at another center. Two patients have congestive heart failure and are moderately disabled. The remaining 35 patients are not significantly limited by their cardiac symptoms. Thus, although delayed cardiac disease after radiotherapy may be common, its prognosis appears excellent.

1682 Contrasting Acute Effects of Vasodilators (Nitroglycerin, Nitroprusside, and Hydralazine) on Right Ventricular Performance in Patients With Chronic Obstructive Pulmonary Disease and Pulmonary Hypertension: A Combined Radionuclide-Hemodynamic Study

BRUCE N. BRENT, HARVEY J. BERGER, RICHARD A. MATTHAY, DONALD MAHLER, LINDA PYTLIK, and BARRY L. ZARET

A combined radionuclide-hemodynamic approach was used to assess the effects of nitroglycerin, nitroprusside, and hydralazine on right ventricular performance and central hemodynamics in patients with chronic obstructive pulmonary disease. Nitroglycerin and nitroprusside significantly decreased mean right atrial pressure, right ven-

New and important evidence affirms the

Slow-K®

potassium chloride slow-release tablets 8 mEq

8-year U.S. record of clinical experience.

Please see last page for brief Prescribing Information.

New endoscopic studies show:

No significant difference in GI lesions between

Slow-K®
potassium chloride
slow-release tablets 8 mEq

and
Micro-K®
potassium chloride
controlled-release Extencaps®
600 mg 8 mEq K

SLOW-K: UNSURPASSED FOR SAFETY AMONG SLOW-RELEASE KCl CAPSULES OR TABLETS

Maximum-dosage (96 mEq) multistudy data*

Results: No significant differences in endoscopic changes found between Slow-K and Micro-K at 96-mEq dosage.†

(Administered as four 8-mEq tablets or capsules, t.i.d.)

These data resulted from four different studies (involving 64 subjects) that used the maximum recommended daily dosage of 96 mEq before food ingestion and with concomitant administration of the maximum recommended dosage of the anticholinergic agent glycopyrrolate (6 mg).[1-4]

Maximum-dosage multistudy data

					Endoscopic findings‡			
N	Treatment	Daily dosage	Glycopyrrolate	Food	Ulcers	3	2	1
27	Slow-K	96 mEq	6 mg	No	1	1	6	12
37	Micro-K	96 mEq	6 mg	No	2	1	2	9

Results from similar studies supported by the A.H. Robins Company have shown a greater incidence of endoscopically observed GI irritation with Slow-K as compared to Micro-K when maximum doses of glycopyrrolate are administered.[5,6] These results, showing a significant difference between the products, are *inconsistent* with the data described herein, which do not show a significant difference.

High-dosage (48 mEq) multistudy data*

Results: No ulcers found with Slow-K or Micro-K. No significant differences in endoscopic changes found with Slow-K and Micro-K at 48-mEq dosage.

(Administered as two 8-mEq tablets or capsules, t.i.d.)

These data resulted from four different studies (involving 36 subjects) that used the high (48 mEq) dosage with food ingestion, and with and without the maximum recommended dosage of the anticholinergic agent glycopyrrolate. (Note: Glycopyrrolate was used in only one group of subjects on Slow-K.)[1-4] This 48-mEq dosage is higher than that normally used prophylactically.

High-dosage multistudy data

					Endoscopic findings‡			
N	Treatment	Daily dosage	Glycopyrrolate	Food	Ulcers	3	2	1
12	Slow-K	48 mEq	6 mg	Yes	0	0	2	6
12	Slow-K	48 mEq	None	Yes	0	0	0	4
12	Micro-K	48 mEq	None	Yes	0	0	1	5

*These studies were conducted by Drs. D. Patterson and G. Jeffries of the Hershey Medical Center, and by Dr. D. Earnest of the University of Arizona (Tucson).

†Also included in these multistudy data were an additional 70 subjects taking an 8-mEq sustained-release KCl capsule, a K^+ elixir, a sustained-release KCl tablet of higher mEq dosage than that currently available, or a placebo. The elixir and the placebo did not produce any endoscopic changes greater than two Grade 1 and five Grade 1 endoscopic findings, respectively. The higher dose sustained-release KCl tablets produced two ulcers, two Grade 2 and six Grade 1 endoscopic findings. The 8-mEq sustained-release capsule produced two Grade 2 and two Grade 1 findings. All Grade 1 endoscopic changes were considered clinically meaningless.

‡Grade 0 = no endoscopic findings
1 = hyperemia and/or edema (the medical consensus is that this category is clinically meaningless)
2 = few erosions
3 = numerous erosions (>3)
4 = ulceration
5 = multiple ulcerations

The anticholinergic agent glycopyrrolate was given to slow gastric emptying, thus ensuring maximum contact of the KCl supplements with the gastric mucosa. The impact, if any, of high-dose glycopyrrolate on the gastric mucosa is unknown.

Please see last page for brief Prescribing Information.

CIBA

New epidemiologic study shows:

No difference between

Slow-K®

potassium chloride slow-release tablets 8 mEq

use and no K^+ therapy in the incidence of upper GI bleeding in a hospital setting.

SLOW-K: UNSURPASSED FOR SAFETY AMONG SLOW-RELEASE KCl CAPSULES OR TABLETS

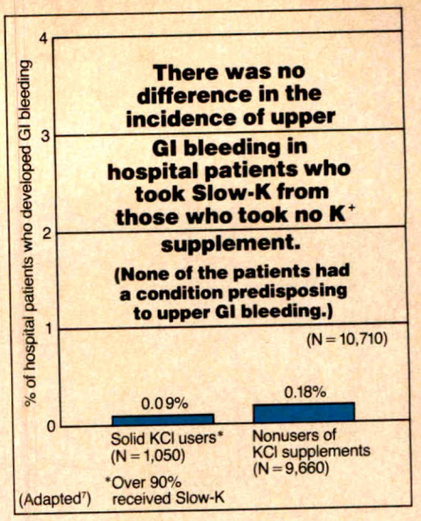
Experience of the Boston Collaborative Drug Surveillance Program[7]
As reported by Aselton and Jick in *Lancet,* January 22, 1983

Purpose of epidemiologic study:
To evaluate the relation between the use of wax-matrix KCl and the development of upper GI bleeding while in the hospital.

Patient population:
A total of 15,791 medical inpatients. Of those, 10,710 had no condition predisposing to upper GI bleeding. Of those, 1,050 received solid KCl* by mouth; 9,660 received no solid KCl.

Findings:
Of the 1,050 KCl users, 1 had GI bleeding (0.09%).
Of the 9,660 nonusers, 17 had GI bleeding (0.18%).

*Over 90% of this group received KCl in the form of Slow-K tablets.



Conclusion: "These findings argue against a positive association between wax matrix KCl use and upper gastrointestinal bleeding over a short period of time."[7]

These new data are consistent with the overwhelming evidence compiled in 8 years of use with Slow-K® potassium chloride slow-release tablets 8 mEq.

Analysis of 5.6 million U.S. patient-years' data: approximately one GI lesion per 100,000 patient-years--and this incidence rate has remained unchanged since Slow-K was introduced in 1975.[8]

*Method of determining incidence:
A: Includes all cases (most conservative method)
B: Excludes cases in which causality was unlikely and/or Slow-K was contraindicated
C: Excludes cases in which B was present *and* in which data were insufficient to assess causality (least conservative method)

Summary of lesion incidence rates per 100,000 patient-years

	Method* A	B	C
Esophagus	0.14	0.02	0.02
Stomach	0.27	0.14	0.11
Duodenum	0.12	0.05	0.05
Small bowel/large bowel; unknown location	0.82	0.43	0.27
Total	1.36	0.64	0.44

(Adapted[8])

Conclusion: Slow-K is a safe agent.

Capsule or tablet slow-release potassium chloride preparations should be reserved for patients who cannot tolerate, refuse to take or have compliance problems with liquid or effervescent potassium preparations, because of reports of intestinal and gastric ulceration and bleeding with slow-release KCl preparations.

Please see last page for brief Prescribing Information.

CIBA

Slow-K®

potassium chloride slow-release tablets 8 mEq

Unsurpassed among K^+ capsules or tablets for clinical safety*

Unrivaled among K^+ capsules or tablets for clinical experience

* Capsule or tablet slow-release potassium chloride preparations should be reserved for patients who cannot tolerate, refuse to take or have compliance problems with liquid or effervescent potassium preparations, because of reports of intestinal and gastric ulceration and bleeding with slow-release KCl preparations.

- 7.3 million patients treated through 1981
- Over 2 million additional patients in 1982 alone
- Over 51.8 million new and refill prescriptions
- 8 years' U.S. clinical experience
- 17 years' worldwide clinical experience
- 5.6 million U.S. patient-years of use
- Listed on 80-85% of the larger U.S. hospital formularies

CIBA

SLOW-K®
potassium chloride slow-release tablets

Brief Summary of Prescribing Information

DESCRIPTION
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.
1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).
Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.
All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS
Hyperkalemia: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.
The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.
Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.
Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains approximately one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distension, or gastrointestinal bleeding occurs.
Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

ADVERSE REACTIONS
The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.
One of the most severe adverse effects is hyperkalemia (see Contraindications, Warnings and Overdosage). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION
The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 40 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.
Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

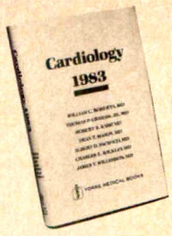
Cardiology 1983



The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

What is Cardiology 1983?

- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research
- A unique, cohesive summary of the state-of-the-art, **written**, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1983 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

• William C. Roberts, MD • Thomas P. Graham, Jr., MD • Robert B. Karp, MD • Dean T. Mason, MD • Albert D. Pacifico, MD • Charles E. Rackley, MD • James T. Willerson, MD

tricular end-diastolic volume index, mean pulmonary artery pressure, cardiac index, and arterial oxygen tension. Nitroglycerin did not affect pulmonary vascular resistance but increased right ventricular ejection fraction. Nitroprusside mildly decreased pulmonary vascular resistance but did not alter right ventricular ejection fraction. In contrast, hydralazine decreased pulmonary vascular resistance and increased cardiac index and right ventricular ejection fraction. The increase in ejection fraction correlated well with the decrease in pulmonary vascular resistance. These data suggest that in patients with mild to moderate secondary pulmonary hypertension, acute administration of hydralazine results in substantial improvement of right ventricular performance by virtue of decreasing pulmonary vascular resistance. In contrast, nitroglycerin and nitroprusside demonstrate predominant effects that reduce preload, cardiac index, and arterial oxygen tension.

CONGENITAL HEART DISEASE

1690 Reoperation for Isthmic Coarctation of the Aorta: Follow-Up of 26 Patients

PHYLLIS POLLACK, MICHAEL D. FREED, ALDO R. CASTANEDA, and WILLIAM I. NORWOOD

Although repair of coarctation of the aorta is a common and safe procedure, inadequate relief or restenosis requiring reoperation is not unusual. The results of reoperation for coarctation of the aorta rarely have been evaluated. This series presents follow-up results in 26 patients who underwent reoperation for coarctation of the aorta. There was no morbidity or mortality. Resting coarctation pressure gradients and arm systolic blood pressures were significantly improved. Systolic hypertension persisted in 5 of 25 patients (20%) on follow-up. Patch aortoplasty appears to be a safe and satisfactory surgical approach. Reoperation for coarctation of the aorta is a very low-risk procedure that improves symptoms and relieves residual or recurrent obstruction. Systolic hypertension, however, does not always resolve postoperatively.

1695 Subxyphoid 2-Dimensional Echocardiographic Identification of Left Ventricular Papillary Muscle Anomalies in Complete Common Atrioventricular Canal

ALVIN J. CHIN, FREDRICK BIERMAN, STEPHEN P. SANDERS, ROBERTA G. WILLIAMS, WILLIAM I. NORWOOD, and ALDO R. CASTANEDA

Two-dimensional (2-D) echocardiography was performed in 31 infants with complete common atrioventricular (AV) canal. Eighty percent had 2 left ventricular (LV) papillary muscles on 2-D echocardiography, 10% had 3 LV papillary muscles, and 10% had a solitary LV papillary muscle. Among the 25 infants with complete common AV canal with 2 LV papillary muscles, there was 1 operative death. Among the 6 infants with complete common AV canal with LV papillary muscle anomalies, 5 underwent surgical repair with 4 early deaths. Subxyphoid 2-D echocardiography is a useful technique for evaluating LV papillary muscle architecture in patients with complete common AV canal and permits identification of those who may be at higher risk for unsuccessful mitral reconstruction.

1701 Anatomic Obstruction of the Right Ventricular Outflow Tract in Transposition of the Great Arteries

RUDOLF J. MOENE, ARENTJE OPPENHEIMER-DEKKER, and MARGOT M. BARTELINGS

In 126 postmortem specimens with transposition of the great arteries (combined with a ventricular septal defect in 55 cases), the morphologic features of the right ventricular outflow tract were studied with the aim of tracing possible relationships with potential subaortic obstruction. Distinct anatomic obstruction was found in 15 hearts with and 2 hearts without ventricular septal defect. The obstruction resulted from anterior displacement of infundibular septum and ventriculoinfundibular fold (12 cases), from bulging of the trabecula septomarginalis and/or ventriculoinfundibular fold (3 cases), or from aberrant muscle bundles (2 cases). Associated anomalies indicative of prenatal subaortic obstruction were dimensional aortic arch malformations in 6 specimens. Six cases had tricuspid valve anomalies. It is concluded that subaortic obstruction may constitute a complicating factor in transposition of the great arteries; it is suggested that in these cases a "switch" procedure might prevent progression of obstruction resulting from maintained systemic blood pressure in the right ventricle.

1705 Quantitative Angiographic and Morphologic Aspects of Aortic Valve Atresia

ALOIS R. HASTREITER, RONALD L. VAN DER HORST, IRA W. DUBROW, and FRIEDRICH O. ECKNER

Quantitative angiographic measurements were performed on 15 infants aged 1 to 35 days who had aortic valve atresia with intact ventricular septum and hypoplastic left ventricle. Thirteen of these infants had similar measurements performed at autopsy. The latter measurements were smaller than those found at angiography (because of shrinkage), but their relationship was predictable. Angiographic right ventricular (RV) volumes were 2 and 4 times normal in diastole and systole, respectively. The RV volume measured at autopsy was >3 times normal. Mean RV ejection fraction was 0.40; it was below normal in 10 infants. Maximal right atrial volume was >2 times normal, and the mean left atrial maximal volume was two-thirds normal. The relation between circumferences of the aortic arch and the ascending and descending aorta was similar at angiography and autopsy.

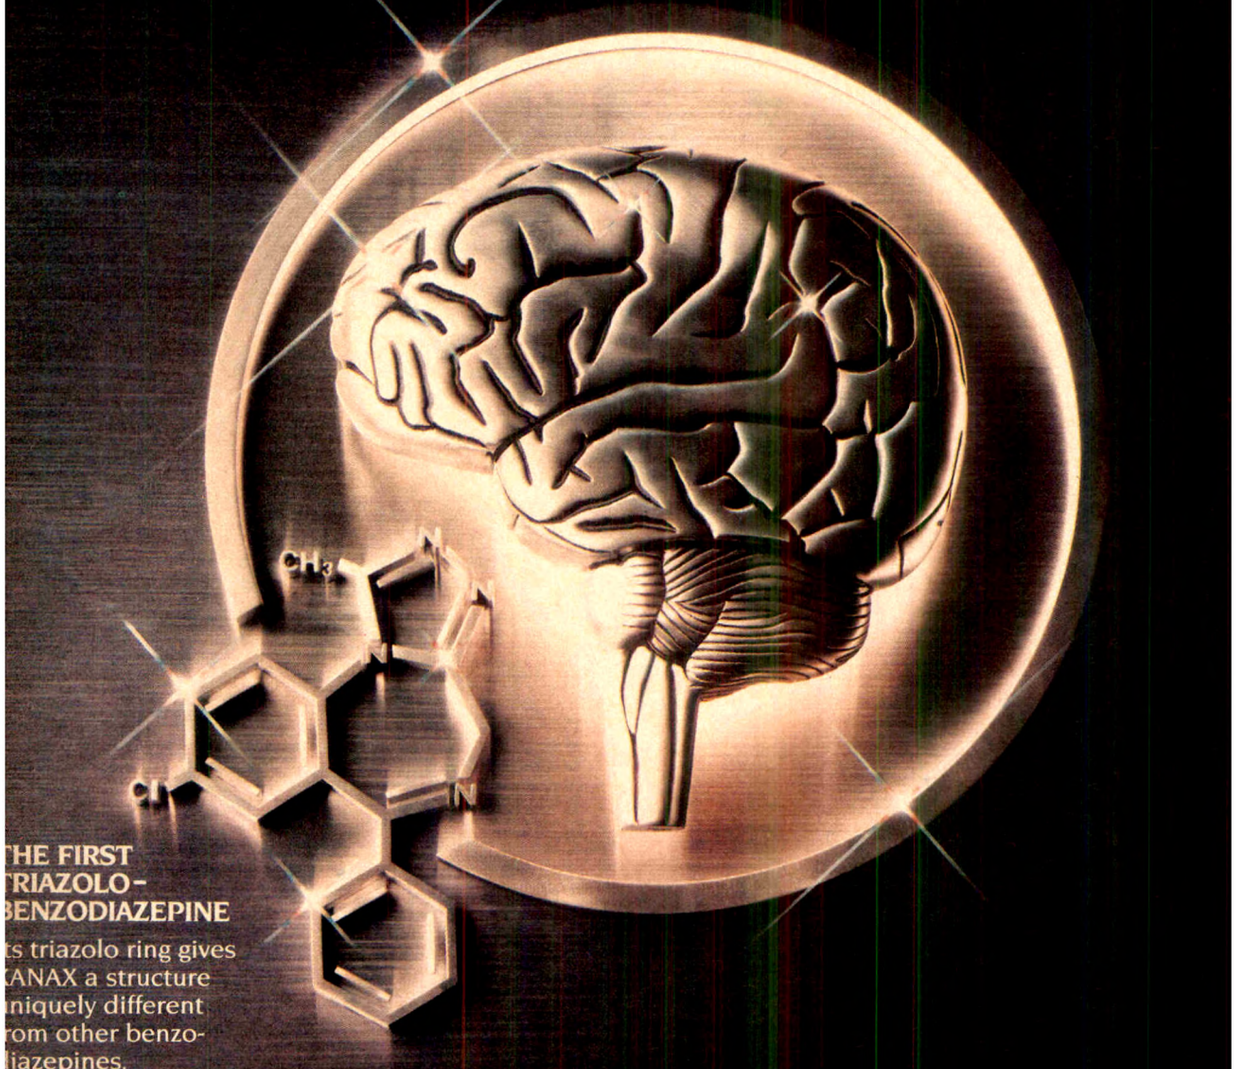
Xanax® 0.5 mg Tablets

alprazolam C IV



THE FIRST TRIAZOLO-BENZODIAZEPINE

Its triazolo ring gives XANAX a structure uniquely different from other benzodiazepines.

THE FIRST OF A UNIQUE CLASS

Upjohn

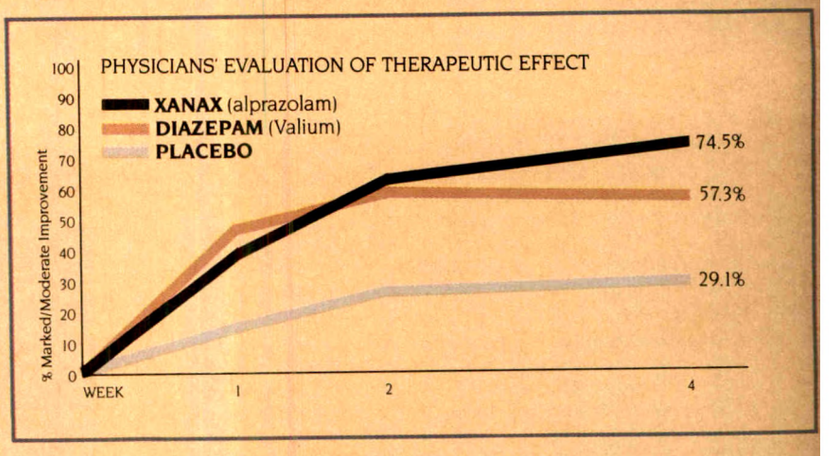
© 1982 The Upjohn Company

FOR CLINICAL ANXIETY

EFFICACY EQUAL TO DIAZEPAM WITH LESS DROWSINESS

In double-blind, placebo-controlled clinical trials in 976 patients with moderate to severe clinical anxiety, therapy with XANAX was compared to diazepam (Valium).*

Patients treated with XANAX *had a significantly lower incidence of drowsiness when compared directly to diazepam* therapy (Valium) in *a 976-patient*, placebo-controlled, multicenter study.*

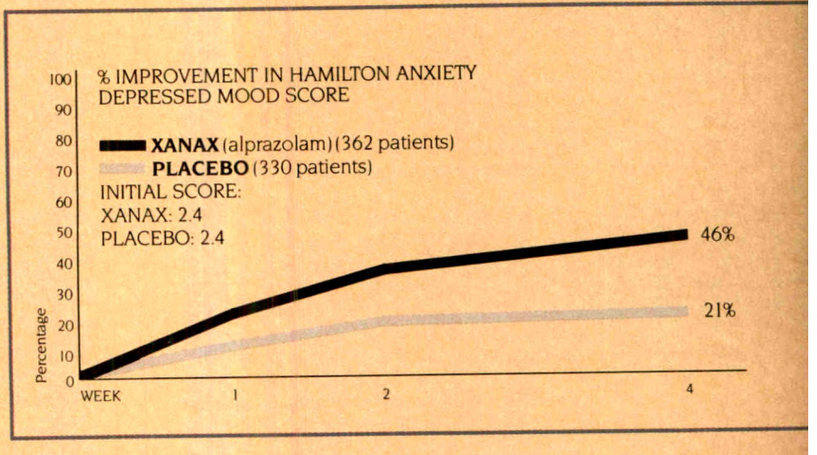


AND CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

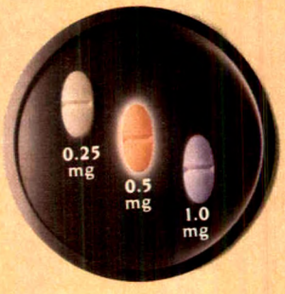
EFFECTIVE IN CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

Patients with clinical anxiety may complain of having feelings of depression, such as sadness, blueness, or loneliness.

Depressed mood is one of 14 items on the Hamilton Anxiety Rating Scale. Special analysis of 692 anxious patients with a significant depressed mood item score showed that treatment with XANAX was significantly better than placebo in decreasing depressed mood score.



SIMPLE DOSAGE:
XANAX 0.25–0.5 mg T.I.D.



The usual starting dose of XANAX is 0.25 to 0.5 mg, three times daily.

Please see next page for brief summary of prescribing information.

Xanax® 0.5 mg Tablets
alprazolam C-IV

XANAX® Tablets ©
(alprazolam)

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation (see Drug Interaction section). Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage (see Dosage and Administration). Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central Nervous System: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other Side Effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analyses are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. After prolonged therapy, dosage should be tapered. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

BS-1

*Cohn JB: Multicenter double-blind efficacy and safety study comparing alprazolam, diazepam and placebo in clinically anxious patients. *J Clin Psychiatry* 42 (9):347-351, 1981.

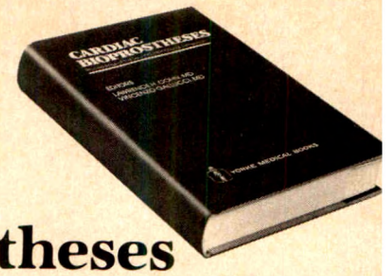
The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.



Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MI
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology,* now available in its second issue, *Cardiology 1982.*

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

METHODS

1709 Increased Left Ventricular Ejection Fraction After a Meal: Potential Source of Error in Performance of Radionuclide Angiography

JERRY M. BROWN, CHRISTOPHER J. WHITE, SAMUEL M. SOBOL, and ROBERT J. LULL

To study the effects of eating on cardiac performance in man, the left ventricular ejection fraction was determined by radionuclide angiography before and after a standardized meal in 16 patients with compensated congestive heart failure. Patients with moderate depression of fasting left ventricular ejection fraction (30 to 50%) had significant increases in left ventricular ejection fraction after a meal. Patients with a severely depressed fasting left ventricular ejection fraction (<30%) had no increase after a meal. Thus, patients' mealtimes constitute an important unmeasured variable in the determination of left ventricular ejection fraction in patients with moderate but not severe left ventricular dysfunction.

1712 Diagnostic Accuracy of Indium-111 Platelet Scintigraphy in Identifying Left Ventricular Thrombi

MICHAEL D. EZEKOWITZ, ROBERT D. BURROW, PAUL W. HEATH, TERRI STREITZ, EILEEN O. SMITH, and DONALD E. PARKER

A retrospective, blinded analysis is presented of 662 indium-111 platelet images from 64 patients read on 2 separate occasions by 3 observers. Tissue confirmation of the presence or absence of thrombus was made at surgery or autopsy. Results indicate that a comparison of images obtained in the left anterior oblique view on the day of injection with those obtained 3 to 4 days later provides the best combination for determining sensitivity, diagnostic accuracy, and specificity (65, 99, and 99%, respectively). Imaging in multiple views (right anterior oblique, anterior, left anterior oblique, and left lateral) greatly facilitates localization of thrombus to the left ventricle. This study also defines the reproducibility of this technique, the mean intraobserver and interobserver agreement being 91 and 88%, respectively.

EXPERIMENTAL STUDIES

1717 Tissue Digoxin Concentrations During the Quinidine-Digoxin Interaction

NATALIE J. WARNER, EDWARD B. LEAHEY, Jr., THOMAS J. HOUGEN, J. THOMAS BIGGER, Jr., and THOMAS W. SMITH

Tissue digoxin concentrations were measured in dogs treated with tritiated digoxin and quinidine. After 24 hours of intravenous quinidine, changes in the ratio of tissue-to-serum digoxin concentration ratios found. Renal-to-serum digoxin concentration decreased, and this decrease was proportional to the serum quinidine concentration. Myocardial-to-serum digoxin concentration increased and occipital muscle and medullary brainstem-to-serum digoxin concentration ratios decreased, but these changes were independent of the serum quinidine concentration. After drug doses calculated to result in steady-state serum drug concentrations, no changes in digoxin concentration in myocardium, skeletal muscle, kidney, liver, or brain tissue were found, nor were there changes in the tissue-to-serum digoxin concentration ratio.

1722 Effect of Atrial Fibrillation on Atrial Blood Flow in Conscious Dogs

PHILIP A. McHALE, JUDITH C. REMBERT, and JOSEPH C. GREENFIELD, Jr.

This study examined the independent effects of atrial tachycardia, ventricular tachycardia, and atrial fibrillation (AF) on atrial and ventricular blood flow in conscious, heart-blocked dogs using radioactive microspheres. Atrial blood flow averaged 0.54 ± 0.08 ml/min/g during the control period at an atrial rate of 124 beats/min and a ventricular rate of 90 beats/min. Atrial flow increased to 0.72 ± 0.12 ml/min/g during atrial pacing at 236 beats/min, but was not significantly altered by ventricular pacing at 200 beats/min. AF at a ventricular rate of 90 beats/min resulted in atrial flow values of 0.91 ± 0.08 ml/min/g. Administration of adenosine during AF further increased atrial flow to 2.18 ± 0.16 ml/min/g. Atrial tachycardia or AF did not significantly affect ventricular blood flow. These data indicate (1) that atrial blood flow increases significantly during AF, reaching flow values per gram of tissue comparable to those of the left ventricle, and (2) that this flow is regulated by the metabolic needs of the atrial tissue and does not represent maximal vasodilation.

1728 Relation of Left Ventricular Mass to Geometry of the Proximal Coronary Arteries in the Dog

RICHARD S. STACK, JUDITH C. REMBERT, BRUCE SCHIRMER, and JOSEPH C. GREENFIELD, Jr.

Proximal epicardial coronary artery luminal diameters were measured from silicone casts formed in situ in freshly excised hearts. Twenty-five coronary arteries from 15 normal dogs and 22 coronary arteries in 13 dogs with either chronic pressure or volume overload hypertrophy were studied. A poor correlation existed between left ventricular mass and coronary artery diameter in both normal and hypertrophy groups. The mean cross-sectional area of the combined left circumflex and left anterior descending was 0.12 cm^2 in the normal group and 0.15

Continued on page A48

cm^2 in the hypertrophy group; this increase was not statistically significant ($p = 0.13$). When the mean cross-sectional area of the combined vessels was adjusted for heart weight, there was a decrease in the cross-sectional area per 100 g of myocardium in the hypertrophy group compared with the control group. These data demonstrate that coronary artery luminal diameter does not increase commensurately with the increase in mass associated with myocardial hypertrophy.

1732 Quantitative Detection of Regional Left Ventricular Contraction Abnormalities by 2-Dimensional Echocardiography. Comparison of Myocardial Thickening and Thinning and Endocardial Motion in a Canine Model

JOSEPH E. O'BOYLE, ALFRED F. PARISI, MARKKU NIEMINEN, ROBERT A. KLONER, and SHUKRI KHURI

Two-dimensional echocardiographic studies were analyzed by 2 algorithms for left ventricular contraction abnormalities in 27 dogs after coronary arterial ligation. Both algorithms detected >90% of the myocardial dysfunction associated with myocardial infarction; however, the thickening algorithm identified normal zones better than the cavity area shrinkage algorithm. Neither algorithm had an advantage in predicting the circumferential extent of myocardial infarction. Therefore, either algorithm can be used to detect the presence and quantify the extent of myocardial infarction.

1739 Pharmacologically Induced Changes in Wall Thickening Dynamics and Mid-Ventricular Volumes in Dogs Assessed by Prospectively Gated Computed Tomography

G. B. JOHN MANCINI, WALLACE W. PECK, ROBERT A. SLUTSKY, ROBERT F. MATTREY, and CHARLES B. HIGGINS, *With the technical assistance of* STEPHEN A. LONG

Assessment of regional wall thickening dynamics is important for monitoring the response of normal and ischemic myocardium to pharmacologic interventions. Since regional wall thickness can be measured on computed tomographic scans of the heart, the ability of electrocardiogram-gated computed tomography to determine the effects of pharmacologic agents on global and segmental left ventricular (LV) function was assessed in 8 conditioned dogs. Changes in contractility and loading conditions were produced by infusions by isoproterenol, phenylephrine, and verapamil. An analysis was made of septal, apical and lateral wall thickness, percent wall thickening, end-diastolic and end-systolic mid-LV volume, and percent change in mid-LV volume. Phenylephrine induced significant thinning of the walls and impairment of systolic thickening, whereas isoproterenol induced opposite effects. Despite a lowering of afterload caused by verapamil, wall thickening showed either no change or a deterioration and global function was not improved, signifying a depression of the contractile state. It is concluded that electrocardiogram-gated computed tomography can be used to assess the effects of pharmacologic interventions on global and segmental LV function.

1744 Coronary Blood Flow During the Development and Regression of Left Ventricular Hypertrophy in Renovascular Hypertensive Rats

PIERRE WICKER, ROBERT C. TARAZI, and KIMINARI KOBAYASHI

Left ventricular (LV) coronary flow (CF) was determined by left atrial injection of microspheres in conscious rats during the development and after the reversal of LV hypertrophy in 2-kidney, 1-clip Goldblatt hypertension. Two groups of untreated renal hypertensive rats (RHR) were studied, the first (RHR_1, $n = 17$) at 10 weeks and the second (RHR_2, $n = 9$) at 24 weeks after clipping. Beginning 9 weeks after clipping, 2 other groups were treated either with captopril (40 to 60 mg/kg/day) in drinking water (RHR-C, $n = 8$) or left nephrectomy (RHR-N, $n = 9$) and followed for 15 weeks. Sham-operated animals followed for similar periods of time served as controls (Sham-1, $n = 12$, as a control for RHR_1, and Sham-2, $n = 11$, as a control for RHR_2). In all groups, LV mass increased or decreased in close correlation with changes in arterial blood pressure, and minimal total LV coronary resistance remained unchanged. The development of hypertrophy was associated with a tendency toward reduction in CF reserve (defined as maximal CF/unit mass); this flow reserve was restored with reversal of hypertrophy. The importance of the relation between pressure and LV mass as a determinant of CF reserve was investigated in a second study in which this relation was changed by altering the periods of captopril therapy; in these cases, CF reserve correlated significantly with the ratio of arterial pressure to LV mass ($r = 0.76$, $n = 12$, $p < 0.01$). The results suggest that maintenance of CF reserve in LV hypertrophy depends on an appropriate balance between arterial pressure and LV mass, and might be disturbed by antihypertensive therapy that leaves LV hypertrophy unchanged.

cardioselectivity*

ONE TABLET A DAY

TENORMIN®

(atenolol)

Tablets 50 mg

*Cardioselectivity denotes a relative preference for β_1 receptors, located chiefly in cardiac tissue. This preference is not absolute.

See last page of this advertisement for brief summary of prescribing information

TENORMIN® (atenolol)

A beta$_1$-selective blocking agent for hypertension.

INDICATIONS AND USAGE: TENORMIN (atenolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide-type diuretic.

CONTRAINDICATIONS: TENORMIN is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure: Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, TENORMIN should be administered cautiously. Both digitalis and atenolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, TENORMIN therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TENORMIN is planned, the patient should be carefully observed and should be advised to limit physical activity to a minimum. TENORMIN should be reinstated if withdrawal symptoms occur.

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASE SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, TENORMIN may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute the lowest possible dose of TENORMIN should be used, with therapy initiated at 50 mg and a beta$_2$-stimulating agent (bronchodilator) made available. If dosage must be increased, dividing the dose should be considered in order to achieve lower peak blood levels.

Anesthesia and Major Surgery: As with all beta-receptor blocking drugs it may be decided to withdraw TENORMIN before surgery. In this case, 48 hours should be allowed to elapse between the last dose and anesthesia. If treatment is continued, care should be taken when using anesthetic agents which depress the myocardium, such as ether, cyclopropane, and trichloroethylene.

TENORMIN, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects on the heart can be reversed by administration of such agents (eg, dobutamine or isoproterenol with caution—see OVERDOSAGE). Manifestations of excessive vagal tone (eg, profound bradycardia, hypotension) may be corrected with atropine (1-2 mg I.V.).

Diabetes and Hypoglycemia: TENORMIN should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. TENORMIN does not potentiate insulin-induced hypoglycemia and, unlike nonselective beta blockers, does not delay recovery of blood glucose to normal levels.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyroidism. Abrupt withdrawal of beta blockade might precipitate a thyroid storm; therefore, patients suspected of developing thyrotoxicosis from whom TENORMIN therapy is to be withdrawn should be monitored closely.

PRECAUTIONS: Impaired Renal Function: The drug should be used with caution in patients with impaired renal function (see DOSAGE AND ADMINISTRATION).

Drug Interactions: Catecholamine-depleting drugs (eg, reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with TENORMIN plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Should it be decided to discontinue therapy in patients receiving beta blockers and clonidine concurrently, the beta blocker should be discontinued several days before the gradual withdrawal of clonidine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Two long-term (maximum dosing duration of 18 or 24 months) rat studies and one long-term (maximum dosing duration of 18 months) mouse study, each employing dose levels as high as 300 mg/kg/day or 150 times the maximum recommended human dose, did not indicate a carcinogenic potential in rodents. Results of various mutagenicity studies support this finding.

Fertility of male or female rats (evaluated at dose levels as high as 200 mg/kg/day or 100 times the maximum recommended human dose) was unaffected by atenolol administration.

Animal Toxicology: Chronic studies performed in animals have revealed the occurrence of vacuolation of epithelial cells of Brunner's glands in the duodenum of both male and female dogs at all tested dose levels of atenolol (starting at 15 mg/kg/day or 7.5 times the maximum recommended human dose) and increased incidence of atrial degeneration of hearts of male rats at 300 mg but not 150 mg atenolol/kg/day (150 and 75 times the maximum recommended human dose, respectively).

USAGE IN PREGNANCY: Pregnancy Category C. Atenolol has been shown to produce a dose-related increase in embryo/fetal resorptions in rats at doses equal to or greater than 50 mg/kg or 25 or more times the maximum recommended human dose. Although similar effects were not seen in rabbits, the compound was not evaluated in rabbits at doses above 25 mg/kg or 12.5 times the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. TENORMIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not established to what extent this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving atenolol.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient. Frequency estimates were derived from controlled studies in which adverse reactions were either volunteered by the patient (U.S. studies) or elicited (eg, by checklist—foreign studies). The reported frequency of elicited adverse effects was higher for both TENORMIN and placebo-treated patients than when these reactions were volunteered. Where frequency of adverse effects for TENORMIN and placebo is similar, causal relationship is uncertain.

The following adverse-reaction data present frequency estimates in terms of percentages: first from the U.S. studies (volunteered side effects) and then from both U.S. and foreign studies (volunteered and elicited side effects):

U.S. STUDIES (% ATENOLOL-% PLACEBO):

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (0%-0.5%), postural hypotension (2%-1%), leg pain (0%-0.5%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (4%-1%), vertigo (2%-0.5%), light-headedness (1%-0%), tiredness (0.6%-0.5%), fatigue (3%-1%), lethargy (1%-0%), drowsiness (0.6%-0%), depression (0.6%-0.5%), dreaming (0%-0%)

GASTROINTESTINAL: diarrhea (2%-0%), nausea (4%-1%)

RESPIRATORY (See WARNINGS): wheeziness (0%-0%), dyspnea (0.6%-1%)

TOTALS U.S. AND FOREIGN STUDIES:

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (12%-5%), postural hypotension (4%-5%), leg pain (3%-1%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (13%-6%), vertigo (2%-0.2%), light-headedness (3%-0.7%), tiredness (26%-13%), fatigue (6%-5%), lethargy (3%-0.7%), drowsiness (2%-0.5%), depression (12%-9%), dreaming (3%-1%)

GASTROINTESTINAL: diarrhea (3%-2%), nausea (3%-1%)

RESPIRATORY (see WARNINGS): wheeziness (3%-3%), dyspnea (6%-4%)

MISCELLANEOUS: There have been reports of skin rashes and/or dry eyes associated with the use of beta-adrenergic blocking drugs. The reported incidence is small and, in most cases, the symptoms have cleared when treatment was withdrawn. Discontinuance of the drug should be considered if any such reaction is not otherwise explicable. Patients should be closely monitored following cessation of therapy.

POTENTIAL ADVERSE EFFECTS: In addition, a variety of adverse effects have been reported with other beta-adrenergic blocking agents, and may be considered potential adverse effects of TENORMIN (atenolol).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Fever, combined with aching and sore throat, laryngospasm and respiratory distress.

Central Nervous System: Reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation of time and place, short-term memory loss, emotional lability with slightly clouded sensorium, decreased performance on neuropsychometrics.

Gastrointestinal: Mesenteric arterial thrombosis, ischemic colitis.

Other: Reversible alopecia, Peyronie's disease, erythematous rash, Raynaud's phenomenon.

Miscellaneous: The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with TENORMIN during investigational use and foreign marketing experience. Furthermore, a number of patients who had previously demonstrated established practolol reactions were transferred to TENORMIN therapy with subsequent resolution or quiescence of the reaction.

OVERDOSAGE: To date, there is no known case of acute overdosage, and no specific information on emergency treatment of overdosage is available. The most common effects expected with overdosage of a beta-adrenergic blocking agent are bradycardia, congestive heart failure, hypotension, bronchospasm, and hypoglycemia.

In the case of overdosage, treatment with TENORMIN should be stopped and the patient carefully observed. TENORMIN can be removed from the general circulation by hemodialysis. In addition to gastric lavage, the following therapeutic measures are suggested if warranted:

Bradycardia: Atropine or another anticholinergic drug.

Heart Block (Second or Third Degree): Isoproterenol or transvenous cardiac pacemaker.

Congestive Heart Failure: Conventional therapy.

Hypotension (Depending on Associated Factors): Epinephrine rather than isoproterenol or norepinephrine may be useful in addition to atropine and digitalis.

Bronchospasm: Aminophylline, isoproterenol, or atropine.

Hypoglycemia: Intravenous glucose.

DOSAGE AND ADMINISTRATION: The initial dose of TENORMIN is 50 mg given as one tablet a day either alone or added to diuretic therapy. The full effect of this dose will usually be seen within one to two weeks. If an optimal response is not achieved, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Increasing the dosage beyond 100 mg a day is unlikely to produce any further benefit.

TENORMIN may be used alone or concomitantly with other antihypertensive agents including thiazide-type diuretics, hydralazine, prazosin, and alpha-methyldopa.

Since TENORMIN is excreted via the kidneys, dosage should be adjusted in cases of severe impairment of renal function. No significant accumulation of TENORMIN occurs until creatinine clearance falls below 35 ml/min/1.73 m^2 (normal range is 100-150 ml/min/1.73 m^2); therefore, the following maximum dosages are recommended for patients with renal impairment:

Creatinine Clearance (ml/min/1.73 m^2)	Atenolol Elimination Half-life (hrs)	Maximum Dosage
15-35	16-27	50 mg daily
<15	>27	50 mg every other day

Patients on hemodialysis should be given 50 mg after each dialysis; this should be done under hospital supervision as marked falls in blood pressure can occur.

HOW SUPPLIED: Tablets of 50 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 105 embossed on the other side are supplied in monthly calendar packages of 28 tablets, bottles of 100 tablets, and unit-dose packages of 100 tablets. Tablets of 100 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 101 embossed on the other side are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Protect from heat, light, and moisture. Store unit-dose and calendar packages at controlled room temperature.

1750 End-Systolic Dimension-Wall Thickness Relations During Myocardial Ischemia in Conscious Dogs. A New Approach for Defining Regional Function

GENTA OSAKADA, OTTO M. HESS, KIM P. GALLAGHER, W. SCOTT KEMPER, and JOHN ROSS, Jr.

Using the relations at end-systole between left ventricular pressure, chamber dimensions, and regional left ventricular wall thickness (ultrasonic dimension gauges), overall and regional left ventricular function were studied during progressive coronary stenosis in conscious dogs. During regional ischemia, the end-systolic pressure-diameter relation shifted progressively, suggesting a global decrease in ventricular contractility. However, the end-systolic points relating left ventricular wall thickness in the ischemic region to end-systolic left ventricular pressure revealed the regional nature of the abnormality, showing a progressive displacement to the left of the control point, whereas there was no significant displacement of this relation in the control region. There was a progressive increase at end-systole in an index of regional wall stress. Regional end-systolic wall thickness-pressure relations provide a new index for defining the regional contractile state of the left ventricular myocardium. This index is potentially load-independent and may have echocardiographic application.

1759 First Ultra-Short-Acting Beta-Adrenergic Blocking Agent: Its Effect on Size and Segmental Wall Dynamics of Reperfused Myocardial Infarcts in Dogs

RÜDIGER LANGE, ROBERT A. KLONER, and EUGENE BRAUNWALD

Beta-adrenergic blocking agents have an established role in the treatment of myocardial ischemia, but precipitation of adverse effects may restrict their use in some patients with acute myocardial infarction or in patients undergoing coronary bypass surgery. ASL-8052 is a new cardioselective ultra-short–acting beta blocker which allows abolition of beta blockade in animals within 16 minutes on termination of an intravenous infusion. The authors investigated the effect of ASL-8052 on myocardial infarct size, regional myocardial wall function, and hemodynamic function during a 3-hour experimental occlusion of the left anterior descending coronary artery followed by 3 hours of reperfusion in dogs. After 3 hours of reperfusion, the incidence of myocardial tissue necrosis, as a function of the in vivo area at risk, was significantly lower in ASL-8052–treated (48 ± 7%) than in control (73 ± 6%) dogs ($p < 0.025$). During the early hours of reperfusion, functional deterioration occurred in control dogs but not in treated dogs. During the occlusion period, infusion of ASL-8052 caused a decrease in heart rate of 22 ± 3% ($p < 0.001$) and of the first derivative of left ventricular pressure of 22 ± 4% ($p < 0.05$). Upon reperfusion, control dogs exhibited an increase in heart rate of 26 ± 1% ($p < 0.05$). In treated dogs, heart rate did not change. Hence, infarct size, reperfusion tachycardia, and myocardial wall asynergy were reduced in ASL-8052–treated dogs. A potential advantage of this agent is that its short duration of action would allow rapid reversal of beta blockade if adverse effects developed.

1768 Sympathetic Denervation Limited to a Region of Acutely Ischemic Canine Myocardium Increases Excitability Threshold and Duration of Bipolar Electrograms

JAMES B. MARTINS, THOMAS M. MUELLER, and DOUGLAS P. ZIPES

This study determines the direct effects of sympathetic denervation on excitability threshold and bipolar electrograms in acutely ischemic myocardium. Regional denervation was performed by application of phenol to the epicardium surrounding the ischemic zone in order to eliminate the possible hemodynamic effects that global cardiac denervation may exert on the ischemic zone. Regional denervation increased the peak excitability threshold and prolonged the duration of bipolar electrograms in epicardium and endocardium. Phenol application did not alter aortic pressure, ischemic wall motion (sonomicrometer technique), or ischemic zone blood flow (microsphere technique). Thus acute sympathetic denervation when limited to ischemic myocardium increases the peak excitability threshold and concomitantly prolongs the duration of bipolar electrograms.

1775 Transvenous Ablation of the Atrioventricular Conduction System in Dogs: Electrophysiologic and Histologic Observations

GUST H. BARDY, RAYMOND E. IDEKER, JACK KASELL, SETH J. WORLEY, WILLIAM M. SMITH, LAWRENCE D. GERMAN, and JOHN J. GALLAGHER

The correlation of histologic and electrophysiologic findings in dogs undergoing transvenous ablation of atrioventricular (AV) conduction has not been described. The creation of complete AV block in 10 dogs was attempted by delivering a direct-current shock transvenously through a standard tripolar electrode catheter. After 1 shock, all dogs were in complete AV block refractory to isoproterenol and atropine. Four weeks later, 5 dogs remained in complete AV block, 1 had first-degree block, and 4 had resumed normal AV conduction. Although temporary heart block occurred in each animal, chronic interruption of AV conduction was more difficult. Catheter location, atrial and His bundle electrogram relations, and the electrode used for delivery of energy were factors determining the effectiveness of this technique.

The Secure Diabetic
When diet alone has failed in NIDDM, successful management with diet and Diabinese® (chlorpropamide) is a source of great security to both patient and physician.
By safely lowering blood sugar, once-a-day Diabinese provides uncomplicated control every day for nearly a million secure diabetics.*
Diabinese is the most widely prescribed oral anti-diabetic agent. Its extensive record of efficacy and safety gives physicians confidence that their patients will be well controlled...while the once-daily regimen, regardless of dosage, helps assure compliance. And, Diabinese is economical.
*As with all sulfonylureas, hypoglycemia may occur with Diabinese, especially when dosage is not properly adjusted to the patient's requirements.

Diet & Diabinese (chlorpropamide)

Tablets 100 mg and 250 mg

A proven regimen... continue it with confidence.

BRIEF SUMMARY
DIABINESE® (chlorpropamide) Tablets

Contraindications: Diabinese is not indicated in patients having juvenile or growth-onset diabetes mellitus, severe or unstable "brittle" diabetes, and diabetes complicated by ketosis and acidosis, diabetic coma, major surgery, severe infection, or severe trauma. Diabinese is contraindicated during pregnancy. Serious consideration should be given to the potential hazard of its use in women of childbearing age who may become pregnant.
Diabinese is contraindicated in patients with serious impairment of hepatic, renal, or thyroid function.
Precautions: Use chlorpropamide with caution with barbiturates, in patients with Addison's disease or in those ingesting: alcohol, antibacterial sulfonamides, thiazides, phenylbutazone, salicylates, probenecid, dicoumarol or MAO inhibitors. Adequate dietary intake should be assured in all patients using Diabinese.
Warnings: DIABINESE (CHLORPROPAMIDE) SHOULD NOT BE USED IN JUVENILE DIABETES OR IN DIABETES COMPLICATED BY ACIDOSIS, COMA, SEVERE INFECTION, MAJOR SURGICAL PROCEDURES, SEVERE TRAUMA, SEVERE DIARRHEA, NAUSEA AND VOMITING, ETC. HERE, INSULIN IS INDISPENSABLE.
HYPOGLYCEMIA, IF IT OCCURS, MAY BE PROLONGED. (SEE ADVERSE REACTIONS.) IN INSTANCES OF CONCOMITANT USE WITH INSULIN, PATIENTS SHOULD BE CAREFULLY MONITORED.
Adverse Reactions: Usually dose-related and generally respond to reduction or withdrawal of therapy. Generally transient and not of a serious nature and include anorexia, nausea, vomiting and gastrointestinal intolerance; weakness and paresthesias.
Certain untoward reactions associated with idiosyncrasy or hypersensitivity have occasionally occurred, including jaundice, skin eruptions rarely progressing to erythema multiforme and exfoliative dermatitis, and probably depression of formed elements of the blood. They occur characteristically during the first six weeks of therapy. With a few exceptions, these manifestations have been mild and readily reversible on the withdrawal of the drug. The more severe manifestations may require other therapeutic measures, including corticosteroid therapy. Diabinese should be discontinued promptly when the development of sensitivity is suspected.
Jaundice has been reported, and is usually promptly reversible on discontinuance of therapy. THE OCCURRENCE OF PROGRESSIVE ALKALINE PHOSPHATASE ELEVATION SHOULD SUGGEST THE POSSIBILITY OF INCIPIENT JAUNDICE AND CONSTITUTES AN INDICATION FOR WITHDRAWAL OF THE DRUG.
Leukopenia, thrombocytopenia and mild anemia, which occur occasionally, are generally benign and revert to normal, following cessation of the drug.
Cases of aplastic anemia and agranulocytosis, generally similar to blood dyscrasias associated with other sulfonylureas, have been reported.
BECAUSE OF THE PROLONGED HYPOGLYCEMIC ACTION OF DIABINESE, PATIENTS WHO BECOME HYPOGLYCEMIC DURING THERAPY WITH THIS DRUG REQUIRE CLOSE SUPERVISION FOR A MINIMUM PERIOD OF 3 TO 5 DAYS, during which time frequent feedings or glucose administration are essential. The anorectic patient or the profoundly hypoglycemic patient should be hospitalized.
Rare cases of phototoxic reactions have been reported.
Edema associated with hyponatremia has been infrequently reported. It is usually readily reversible when medication is discontinued.
Dosage: The total daily dosage is generally taken at a single time each morning with breakfast. Occasionally, cases of gastrointestinal intolerance may be relieved by dividing the daily dosage. A LOADING OR PRIMING DOSE IS NOT NECESSARY AND SHOULD NOT BE USED. The mild to moderately severe, middle-aged, stable diabetic should be started on 250 mg daily. Because the geriatric diabetic patient appears to be more sensitive to the hypoglycemic effect of sulfonylurea drugs, older patients should be started on smaller amounts of Diabinese, in the range of 100 to 125 mg daily.
After five to seven days following initiation of therapy, dosage may be adjusted upward or downward in increments of 50 to 125 mg at intervals of three to five days. PATIENTS WHO DO NOT RESPOND COMPLETELY TO 500 MG DAILY WILL USUALLY NOT RESPOND TO HIGHER DOSES. Maintenance doses above 750 mg daily should be avoided.
Supply: 100 mg and 250 mg, blue, 'D'-shaped, scored tablets.
More detailed professional information available on request.

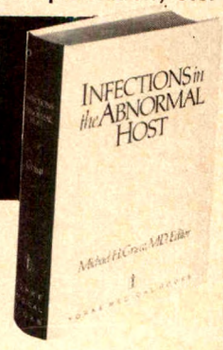
NOW AT YOUR FINGERTIPS...

the knowledge of world-renowned specialists to help you understand, diagnose, and manage infections which strike patients with:

Diabetes / Alcoholism / Cancer / Drug Addiction / Rheumatic Disease / Uremia / Pulmonary Disease / Hepatic Insufficiency / Allograft Transplantation, etc.

INFECTIONS IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color



Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

Yorke Medical Books, Box C-757, Brooklyn, NY 11205 AJCF3

Please send, on approval, _____ copies of INFECTIONS IN THE ABNORMAL HOST, edited by Michael H. Grieco. I will be free to read and consult the book in any and all relevant situations for 30 days. If I am not convinced it is a valuable professional tool, I will return it and owe nothing. Otherwise I will remit $85.00.

☐ Send invoice, plus shipping
☐ Payment enclosed, publisher pays shipping (same return privilege)
☐ Charge my credit card ☐ MasterCard ☐ Visa

Before you decide on invasive diagnosis, look at the alternatives in...

NONINVASIVE DIAGNOSTIC METHODS IN CARDIOLOGY

Volume 13, Number 3, Cardiovascular Clinics

Guest Editor: **Noble O. Fowler,** MD, Professor of Medicine, Director Division of Cardiology, University of Cincinnati Medical Center, Cincinnati, Ohio; with 45 contributing authors.

In his Prologue, Dr. Fowler states: "Not only are noninvasive diagnostic methods safer and less painful, they do not require hospitalization. Furthermore, since they can be done often, they permit the serial evaluation of heart disease over an extended period of time by carefully spaced observations." These very important reasons show why every clinician should investigate the new alternatives to invasive diagnostic techniques. In **Noninvasive Diagnostic Methods in Cardiology,** the many alternative procedures available to the clinician are discussed in detail. The book explains methods for noninvasive diagnosis and testing for virtually every form of cardiac dysfunction. Just a glance through the chapter headings reveals the breadth of its scrutiny.

Contents: Identification and Quantification of Ventricular Dysfunction by Echocardiography • Echocardiography in Congenital Heart Disease • Echocardiography in the Diagnosis and Quantification of Valvular Heart Disease • Echophonocardiographic Evaluation of Normal and Abnormal Prosthetic Valve Function • Echocardiographic Findings in Infective Endocarditis • Value and Limitations of Contrast Echocardiography in Cardiac Diagnosis • Echocardiography in Pericardial Disease • Clinical Applications of Two-Dimensional/Doppler Echocardiography • Myocardial Imaging in Myocardial Infarction: Technetium vs. Thallium • Exercise Radionuclide Angiography: Role in Diagnosis and Management of Cardiovascular Disease • Exercise Echocardiography and Stress Thallium-201 Imaging in Coronary Artery Disease • Prognostic Value and Safety of Exercise Testing Soon After Uncomplicated Myocardial Infarction • Exercise Testing in Patients with Aortic and Mitral Valve Disease: Current Applications • Electrophysiologic Testing: Clinical Applications • Ambulatory Electrocardiogram: Clinical Applications • The Use of Systolic Time Intervals for Evaluation of Left Ventricular Function • Serum Enzymes, Isoenzymes, Myoglobin, and Contractile Proteins in Acute Myocardial Infarction • Provocation of Coronary Artery Spasm • CT Scanning of the Heart.

410 pp. 239 ill. Ready July 1983. About $50.00.

The Editor-in-Chief of the Cardiovascular Clinics is Albert N. Brest, MD.

PRECAUTIONS.

Siemens Dialog 700 Programmer.

- As certain settings may subject the patient to adverse effects, it is recommended that only qualified personnel use the programming unit.
- The programming wands contain strong permanent magnets. Therefore, items sensitive to magnetic fields such as watches, TV sets etc. may be adversely affected or damaged if held close to these magnets.
- If the programming unit is not to be used for some time, the batteries should be removed.

Siemens Implantable Pulse Generators and Leads.
For implantation procedure and more comprehensive warnings, please read Physician's Product Manual (ME 372/5455.101).

General.
Although extensive testing is done before, during and after t assembly against high quality standards, this device has not been subject to in-vivo tests where the full capacity of the batt has been utilized.

The electronics
used in this pulse generator consists of two highly reliable m lithic circuitries with a few additional discrete passive compo

art - by Siemens:

(Our new DIALOG Programmer 700 retrieves important information from your patient's heart, and gives the instructions to the pacemaker.)

— This is your doctor speaking. Please identify yourself.
— Here Pacemaker Siemens 718, serial No. 241800781.
— The date of last programming?
— Oct. 21, 1982.
— Any major events since last follow-up?
— Yes. Three tachy-arrhythmia attacks. And 5.6 millions of stimuli emitted.
— Please give me the programmed rate, amplitude, pulse duration, refractory period, hysteresis value, sensitivity, mode...

With the Siemens DIALOG, you can have a true dialog with your patient's heart. The portable Programmer 700 is easy and safe to operate with very little training. The step-by- step instruction shows at the display to guide you through the menu organized software.

The functions of the eight membrane keys depend on the menu chosen and are shown on the display.

The Programmer presents the eight programmable parameters one by one and their range of adjustment. Interrogation of the pacemaker is made similarly.

* The Siemens Dialog System is in short the most sophisticated clinical aid for pacemaker diagnosis and treatment available today.

And not only today. The Programmer 700 is versatile even in the sense of communicating with earlier pulse generators, as well as being ready for future generators.

WE WERE THE FIRST. WE STILL ARE.

Headquarters: Siemens-Elema Pacemaker Division, S-171 95 Solna, Sweden. U.S. Division: Siemens-Elema Pacemaker Systems, 1765 Commerce Drive, Elk Grove Village, Illinois 60007. Tel. (312) 981 49 10/(800) 323 06 19.

The power source
is a lithium-iodine cell, manufactured to the highest standard for use in cardiac pulse generators. Statistics proving the expected service life for this cell are not yet available.

The final service life of implanted pulse generators depends on many factors such as pulse rate, pulse duration, pulse amplitude, the proportion of time during which the generator is inhibited, the load from the pacing lead, etc.

Intermittent stimulation
may be caused by different kinds of lead complications, such as a broken electrode insulation or an electrode tip which is not sufficiently fixed in the ventricle.

A perforation of the ventricular wall is possible if the guide catheter/stylet is handled the wrong way during the lead implantation.

Complications
resulting from surgical procedures could be extrusion of t generator, infection, fluid accumulation etc.

Stimulation of muscles adjacent to the pulse generator pocket may occur in the case of a unipolar lead system.

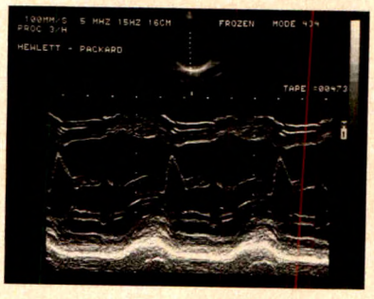
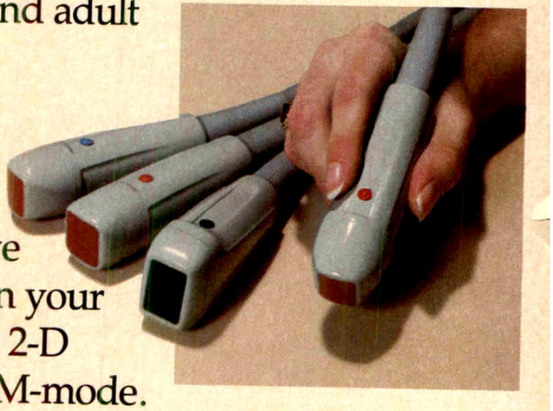
8 penetrating questions about any cardiac

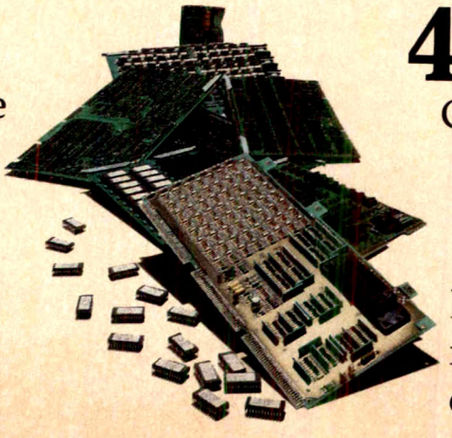
1. Does it produce high-resolution images? Hewlett-Packard's phased array Cardiac Imaging System does. Images are crisp, with well-defined boundaries, and free of artifact. Automatic focusing assures sharpness at all depths. And an extended gray scale reveals even the slightest difference in cardiac tissue.



2. What about new developments? You can upgrade the Hewlett-Packard modular system. Our latest improvement? 5MHz phased array imaging. It provides ultra-high resolution for pediatric and adult echocardiography.



3. How clinically versatile is it? Hewlett-Packard's Cardiac Imaging System can scan a wide variety of patients. Choose from five different transducers, depending on your clinical need. Display simultaneous 2-D sector and M-mode, single or dual M-mode. View the image in motion on the video screen. Tape it. Freeze it. Or generate a strip chart recording.



4. Is it reliable? Our microprocessor-based Cardiac Imaging System is highly reliable. Since the phased array system has electronic heads, there are no moving parts to break down.

questions to ask imaging system.

5. What about maintenance? The Hewlett-Packard System monitors its own performance with a series of built-in self-tests. If there's an error, it signals the operator. Problems can often be identified over the phone, minimizing downtime. Service, if needed, is both fast and economical.

6. Is it easy to use? Extremely. All controls are at your fingertips. Just set it up once, then make only fine adjustments for each patient. The system even includes a comprehensive on-line cardiac analysis package for automatic computation of cardiac parameters and generation of reports.

7. Is it mobile? The compact system can be taken where it's needed, from Echo Lab to CCU to Surgery. It's an Echo Lab on wheels.

8. Is it a solid investment? Image quality, upgradeability, versatility, reliability and Hewlett-Packard's commitment to worldwide service and support make our Cardiac Imaging System a sound investment. For more information, call your HP Sales Office and ask for the Medical Systems Department, or write to us: Hewlett-Packard, 100 Fifth Avenue, Waltham, Massachusetts 02254. Do it today. **The Ultra Sound Investment.**

CORONARY HEART DISEASE

Intracoronary Thrombolysis in Acute Myocardial Infarction: An Attempt to Quantitate Its Effect by Comparison of Enzymatic Estimate of Myocardial Necrosis With Left Ventricular Ejection Fraction

FRANZ SCHWARZ, MD, ANDREAS FAURE, MD, HUGO KATUS, MD, KLAUS VON OLSHAUSEN, MD, MANFRED HOFMANN, MD, GERHARD SCHULER, MD, JOACHIM MANTHEY, MD, and WOLFGANG KÜBLER, MD

The quantity of myocardium was estimated that can be salvaged by reperfusion of acute transmural myocardial infarction (MI). Serial analysis of serum creatine kinase (CK) activity was carried out in 41 consecutive patients with acute MI who underwent intracoronary thrombolysis. Enzymatic estimate of MI size was calculated using an average (method A) and an individually determined elimination constant (method B). Left ventricular ejection fraction 4 weeks after successful thrombolysis (cineangiogram) correlated inversely with MI size (method A: $r = -0.85$, method B: $r = -0.76$; both $p < 0.001$). Patients with recanalization within 4 hours after the onset of symptoms were assembled in group A_1 ($n = 13$, early reperfusion), and patients with successful recanalization after 4 hours in group A_2 ($n = 16$, late reperfusion). Group B consisted of 12 patients without reperfusion. MI size in group A_1 was 21 CK-g-Eq (method A) and 23 CK-g-Eq (method B), in group A_2 50 CK-g-Eq (method A) and 54 CK-g-Eq (method B), and in group B 73 CK-g-Eq (method A) and 63 CK-g-Eq (method B). Mean values in group A_1 were lower than in group A_2 and group B ($p < 0.05$). It is concluded that MI size was significantly reduced to about one third after early reperfusion as compared with no reperfusion. In contrast, MI size was not significantly reduced after late reperfusion.

The salvage of myocardium after coronary artery reperfusion in acute transmural myocardial infarction (MI) is critically dependent on the duration of coronary artery occlusion.[1] Non-surgical reperfusion has been established by use of intracoronary thrombolysis with streptokinase infusion in patients with acute MI.[2] The effect of the duration of ischemia on contraction of MI area has been studied,[3] but the effect on the enzymatic estimate of MI size has not clearly been defined. The present study quantitates the effects of early reperfusion (<4 hours after onset of symptoms) and late reperfusion (>4 hours after onset of symptoms) by the use of MI size.

From the Abteilung Innere Medizin III der Medizinischen Universitätsklinik, Heidelberg, West Germany. This study was supported by a grant from the Deutsche Forschungsgemeinschaft, Bonn Bad Godesberg, within the SFB 90 Kardiovaskuläres System, University of Heidelberg, Heidelberg, West Germany. Manuscript received November 24, 1982; revised manuscript received February 18, 1983, accepted February 22, 1983.

Address for reprints: Franz Schwarz, MD, Abteilung Innere Medizin III, Medizinische Universitätsklinik, Bergheimer Strasse 58, 6900 Heidelberg, West Germany.

Methods

Patients: Forty-one consecutive patients with acute MI in whom intracoronary infusion with streptokinase was performed to recanalize the obstructed coronary artery were studied. The diagnosis of acute MI was based on (1) acute chest pain lasting >30 minutes, (2) persistent S-T segment elevation (>2 mm in ≥3 leads of the standard 12-lead electrocardiogram) lasting >30 minutes and progressing to new Q waves. Not accepted to the study were (1) patients with symptoms >6 hours at entry into the coronary care unit, (2) patients with recurrent MI of a perviously infarcted area, and (3) patients >75 years of age. No patient was excluded from

invasive therapy because of poor hemodynamic condition. The clinical class was evaluated immediately after entry into the coronary care unit.[4]

Cardiac catheterization: Patients were studied with selective coronary arteriography using the femoral percutaneous technique. Heparin, 7,500 U intraarterially, and prednisolone, 250 mg intravenously, were given to prevent allergic reactions to streptokinase. Diazepam and morphine sulfate were administered when necessary. Selective arteriography of the right and left coronary artery (by manual injection) was performed in 6 projections, including 3 hemiaxial projections, after left ventricular (LV) cineangiography. When coronary occlusion was clearly visualized, intracoronary injection of 0.2 to 0.4 mg of nitroglycerin was performed to exclude spastic occlusion; thereafter, continuous infusion of streptokinase (2,000 U/min) was started with the coronary catheter in the coronary ostium. Injections of contrast material were repeated every 15 minutes and the infusion was stopped 15 minutes after reperfusion. If the coronary vessel was not reopened after infusion of 200,000 U of streptokinase, the attempt was given up. Successful reperfusion was defined as reopening of the occluded vessel with good runoff or markedly improved runoff in cases of subtotal occlusion. After the invasive diagnostic and therapeutic maneuvers, the patient was transferred to the coronary care unit.

Patient care: Patients were treated with bedrest. Administration of intravenous heparin was begun according to thrombin time to achieve therapeutic anticoagulation (prolongation of thrombin time 2 to 3 times the normal value). This therapy was followed by oral phenprocoumon. Patients left the coronary care unit after 4 to 5 days. LV and coronary angiography was repeated in 35 patients 4 weeks after acute MI. Monoplane LV cineangiography was performed in the 30° right anterior oblique projection (40 ml of Urografin® 76, 35-mm film, 50 frames/s, Philips dual-field 9–5–inch image intensifier system). Patients were discharged from the hospital 1 day later.

Enzymatic estimate of myocardial necrosis (MI size): Blood samples were taken from the patients immediately after admission and thereafter at hourly intervals for 12 hours, at intervals of 2 hours up to 20 hours, at intervals of 4 hours up to 48 hours, and at intervals of 12 hours up to 80 to 100 hours. Serum creatine kinase (CK) activity was determined by the enzymatic method, using a commercial monotest and a Centrifichem autoanalyzer.[5] Normal range of CK in serum is up to 80 U/liter.[5] Repeated measurements of serum CK activity from the same samples correlated closely: $y = -3.9 \pm 1.03\,x$, where y equals the second determination and x equals the first determination, $r = 0.95$. From the serum CK curves, the area under the curve was calculated by segmented approximation.[6] The elimination constant was determined in each patient from the declining slope of the time-activity curve by linear regression analysis using a logarithmic scale for serum CK activity.[7] Individual appearance curves were calculated and included the quantity of CK activity normally lost by excretion. Finally, MI size was calculated according to Sobel et al[8] with the use of the constants suggested by Bleifeld et al[6] with an average elimination constant of 0.06 (method A) as well as with individually determined elimination constants (method B).

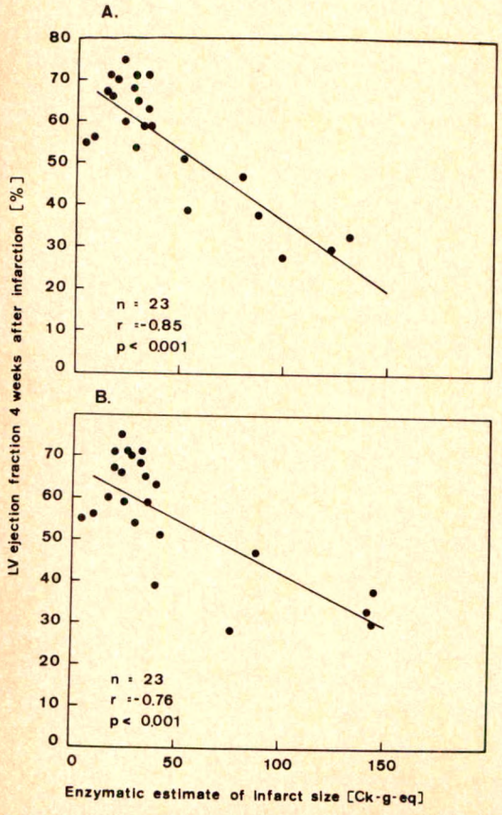

FIGURE 1. Inverse linear relations between enzymatic estimate of infarct size and left ventricular ejection fraction 4 weeks after successful thrombolysis. **A,** method A (enzymatic estimate calculated with an elimination constant of 0.06); **B,** method B (enzymatic estimate calculated with individual elimination constants).

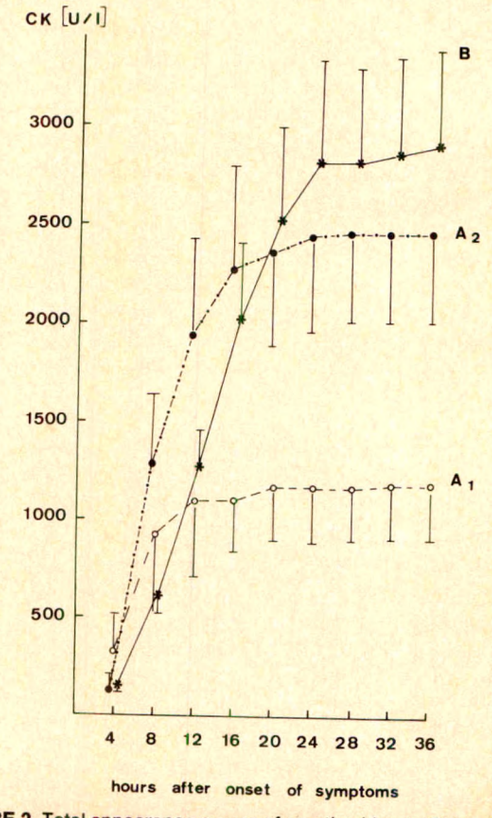

FIGURE 2. Total appearance curves of creatine kinase (CK) activities which were averaged at 4 hourly intervals for the 3 groups: group A_1 = reperfusion within 4 hours; group A_2 = reperfusion after 4 hours; group B = no reperfusion. The plateau of the curve of group A_1 was lower than that of both other groups ($p < 0.05$).

MB fraction of CK was determined by radioimmunoassay of our own design (HK). The interassay variations are <10%. The peak values of CK activity and the MB fraction were compared in 24 patients with acute MI, and a close correlation was obtained between both measurements (r = 0.85).

Analysis of angiograms: The angiograms were interpreted independently by 2 experienced observers. From coronary arteriograms, obstructions were determined and collateral circulation to the distal vessel segment (infarct vessel before recanalization) was carefully noted. Coronary anatomy was scored as suggested by Gensini[9] and scores were calculated for all coronary vessels and for the MI vessel. The Gensini score evaluates (1) the geometrically increasing severity of coronary lesions (based on the nonlinear correlation between percentage stenosis and coronary flow), (2) the significance of their location (estimate of the size of the perfusion area), and (3) the modifying influence of the coronary collateral vessels. Estimates of the severity of coronary anatomy by 2 observers correlated highly (r = 0.90, n = 60). From the LV angiograms, end-diastolic, end-systolic, and stroke volumes were determined, and the ejection fraction (EF) was calculated.[10] The EF was measured by 2 experienced observers independently in 15 patients and comparison of data revealed a good correlation coefficient of 0.93.

Statistical analysis: For statistical analysis, the analysis of variance, the Student-Newman-Keuls test, and the chi-square procedure (Brandt-Snedecor) were used.[11] Differences were considered significant when p was <0.05. Mean values ± the standard deviation are given in the tables and the Results section. In Figure 2 the standard error of the mean is depicted.

TABLE I Clinical and Baseline Hemodynamic Characteristics

	Group A_1: Early Reperfusion	Group A_2: Late Reperfusion	Group B: No Reperfusion
Patients (n)	13	16	12
Age (yr)	57 ± 10	58 ± 8	53 ± 10
Sex, male	10	14	12
Killip class I before therapy	12	13	10
Killip class II before therapy	1	3	2
Anterior infarction	6	6	5
Inferior infarction	7	10	7
Previous infarction	0	2	2
Gensini score (all vessels)	47 ± 19	50 ± 27	60 ± 24
Gensini score (infarct vessel)	41 ± 18	39 ± 21	46 ± 19
Infarct vessel			
Left anterior descending branch	6	6	5
Left circumflex branch	2	3	2
Right coronary artery	5	7	5
Angiographically visible collaterals to infarct	4	7	4
Left ventricular ejection fraction before therapy (%)	52 ± 10	46 ± 11	45 ± 14
Interval (h) between onset of symptoms and catheterization	2.9 ± 0.7*†	4.3 ± 0.8	3.8 ± 0.7
Interval (h) between onset of symptoms and reperfusion	3.1 ± 0.6	5.1 ± 0.7	. . .
Serum CK activity before therapy (U/liter)	41 ± 14	55 ± 45	45 ± 14
Dose of streptokinase ($\times 10^3$ IU)	113 ± 46*†	167 ± 44	173 ± 48
Direct-current shock during acute MI	1	3	2

Results

MI size versus LVEF 4 weeks after thrombolysis (Fig. 1): Data on MI size and LVEF 4 weeks after successful thrombolysis (as a quantitative measure of LV dysfunction in the chronic stage of MI) were compared. Patients who had previous MI were excluded from the comparison.[12] Significant close inverse linear correlations were obtained (Fig. 1).

To quantitate the effect of early and late reperfusion on MI size, the following 3 groups were established: 13 patients with successful recanalization of the MI vessel <4 hours after the onset of symptoms were assembled in group A_1, 16 patients with recanalization after >4 hours in group A_2 and 12 patients with unsuccessful attempts to recanalize in group B.

LVEF 4 weeks after acute MI was 62 ± 9% in group A_1 (n = 10), 52 ± 16% in group A_2 (n = 13), and 43 ± 13% in group B (n = 9). The mean values in group A_1 and group B differed significantly (p <0.05), whereas differences between groups A_1 and A_2 as well as A_2 and B were not significant (p >0.05). Patients with reocclusion of the MI vessel (groups A_1 and A_2) were excluded from this comparison.

Quantification of the effect of early and late reperfusion and comparison with no reperfusion (Fig. 2): The age of the patients, sex, Killip class at entry into the coronary care unit, the number of anterior and inferior MI, the number of previous MI, baseline Gensini score for all coronary vessels, Gensini score for the MI vessel, localization of MI vessel, collateral supply to MI vessel, baseline EF, and serum CK activity were comparable among the groups (Table I). The interval between the onset of symptoms and recanalization was 3.1 hours in group A_1 and 5.1 hours in group A_2. The time between the onset of symptoms and the start of catheterization was shorter in group A_1 than in both other groups (Table I). The dose of intracoronary streptokinase was smaller in group A_1 than in groups A_2 and B. In group A_1, 12 of 13 patients had total occlusion of the MI vessel and 1 patient had subtotal occlusion with poor runoff. In group A_2, 14 of 16 patients had total occlusion and 2 patients had subtotal occlusion before therapy.

Table II lists the different time intervals between the onset of symptoms and peak CK activity, respectively, the time at which 80% of plateau of total CK activity was reached. The values were significantly lower in groups A_1 and A_2 as compared with group B. The plateau of total appearance of CK activity was significantly lower in group A_1 than in both other groups. Figure 2 illustrates average CK values (appearance curves) at 4 hourly intervals in the 3 groups. The elimination constants of CK activity from serum did not differ significantly among groups (Table II). MI size (Table II) was lower in group A_1 than in both other groups. In contrast,

* $p < 0.01$ versus group B; † $p < 0.05$ versus group A_2; ‡ $p < 0.05$ versus group B; CK = creatine kinase; SD = standard deviation.

MI size in group A_2 was not different from that in group B.

Hospital course: Patients were hospitalized for 4 weeks after acute MI. Recurrence of MI by clinical or enzymatic criteria, or both, was observed in 3 patients in group A_1 and in 2 patients in group A_2 during the hospital course. Complications of intracoronary streptokinase were minor bleeding at the puncture site in 5 patients, and gastrointestinal bleeding requiring blood transfusions in 1 patient. No patient in group A_1 and A_2 but 3 patients in group B died during their hospital course.

The drugs used during acute MI and during the hospital course are listed in Table I. No significant differences existed between groups except in the use of beta-adrenergic agonists which were more often used in group B than in group A_1.

Discussion

The data in the present study reveal that early reperfusion (<4 hours after the onset of symptoms [group A_1]) reduces the MI size to about one third of that observed in patients without recanalization of the MI vessel (group B). In contrast, reperfusion after periods >4 hours (group A_2) had little effect on MI size. Furthermore, group A_1 patients had a significantly smaller MI size than did those in group A_2.

The size of the MI is determined by (1) the duration of ischemia,[1] (2) the residual flow to the ischemic area[13] through collateral vessels, and (3) the size of the perfusion area of the MI vessel (area at risk,[14]). In the present study the groups were comparable with regard to the MI vessel and angiographically visible collaterals to the ischemic area. Therefore, residual blood flow to the ischemic area can be assumed to be similar. The size of the perfusion area was estimated by the Gensini score which incorporates the size of the territory perfused by a coronary vessel; this score was similar among groups.

Validity of enzymatic estimate of MI size: MI size determined by analysis of total serum CK activity correlated closely to the pathologically measured MI size ($r = 0.93$) in 15 patients with acute MI studied by Bleifeld et al.[5] A more recent study by Grande et al[15] described highly significant correlations (r between 0.71 and 0.87) between MI size and myocardial necrosis (nitroblue tetrazolium staining and histologic study). Myocardial necrosis ranged between 5 and 160 g of tissue in the latter study,[15] therefore including even large MI. These studies confirm that MI size in patients with acute MI can be estimated with acceptable accuracy from serial analysis of total CK activity in serum. The influence of reperfusion and of streptokinase on myocardial CK release and degradation in serum is not yet fully understood. However, because streptokinase was used in all 3 groups, a systematic error can be excluded. In addition, the determination of CK activity and MB fraction showed a close correlation ($r = 0.85$) in the present study, thereby excluding the possibility of altered enzyme activity due to the therapeutic intervention.

In the present study, MI size was calculated by using an average elimination constant (method A) and by determining an individual elimination constant (method B). In the larger MI the elimination constant is easily determined from the monoexponential part of the plasma curve, but with the smaller MI the determination becomes less precise. The use of an average elimination constant is supported by the finding that

the elimination constants were similar in both large and small MI.[15] The elimination constant may vary among different individuals with a range of 0.036 to 0.096 in the present series: the mean value among reperfused patients was 0.067 and was similar to the value of 0.057 in nonreperfused patients (Table II). The results and conclusions in this study are independent of whether the elimination constant was assumed constant or determined individually.

LV function as measured by the EF 4 weeks after reperfusion correlated with MI size. We assumed that after 4 weeks the LVEF reflected the size of myocardial necrosis which was measured by MI size during acute MI. The close inverse correlation observed is an argument that enzymes reflect MI size even under conditions of reperfusion in man. A correlation of MI size and EF was not previously documented in patients with reperfusion in acute MI. Rogers et al[12] described a close inverse correlation ($r = -0.78$) between MI size and EF in patients with acute MI without reperfusion. Morrison et al[16] described a similar correlation ($r = -0.78$) when excluding patients with previous MI. In some rare cases with extensive right ventricular MI, the correlation was poor because of the excessive release of enzymes from the right ventricle.[16] Our findings in patients with reperfusion of acute MI are in accordance with these studies. Extensive right ventricular MI, a relatively rare complication of inferior MI,[17] was not observed after reperfusion in the present series. It has to be considered that reperfusion in man incorporates restricted reflow through residual coronary stenosis into infarcted and ischemic tissue. Thus, although the enzymatic method may have limitations,[18–20] our data support the conclusion that in patients with thrombolysis enzymes can be used to estimate MI size.

Limitations of enzymatic method for determination of MI size: The enzymatic method has certain limitations: (1) subendocardial MI, scattered MIs, and small transmural MIs release a greater amount of CK into the blood compared with large MIs.[18–20] Therefore, the size of a large MI may become underestimated because the serum entry ratio of CK decreases as the size of the necrosis increases in the experimental animal.[19,20] Two studies of the same group[19,20] have investigated the problem of a variable serum entry ratio of CK after experimental coronary artery ligation in the dog. Two different conclusions have been reached: the first study[19] could not distinguish small from large histologic MI by serum enzyme measurements; the second study[20] described a linear relation with the coefficient $r = 0.75$ between enzymatic and pathologic MI size. The discrepancy between both studies was explained by technical reasons (interval of blood sampling and location of coronary ligation). The latter study finally concluded that MI size underestimated histologic necrosis in large experimental MI to some extent.[20] Whether a similar underestimation occurs in MI in human subjects is unknown: a linear relation between MI size and histologic MI was described in man.[6,15] Coronary artery reperfusion during acute MI causes greater release of enzymes per gram of infarcted tissue than does permanent coronary occlusion.[21,22] Vatner et al[21] measured MI size in dogs reperfused after 1 or 3 hours of coronary occlusion. The average amount of CK in the blood over 24 hours was higher after reperfusion as compared with permanent occlusion (per gram of pathologically infarcted tissue). Nevertheless, a good correlation existed between MI size and the pathologically determined extent of MI ($r = 0.90$). These findings justify comparison of MI size between groups with reperfusion as in the present study (groups A_1 and A_2). The data revealed a shorter time interval between the onset of symptoms and peak serum CK activity in groups with reperfusion as compared with the group without reperfusion. This finding may be due to a washout effect[21] and may produce some overestimation of MI size in groups A_1 and A_2. The reduction in myocardial necrosis in the present study should be even greater than that in groups A_1 and A_2 as compared with group B.

Clinical implications: A beneficial effect of early reperfusion on MI size and on LVEF was shown compared with patients with late reperfusion and without reperfusion. Early reperfusion reduced MI size to about one third of that seen in the group without reperfusion. Late reperfusion seemed to have only a minor effect, although it cannot be excluded that some overestimation of MI size due to enhanced enzyme washout occurred in this group. The duration of ischemia is a major determinant of therapeutic success of reperfusion of acute MI.

The present study is a retrospective analysis and quantitates the amount of myocardium that can be salvaged by early reperfusion in human subjects. The question being investigated was whether early reperfusion limits MI size as compared with no reperfusion. A randomized study may answer the question of whether streptokinase therapy is superior to conventional therapy. However, we are not aware of a method for randomization that could answer the question of whether early reperfusion limits MI size.

*Predicted theoretical service life of 10 years based on 100% dual-chamber demand (DDD) pacing at 70 ppm and delivering 0.6 ms/6 mA pulse into a 510-ohm load.

Cordis Sequicor II Technical Information

The nominal parameter values of the Sequicor II, Model 233F

Modes	DDD, DVI, DAD, VDD, VAT, VVI, DOO, VOO		
Programmed pacing rate, ppm	30 to 120 in 5-ppm increments		
Sensitivity mV (each channel)	Off, 0.5, 1.3, 2.5		
Pulse duration/ output current, ms/mA (each channel)	0.2/2 0.3/3 0.4/4	0.5/5 0.6/6 0.8/8	1.0/10 2.0/12
A-V delay, ms	75, 100, 125, 150, 175, 200, 250		
Refractory, ms (each channel)	250, 300, 350, 400, 500		
Output voltage, V (open circuit)	8 mA or higher below 8 mA	8.4 4.0	
Pace limit, ppm	160		
Battery test rates, magnet applied, ppm	70 62½ 52½	Battery satisfactory Battery nearing depletion Backup pacing (VOO) activated	
Pacing configuration	Unipolar		
Parameters revealed through telemetry	Mode, rate, sensitivity, output current, pulse duration, refractory period, and last two digits of pacer serial number.		

Specifications

Power source	Two Cordis lithium cells
Specific gravity	1.8
Weight, g	73
Thickness, mm	15
Width, mm	57
Height, mm	69
Radiopaque I.D. letters	HK

Important Information—Sequicor II

Indications and Contraindications

The medical literature describes currently accepted indications and contraindications for various pacing/sensing modes. The physician's clinical experience and judgment must ultimately be the guide in selecting the pacing mode best suited to the patient's needs.

Pacing of the ventricles (VVI) is indicated for control of heart rate in patients with A-V block or sick sinus syndrome. *Asynchronous pacing may be contraindicated for long-term pacing when inherent activity is present or is likely to be present in the chamber being paced.* There are no other known contraindications for ventricular pacing to control heart rate.

Atrial-synchronized ventricular pacing (VVD) is indicated for permanent or intermittent complete heart block with normal atrial rhythm. A-V sequential (DVI) pacing is indicated for permanent sinus bradycardia with or without heart block. Automatic dual-chamber demand pacing (DDD) is indicated when there is an A-V conduction disturbance and/or sinus node dysfunction (sinus bradycardia with A-V block or bradytachy syndrome). These atrial pacing modes are intended for patients who would benefit from the restoration of atrial contribution to cardiac output.

Atrial-synchronized ventricular pacing and automatic dual-chamber demand pacing modes are contraindicated for use in the presence of persistent atrial flutter or atrial fibrillation.

Precautions

Use Only Models 255A and 256A Cordis Programmers

Only a Cordis Model 255A Programmer III or Cordis Model 256A Interactive Programmer can be used with the Cordis Model 233F Sequicor pacer. The Sequicor II pacer *will not respond* to programming transmissions from other programmers. Do not use Cordis Models 166 and 222 Omnicor Programmers or programmers of other manufacturers.

"Use Before" Date

To assure maximum service life, pacers must be implanted before the "Use before" date shown on the package label.

Warnings

None.

Adverse Effects

A number of complications related to pacer therapy have been reported in the medical literature. The complications listed below may occur at any time after implantation.

Pacer—battery depletion, electromagnetic interference, component malfunction.

Lead—unsatisfactory electrode position, fracture, displacement, perforation of heart wall, faulty connection with pacer, migration through body tissue.

Patient—reaction, infection/erosion, increase in stimulation threshold, hemothorax, pneumothorax, embolism, thrombosis.

Read the *Instructions for Use* for more complete information prior to using.

Caution: Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

Less chance of depression, insomnia and nightmares than propranolol
Because hydrophilic (water-soluble) Corgard® (nadolol tablets) does not readily cross the blood-brain barrier, CNS side effects should occur less frequently than with highly lipophilic propranolol.*
The most commonly reported CNS side effects of Corgard, dizziness and fatigue, have each been reported in approximately 2 of 100 patients receiving Corgard.*
Once-a-day Corgard is as effective as propranolol, qid, in both hypertension and angina pectoris.[1]
CORGARD®

ONCE A DAY FOR HYPERTENSION

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure — Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evidence of embry fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times (on a mg/kg basis) than maximum indicated human dose; no teratogenic potenti seen in any of these species. There are no well-controlled studies in pregnant w therefore, use nadolol in pregnant women only if potential benefit justifies potenti to the fetus.

Nursing Mothers — It is not known whether this drug is excreted in humar Because many drugs are excreted in human milk, exercise caution when nad administered to a nursing woman. Animal studies showed that nadolol is found milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have not been establish

ADVERSE REACTIONS: Most adverse effects have been mild and transient an rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than 60 beats per r occurs commonly, and heart rates below 40 beats per minute and/or sympt bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral va insufficiency, usually of the Raynaud type, have occurred in approximately 2 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have occurred in about 1 of 100 patients. Single instances of first degree and third degree block have been reported; intensification of AV block is a known effect of beta-bl (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Ner System —** Dizziness or fatigue reported in approximately 2 of 100 patients; paresth sedation, and change in behavior reported in approximately 6 of 1000 pa **Respiratory —** Bronchospasm reported in approximately 1 of 1000 patient CONTRAINDICATIONS and WARNINGS). **Gastrointestinal —** Nausea, dia abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous —** Each following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, ey skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; c nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug us not clear, sleep disturbances have been reported. The oculomucocutaneous sync associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects reported with other adrenergic blocking agents have not been reported with nadolol, they shou considered potential adverse effects of nadolol. **Central Nervous System —** reve mental depression progressing to catatonia; visual disturbances; hallucinations; an reversible syndrome characterized by disorientation for time and place; short memory loss, emotional lability with slightly clouded sensorium; decreased perform on neuropsychometrics. **Gastrointestinal —** mesenteric arterial thrombosis; isch colitis. **Hematologic —** agranulocytosis; thrombocytopenic or nonthrombocyto purpura. **Allergic —** fever combined with aching and sore throat; laryngosp respiratory distress. **Miscellaneous —** reversible alopecia; Peyronie's dis erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodia In addition to gastric lavage, employ the following measures as appropriat determining duration of corrective therapy, take note of long duration of effect of na

Excessive Bradycardia — Administer atropine (0.25 to 1.0 mg). If there response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diuretic. It has been rep that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or levarterenol. (Th evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a $beta_2$-stimulating agent and/or a theophy derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronou slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most pat respond to 160 mg or less daily). If treatment is to be discontinued, reduce do gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 8 increments until optimum blood pressure reduction is achieved; usual maintenance is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval; see package inse dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per t in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets. 40 mg and 80 mg tablets are also available in convenience packages containing 4 b cards of 7 tablets each.

Coronary Dilatory Capacity in Idiopathic Dilated Cardiomyopathy: Analysis of 16 Patients

DIETER OPHERK, MD, FRANZ SCHWARZ, MD, GERHARD MALL, MD, JOACHIM MANTHEY, MD, DETLEV BALLER, MD, and WOLFGANG KÜBLER, MD

Hemodynamic function and overall coronary blood flow (argon technique) were measured in 16 patients with idiopathic dilated cardiomyopathy (IDC) and in 12 patients without detectable heart disease (control subjects) referred for precordial pain. In patients with IDC, coronary blood flow was normal at rest (78 ± 17 ml/100 g·min versus 78 ± 9 in control subjects). During maximal inducible coronary vasodilation (dipyridamole, 0.5 mg/kg), coronary blood flow was significantly reduced (142 ± 38 ml/100 g·min versus 301 ± 64 in control subjects; p <0.001). Consequently, obtainable minimal coronary resistance was increased in IDC (0.54 ± 0.20 mm Hg/ml/100 g·min versus 0.23 ± 0.04 in control subjects; p <0.001). In patients with IDC, left ventricular (LV) end-diastolic pressure was significantly increased (19 ± 11 mm Hg versus 6 ± 3 in control subjects; p <0.005), and the LV ejection fraction was diminished (36 ± 11% versus 72 ± 3% in control subjects; p <0.001). In patients with IDC, LV end-diastolic pressure correlated significantly with the obtained minimal coronary resistance after application of dipyridamole (r = 0.85; p <0.001). LV catheter biopsy specimens revealed no alterations in myocardial microvasculature. Thus, coronary dilatory capacity is impaired in patients with IDC, due partially to an increase in extravascular component of coronary resistance.

Patients with idiopathic dilated cardiomyopathy (IDC) frequently have chest pain suggestive of ischemic heart disease, despite the presence of normal coronary arteries. There have been only a few studies of coronary circulation in patients with IDC, and these have yielded conflicting results.[1–6] Coronary dilatory capacity has not been systematically evaluated in patients with IDC, although a possible inadequacy of myocardial perfusion might be involved. Therefore, coronary blood flow was measured by an improved inert gas technique at rest and during pharmacologically induced coronary vasodilation leading to an exhaustion of coronary dilatory capacity.

Methods

Group A (control) consisted of 12 patients (7 male and 5 female, mean age 45 ± 9 years) without detectable heart disease. These patients had recurrent atypical chest pain and were referred for coronary arteriography to exclude an organic cause of the symptoms. All patients in this group had normal electrocardiograms at rest and during exercise and normal coronary and left ventricular (LV) angiograms.

Group B consisted of 16 patients (14 male and 2 female, mean age 42 ± 9 years) with clinical and angiographic evidence of IDC. The origin was unknown in all patients. None of these patients had valvular or coronary heart disease. Hemodynamic and angiographic data from patients in Groups A and B are given in Table I. All patients in Group B had an abnormal electrocardiogram with left bundle branch block (n = 8), right bundle block (n = 1), multifocal premature ventricular beats (n = 4), abnormal depression of the S-T segment in leads V_5 and V_6 (n = 4), and lack of R progression in leads V_2 and V_3 (n = 3). Sinus rhythm was present in all patients in Group B except Patient 14. They received premedication with 10 mg of oral diazepam and were in the fasting state.

Determination of coronary blood flow: Coronary blood flow was determined by the argon method after right and left-sided cardiac catheterization. Details on this method as well as its accuracy, which allows measurement of even high coronary flow rates of >300 ml/100 g·min, were reported previously.[7–12] The argon method represents an improved inert gas saturation technique. The patient spontaneously inspired a gaseous mixture (79% argon, 21% oxygen) over a period of 5 minutes. Simultaneously, arterial and coronary venous blood samples were continuously collected. Argon analyses were carried out by gas chromatography.

According to the formula of Kety,[13] coronary blood flow is proportional to tissue concentration of the indicator divided

AOP = aortic pressure; CBF = coronary blood flow; CR = coronary resistance; D = dipyridamole (0.5 mg/kg intravenously); HR = heart rate; LVEDP = left ventricular end-diastolic pressure; LVEF = left ventricular ejection fraction; LV Mass = left ventricular mass; NS = not significant; PAP = mean pulmonary arterial pressure; R = resting conditions; RAP = mean right atrial pressure; Vcf = mean velocity of circumferential fiber shortening.

by the mean arteriocoronary venous difference of the indicator. Tissue concentration of the myocardium results from the coronary venous concentration at the end of the saturation period multiplied by the tissue partition coefficient of the indicator (argon = 1.1). Coronary resistance was calculated as follows: [Mean diastolic aortic pressure − mean right atrial pressure (mm Hg)]/[coronary blood flow (ml/100 g·min)].

Evaluation of maximal coronary vasodilation: Measurements of coronary blood flow were carried out under resting conditions and during maximal inducible coronary vasodilation. The latter was achieved by the intravenous injection of 0.5 mg/kg of dipyridamole, which was administered over a period of 10 minutes. Immediately thereafter, blood sampling was started.

Minimal coronary resistance of normal coronary vessels of the dog heart has been found to be approximately 0.20 mm Hg/ml/100 g·min.[14–16] Comparable values of minimal coronary resistance measured in control subjects after intravenous application of dipyridamole[10,11,17] demonstrate that maximal vasodilation can be achieved by dipyridamole infusion (0.5 mg/kg intravenously). In order to confirm that the dose of dipyridamole was adequate for induction of maximal coronary vasodilation in patients with IDC, in 5 of these patients coronary resistance was measured (1) after an initial infusion of dipyridamole (0.5 mg/kg over a period of 10 minutes), and (2) immediately after a second infusion of dipyridamole in the same dose. The minimal coronary resistance after the first infusion was 0.45 ± 0.08 mm Hg/ml/100 g·min; the respective value after the second infusion was 0.43 ± 0.07 mm Hg/ml/100 g·min (the values are not significantly different). This observation suggests that even in patients with IDC the minimal coronary resistance is achieved by dipyridamole in a dose of 0.5 mg/kg body weight.

Coronary and left ventricular angiography: Selective coronary arteriography was performed with multiple views of the right (at least 3 projections) and left (at least 5 projec-

tions) coronary arteries, including hemiaxial projections. Intracardiac pressure were obtained by means of a fluid-filled catheter pressure transducer system. End-diastolic and end-systolic volumes, the ejection fraction, and mean velocity of circumferential fiber shortening were calculated from the monoplane angiogram in a 30° right anterior oblique projection. A representative measurement of LV wall thickness was made from right anterior oblique projection of the ventriculogram in end-diastole at the point approximately halfway between the apex and the aortic valve. LV muscle mass was calculated according to Rackley et al.[18]

Transarterial left ventricular endomyocardial biopsy: Using King's College bioptome and the St. Thomas' sheath,[19] biopsy specimens of 12 patients with IDC were taken from LV myocardium and immediately fixed by immersion with a 1.5% glutaraldehyde-1.5% formaldehyde mixture in 0.1 *M* phosphate buffer. The tissue was embedded and oriented in the block in such a way that endocardium, Purkinje fibers, and myocardium could be clearly identified by light and electron microscopic analysis. The amount of interstitial fibrous tissue was determined morphometrically[20] using point counting (5 to 20 test areas per patient, 36 test points per test area) at a magnification of 160:1.

Statistical analyses of the data were performed using *t* test for paired and unpaired analysis when appropriate. Statistical significance was accepted at the $p < 0.05$ level.

Results

Coronary blood flow: Coronary blood flow was 78 ml/100 g·min in control subjects (Group A) and reached the same value of 78 ml/100 g·min in patients with IDC (Group B, Table I) under resting conditions. After administration of dipyridamole, however, in patients in Group B, maximal obtainable coronary blood flow was markedly reduced to 142 ± 38 ml/100 g·min, that is, approximately 50% of the value obtained in Group A with maximal coronary flow rates of 301 ml/100 g·min ($p < 0.001$) (Table I, Fig. 1). Under resting conditions, coronary resistance was 1.03 mm Hg/ml/100 g·min in Group A and 1.04 in Group B (difference not significant [NS]). After dipyridamole administration, coronary

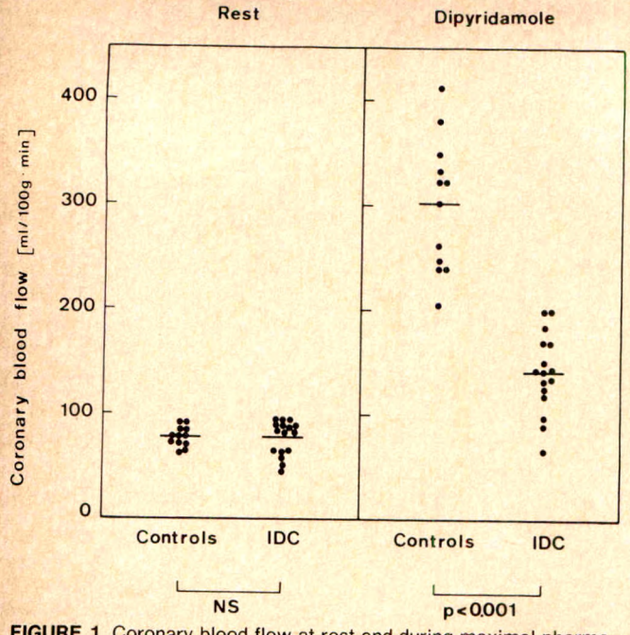

FIGURE 1. Coronary blood flow at rest and during maximal pharmacologically induced coronary vasodilation (dipyridamole 0.5 mg/kg intravenously) in control subjects and in patients with idiopathic dilated cardiomyopathy (IDC). A significant difference in coronary blood flow in control subjects and in patients with IDC was only found after vasodilation with dipyridamole ($p < 0.001$). NS = not significant.

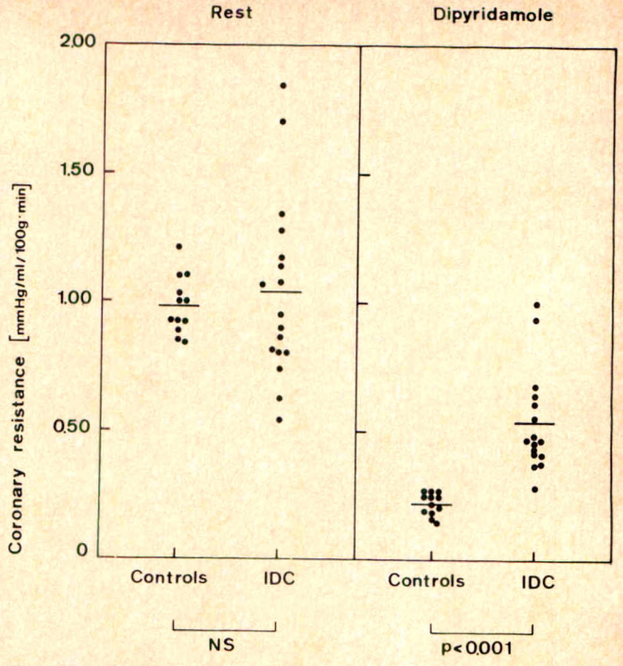

FIGURE 2. Coronary resistance at rest and after application of dipyridamole (0.5 mg/kg intravenously) in control subjects and in patients with idiopathic dilated cardiomyopathy (IDC). A significant difference in coronary resistance in control subjects and in patients with IDC was only found after vasodilation with dipyridamole ($p < 0.001$). NS = not significant.

resistance was reduced to 0.23 mm Hg/ml/100 g·min in Group A, versus 0.54 in Group B; this difference was highly significant ($p < 0.001$) (Table I, Fig. 2). In Group B, mean pulmonary arterial pressure and mean right atrial pressure were significantly elevated under resting conditions ($p < 0.01$ versus control values). After dipyridamole administration, pulmonary arterial pressure and right atrial pressure did not change significantly in either group. Heart rate and systolic and diastolic aortic pressures were comparable in patients in Groups A and B. In Group B, LV end-diastolic pressure was significantly ($p < 0.005$) higher than control values (18.6 mm Hg versus 6.5 mm Hg, Table I).

Coronary and left ventricular angiography: In patients in Groups A and B, coronary arteries and their subbranches were found to be free of even minor luminal irregularities. Data obtained at rest for LV ejection fraction, mean velocity of circumferential fiber shortening, and LV mass are given in Table I. Patients in Group A had a mean LV ejection fraction of 72% (range 68 to 78), compared with 36% (range 18 to 53) in patients in Group B, ($p < 0.001$, Table I). The mean velocity of circumferential fiber shortening in patients in Group B was significantly below the control values (Group A, 1.38 circ/s; Group B, 0.55 circ/s; $p < 0.001$). LV wall thickness was not significantly different in the 2 groups studied: LV mass averaged 73 ± 12.7 g/m^2 in Group A and 122 ± 45.7 in Group B ($p < 0.005$). Regression analysis in patients with IDC indicated that LV end-diastolic pressure ($r = 0.85$) is positively and LV ejection fraction ($r = -0.59$) is negatively related to minimal coronary resistance (Fig. 3 and 4). The 2 regressions are statistically significant ($p < 0.001$, $p < 0.05$). On the other hand, no significant correlation was found between minimal coronary resistance and LV mass ($r = 0.34$, $p > 0.05$).

Left ventricular biopsy: In patients with IDC, light and electron microscopy of specimens taken from LV myocardium (n = 12) showed hypertrophy of the muscle fibers, alterations of the nucleus, and a loss of myofibrils. From each patient, about 10 to 15 arterioles, metarterioles, capillaries, and venules could be analyzed. The arteriolar microvascular segments, ranging in external diameter from 5 to 50 μm, showed no pathologic changes such as intimal proliferation, medial dissection, or mural deposits. The capillary and venular segments also had a normal appearance without thickening of the basal lamina. Volume fraction of the interstitial fibrous tissue was 5.87 ± 5.51 ml/100 ml.

Discussion

Minimal coronary resistance in idiopathic dilated cardiomyopathy: The present study shows almost identical values for coronary blood flow under resting conditions in control subjects and in patients with IDC. A complete separation of the 2 groups, however, could be achieved after pharmacologic vasodilation by application of dipyridamole. Dipyridamole is an almost selective dilator of the coronary artery system[21] which was found to induce maximal coronary vasodilation in control patients at the dosage used in this

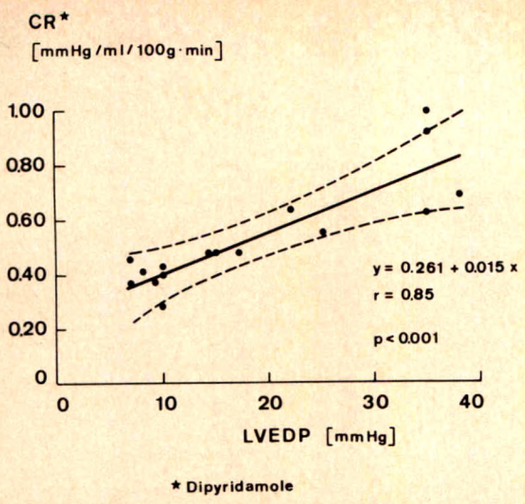

FIGURE 3. Relationship between minimal coronary resistance (CR) after application of dipyridamole (0.5 mg/kg intravenously) and left ventricular end-diastolic pressure (LVEDP) in 16 patients with idiopathic dilated cardiomyopathy. A significant ($p < 0.001$) linear correlation was found. The **dashed lines** represent 95th percentile confidence limits of the regression curve.

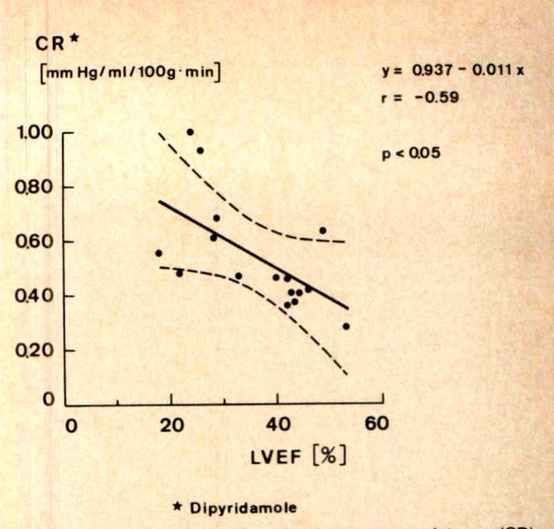

FIGURE 4. Relationship between minimal coronary resistance (CR) and left ventricular ejection fraction (LVEF) in 16 patients with idiopathic dilated cardiomyopathy. A significant ($p < 0.05$) negative linear correlation was found.

study.[9,11,17] Our data confirm that this dosage is sufficient to achieve exhaustion of coronary vascular reserve even in patients with IDC. After application of dipyridamole, minimal coronary resistance could be reduced to 0.23 ± 0.04 mm Hg/ml/100 g·min (range 0.17 to 0.27) in control subjects compared with only 0.54 ± 0.20 (range 0.28 to 1.00) in patients with IDC. The difference between the 2 groups is highly significant ($p < 0.001$) without overlap of the individual values.

Causes of increased minimal coronary resistance in patients with IDC: A similar reduction in coronary dilatory capacity has been observed in patients with coronary heart disease, and has been explained by obstructive lesions of the great epicardial arteries.[9,17] Since in patients with IDC obstructive lesions were not visible in the coronary angiogram, the reduced coronary dilatory capacity could be attributed to 1 of the following mechanisms:

1. The reduction in coronary reserve could be due to abnormalities of small intramyocardial vessels. If this were indeed the case, structural changes would be expected in the specimens taken from LV myocardium. Histopathologic study, however, revealed normal arterioles, metarterioles, capillaries, and venules in the patients studied.

2. A second mechanism that may cause a reduction of coronary reserve in patients with IDC relates to the adaptation of coronary microcirculation to myocardial hypertrophy. Clinical studies[22,23] suggested that increases in minimal coronary resistance do occur in association with LV hypertrophy. Although patients with IDC had an increased LV mass, no significant correlation was found between minimal coronary resistance and LV mass.

3. A third cause of the decreased coronary reserve in patients with IDC could be an increase in the extravascular component of coronary resistance.[14,15,24,25] Studies in animals during maximal coronary vasodilation have demonstrated that extravascular component of coronary resistance is important in the failing heart with increased LV filling pressure.[15] The positive correlation found between minimal coronary resistance and LV end-diastolic pressure confirms that an increased extravascular component of coronary resistance is at least partly responsible for the reduction of coronary dilatory capacity in patients with IDC. In addition, the results obtained in these patients suggest that impaired LV contraction contributes to the reduction in coronary dilatory capacity.

Clinical implications: These findings demonstrate a severe reduction of coronary dilatory capacity in patients with IDC, which may explain the frequent observation of anginal pain during physical exercise. With exertion, LV filling pressure increases, the ejection fraction decreases further, and the end-diastolic volume may increase—all of which will lead to increased intramyocardial extravascular pressure. This might further increase coronary resistance, resulting in myocardial ischemia that may contribute to a deterioration of pump function.

Prevalence and Significance of an Abnormal S-T Segment Response to Exercise in a Young Athletic Population

PAOLO SPIRITO, MD, BARRY J. MARON, MD, ROBERT O. BONOW, MD, and STEPHEN E. EPSTEIN, MD

Treadmill stress electrocardiography is employed widely to detect underlying cardiovascular disease in asymptomatic persons. To determine the frequency and significance of an abnormal S-T segment response to exercise in young athletes with increased left ventricular (LV) mass induced by physical conditioning, 75 male isometrically trained athletes without evidence of heart disease (mean age 21 years) and 48 nonathletic young normal subjects were studied by M-mode echocardiography and exercise electrocardiography. Ventricular septal and posterior free wall thicknesses and calculated LV mass were significantly greater in athletes than in control subjects.

An abnormal S-T segment response to exercise was present in 7 (9%) of the 75 athletes, all of whom had a LV mass >275 g and in 5 the LV mass was above the 95th percentile of that of the control subjects. An abnormal treadmill exercise test result also was present in 3 (6%) of 48 control subjects. Seven of the 10 subjects with abnormal exercise test results had radionuclide angiograms at rest and with exercise, each of which was normal. It is concluded, therefore, that (1) abnormal exercise test results occur commonly in both athletes and nonathletes; (2) almost 10% of isometrically trained athletes have "false-positive" exercise electrocardiograms, suggesting that this test has major limitations in screening for underlying cardiovascular disease in athletes; and (3) in athletes, a relation was present between "physiologically" increased LV mass and false-positive exercise test results.

It is well established that chronic athletic conditioning may produce alterations in cardiac structure and function that are usually relatively mild but can mimic certain organic heart diseases.[1,2] In addition, there have been several recent reports of sudden death in athletes,[3,4] causing concern and uncertainty regarding the proper medical evaluation of conditioned athletes.

The exercise (treadmill) electrocardiogram has been employed extensively as a noninvasive screening test to detect underlying cardiovascular disease (particularly coronary artery disease) in asymptomatic persons.[5] However, the frequency and significance of an "abnormal" S-T segment response to exercise in individuals in whom left ventricular (LV) mass was thought to be physiologically increased (that is, induced by athletic conditioning) are unknown. Therefore, to determine the prevalence of positive exercise test results in an athletic population, the relation of such positive tests to "physiologic" left ventricular hypertrophy, and the efficacy of the exercise electrocardiogram in the cardiovascular evaluation of athletes, we performed treadmill exercise studies in 75 young trained athletes, with 48 unconditioned individuals serving as control subjects.

Methods

The study group consisted of 75 male athletes aged 18 to 39 years (mean 21). Each was engaged in a formal conditioning program which included extensive isometric exercise training (that is, weight lifting). Fifty-nine athletes (40 football players and 19 wrestlers) were participating in intercollegiate athletics at the University of Maryland; the remaining 16 athletes were world-class weight lifters. Each athlete was considered free of organic cardiovascular disease on the basis of medical history and physical examination and the interpretation of the 12-lead electrocardiogram and M-mode echocardiograms. Forty-eight untrained subjects of similar age (range 20 to 57 years, mean 33) without cardiac symptoms or evidence of heart disease served as control subjects.

TABLE I Echocardiographic Findings in 75 Trained Intercollegiate Athletes and 48 Untrained Control Subjects*

	BSA	Wall Thickness VS (mm)	Wall Thickness PW (mm)	LV Mass (g)	$LVID_d$ (mm)
Athletes	2.1 ± 0.2* (1.6–2.6)	11 ± 1 (8–15)	11 ± 1 (8–14)	313 ± 63 (132–429)	55 ± 4 (39–63)
Control subjects	1.9 ± 0.1 (1.5–2.2)	9 ± 1 (8–12)	9 ± 1 (7–11)	205 ± 38 (134–295)	50 ± 3 (43–56)
p value	<0.001	<0.001	<0.001	<0.001	<0.001†

* Data are expressed as mean ± 1 standard deviation; ranges are shown in parentheses.
† When corrected for body surface area, this parameter showed no statistically significant difference between athletes and control subjects.
BSA = body surface area; LV = left ventricular; $LVID_d$ = left ventricular internal dimension in diastole; PW = posterior wall; VS = ventricular septum.

M-mode echocardiography was performed in a standard fashion[6] with a 2.25-MHz, 1.2 cm diameter transducer connected to a Hoffrel 201 ultrasound unit and recorded continuously on light-sensitive paper. Echocardiographic parameters were measured according to the recommendations of the American Society of Echocardiography.[7] Estimated LV mass was calculated from the echocardiogram using the method of Troy et al.[8]

A maximal graded treadmill exercise test was performed in all subjects, using a protocol in which the speed was increased 4 mph and the angle of incline increased 2% every 2.5 minutes. A positive S-T segment response to exercise was defined as S-T segment depression ≥1 mm from the J-point, with horizontal or negative slope for a duration of ≥0.08 second, during or immediately after exercise. Radionuclide angiography was performed in 7 subjects at rest and during supine bicycle exercise.[9,10] Before imaging, 10 mCi of technetium-99m–labeled human serum albumin was injected into an antecubital vein. Imaging was accomplished with a conventional Anger camera equipped with a high-sensitivity parallel-hole collimator oriented in a modified left anterior oblique position to isolate the left ventricle. Statistical analyses were performed using Student's *t* test for nonpaired variables and the chi-square test.

Results

Echocardiographic studies in the athletes showed alterations in cardiac structure consistent with the effects of isometric training[2,11] (Table I, Fig. 1). Ventricular septal and LV posterior free wall thicknesses and calculated LV mass were significantly greater in athletes than in the control subjects, both in absolute terms and when the data were normalized for body surface area. Ratios of ventricular septal to posterior free wall thickness ranged from 0.8 to 1.2 (mean 1.0), and hence no athlete met our criteria for asymmetric septal hypertrophy.[12] Left ventricular transverse diastolic dimension was greater in athletes than in control subjects; however, this difference did not achieve statistical significance when the values were corrected for body surface area. No statistically significant differences were found in the echocardiographic measurements among the 3 different groups of athletes (football players, wrestlers, and weight lifters).

Positive S-T segment response to exercise was present in 7 (9%) of the 75 athletes, 5 of whom had increased LV mass (above the 95th percentile of that of the control subjects). All athletes with positive S-T segment responses had an LV mass >275 g (Fig. 2).

TABLE II Echocardiographic Findings in Athletes and Control Subjects With Negative and Positive Exercise Tests*

	Patients (n)	Wall Thickness		LV Mass (g)
		VS (mm)	PW (mm)	
Athletes				
Negative Ex test	68	11 ± 1 (8–15)	11 ± 1 (8–13)	311 ± 64 (132–429)
Positive Ex test	7	11 ± 2 (10–15) p >0.05	11 ± 2 (10–14) p >0.05	321 ± 55 (276–410) p >0.05
Control subjects				
Negative Ex test	45	9 ± 1 (8–12)	9 ± 2 (7–11)	208 ± 36 (134–295)
Positive Ex test	3	9 ± 1 (8–10) p >0.05	9 ± 2 (7–10) p >0.05	162 ± 34 (136–200) p <0.05†

* Data are expressed as mean ± 1 standard deviation; ranges are shown in parentheses.
† When corrected for body surface area, this parameter showed no statistically significant difference between controls with negative and positive exercise test results.
Ex = exercise; LV = left ventricular; PW = posterior left ventricular free wall; VS = ventricular septum.

TABLE III Clinical and Echocardiographic Findings in 7 Athletes With Abnormal Exercise Tests

Athlete	Age (yr)	HR (beats/min) at Onset of S-T Depression	LV Mass		LV Function*
			g	g/m²	
1	17	140	276	156	Not tested
2	19	145	384	214	Normal
3	20	145	333	157	Normal
4	19	160	278	149	Normal
5	21	170	410	188	Normal
6	27	170	285	124	Normal
7	20	190	284	141	Not tested

* Evaluated by gated blood pool scintigraphy at rest and with bicycle exercise.
g/m² = mass (in grams) corrected for body surface area in meters squared; HR = heart rate; LV = left ventricular.

However, when athletes (or control subjects) with positive results on exercise tests were compared to those with normal test results, the groups did not differ significantly with regard to the magnitude of ventricular wall thicknesses and LV mass (Table II).

S-T segment depression appeared at heart rates <150 beats/min in 3 athletes and >150 beats/min in the other 4 (Table III). The 7 athletes with abnormal treadmill electrocardiograms were aged 17 to 27 years (mean 21).

A positive S-T segment response to exercise also was identified in 3 (6%) of the 48 control subjects. The 3 control subjects with abnormal treadmill electrocardiograms were aged 22 to 26 years (mean 24). Although positive exercise test results were more common in athletes than in control subjects, this difference did not achieve statistical significance (p >0.05).

Radionuclide angiography was performed in 7 of the 10 individuals with abnormal treadmill electrocardiograms (5 athletes and 2 control subjects). In each of these subjects the ejection fraction was within normal limits at rest (mean 58%, range 47 to 68) and increased by >5% during bicycle exercise (mean 72%, range 60 to 90). Left ventricular wall motion also was normal at rest and during exercise in each subject. The 2 athletes and 1 control subject with abnormal treadmill electrocardiograms who did not have radionuclide angiographic studies were 17, 20, and 26 years of age, respectively.

Discussion

These data show that young trained athletes without cardiovascular disease but with "physiologic" hypertrophy (that is, increased LV mass induced by chronic conditioning) commonly have an abnormal S-T segment response to treadmill exercise. The prevalence of "false-positive" exercise tests in our athletic population was slightly higher, but did not differ significantly from that in a nonathletic youthful control group. Evidence that these positive exercise tests do represent false-positive results rather than a manifestation of covert coronary artery disease is suggested by the finding that all athletes with abnormal exercise electrocardiograms (who underwent exercise radionuclide studies) demonstrated normal global and regional wall function. Furthermore, each athlete was young (≤30 years) and asymptomatic, making the possibility of coronary artery disease quite unlikely.

This study suggests that the increased LV mass induced by physical training might be partly responsible for the "ischemic" electrocardiographic changes seen with exercise. Each "abnormal" exercise test result in

the athletes occurred in subjects with LV mass >275 g; furthermore, in 5 of the 7 athletes with an abnormal exercise response the LV mass was above the 95th percentile of that of the control population. However, the relation between estimated LV mass and positive S-T segment response to exercise that we identified cannot be considered definitive. Mean LV mass in athletes with a positive S-T segment response to exercise was greater, but not significantly different from the LV mass in athletes with normal exercise test results. Also, we found no relation between calculated LV mass and abnormal S-T segment response to exercise in the control group.

Recently, investigators have emphasized that asymptomatic and healthy appearing competitive or recreational athletes may die of undetected and unsuspected cardiovascular disease.[3,4] Although a variety of cardiac structural malformations may be responsible for these deaths, hypertrophic cardiomyopathy is most common in young athletes and coronary artery disease is most common in older persons. However, the most efficient and reliable method for screening athletes for occult cardiovascular disease before participation in sports has not been established. This problem is important, affecting enormous numbers of vigorous and otherwise healthy young men competing in athletic programs. Our finding that a substantial proportion (almost 10%) of primarily isometrically trained athletes have false-positive results on exercise electrocardiograms suggests that the exercise stress electrocardiogram has major limitations as a reliable screening test for underlying cardiovascular disease in young athletes.

Heterogeneity of Left Ventricular Segmental Wall Thickening and Excursion in 2-Dimensional Echocardiograms of Normal Human Subjects

NATESA G. PANDIAN, MD, DAVID J. SKORTON, MD, STEVE M. COLLINS, PhD, HERMAN L. FALSETTI, MD, EDMUND R. BURKE, PhD, and RICHARD E. KERBER, MD

Regional abnormalities of left ventricular (LV) wall thickening and excursion have been demonstrated by 2-dimensional (2-D) echocardiography. However, the variability of normal segmental contraction has not previously been defined. We performed 2-D echocardiography in 12 normal men aged 19 to 27 years. We obtained short-axis images at the level of the mitral valve, chordae tendineae, papillary muscles, and apex at end-diastole and end-systole. A computer-based system divided each short-axis image into 12 cavity and wall segments, and analyzed percent systolic wall thickening along each radius and percent area change of each cavity segment. Overall variability of contraction as well as the contributions of several sources of variability were determined. The overall range of cavity segment area change was 0 to 100% and of segmental wall thickening was 0 to 150% in these normal subjects. Average contraction was similar at different ventricular levels. Significant differences were found between adjacent segments at each level as well as between subjects. Intrathoracic cardiac rotation and motion were minimal; correction for these movements did not significantly alter the variability of contraction as calculated from 2-D echocardiograms. Temporal asynergy of contraction did contribute to variability; correction resulted in a significant alteration in mean segmental area change (from 59 ± 20% [standard deviation] uncorrected to 66 ± 16% corrected, $p < 0.001$) and in mean segmental wall thickening (58 ± 29% uncorrected to 71 ± 34% corrected, $p < 0.01$). Substantial interexamination variability also occurred with an average difference in cavity segment area change of 20% per segment and in segmental wall thickening of 29% per segment between 2 analyses by the same observer. Thus, considerable intersegmental and intersubject variability of LV contraction occurs in normal subjects as exhibited on 2-D echocardiograms, exaggerated by technical difficulties in analyzing and reproducing the echocardiographic tracings. Significant differences in segmental wall thickening and endocardial excursion may occur in adjacent segments in normal subjects, and therefore such differences alone may not indicate cardiac disease.

Two-dimensional (2-D) echocardiography is well suited to the study of regional left ventricular (LV) contraction because of its ability to detect and depict wall excursion and thickening in real time.[1] Regional LV function is commonly evaluated by inspection of real-time echocardiographic images to qualitatively assess the symmetry of LV contraction. Regional asymmetry of LV wall motion and thickening is generally taken to indicate myocardial ischemia or infarction, or both.[2–5] This approach requires the assumption that symmetric wall motion is characteristic of normal LV function and that segmental variation or hypokinesia is a specific sign of ischemic heart disease. However, experimental and clinical studies have defined important regional differences in normal myocardial contraction.[6–14] Recent evidence suggests that LV contraction may exhibit considerable regional variability in 2-D echocardiograms.[12,13] The extent of this variability in 2-D echocardiograms in normal subjects must be defined to use the echocardiographic technique in accurately identifying and diagnosing segmental ventricular dysfunction.

Our hypothesis was that regional variability in LV wall excursion and thickening would be found in 2-D echocardiograms and that this variability would be due

to both biologic and technical factors. It was the goal of this study to (1) define the range of regional LV wall thickening and excursion in normal human subjects at rest, studied by standard 2-D echocardiographic techniques, and (2) explore some technical and physiologic factors contributing to regional variability of contraction on echocardiograms.

Methods

Subjects: Twelve men aged 19 to 27 years comprised the study population. No subject gave a history of cardiac disease or symptoms. All had a normal physical examination and M-mode echocardiogram. All subjects were in normal sinus rhythm without electrocardiographic conduction abnormalities. An additional criterion for inclusion in the study was our ability to obtain excellent quality 2-D echocardiographic images in each subject.

Echocardiographic recording: Two-dimensional echocardiograms were obtained using a Toshiba SSH-10A Sonolayergraph, with an electronically phased array transducer operating at 2.4 MHz. Studies were performed with the patient in the left lateral decubitus position, using standard techniques.[1] Short-axis parasternal images were obtained at the level of the mitral valve leaflets, chordae tendineae, papillary muscles, and apex (that is, below the papillary muscles). Echocardiograms were recorded on videotape for subsequent analysis.

Analysis of Echocardiograms

1. Echocardiograms recorded on videotape were reviewed in realtime and in slow motion. Our initial time references for stop-frame analysis were *end-diastole*, defined as the peak of the electrocardiographic R wave and *end-systole*, defined as the minimum apparent cross-sectional cavity area. The end-diastolic and end-systolic epicardial and endocardial boundaries, and centimeter calibration marks, were traced from stop-frames using transparent plastic sheets placed over the video monitor. For consistency, we traced the inner borders of the endocardium and epicardium. When tracing the borders on the papillary muscle level images, the outlines of the papillary muscles themselves were excluded from the contour.

2. The epicardial and endocardial boundaries and calibration marks were digitized using a Talos digitizing tablet, interfaced to a PDP 11/34 computer and to a Ramtek image display system. This method was interactive and allowed the investigators to immediately view the digitized contours and retrace if necessary.

3. A landmark in each image was the posterior junction between the endocardium of the right ventricular free wall and the right ventricular septal endocardium. We defined the ventricular diameter as the longest line (determined by the computer) from this landmark to the LV anterolateral wall epicardium; this divided the ventricle approximately in half (Fig. 1). The midpoint of this diameter was used as the center of the short-axis image. From this center, 12 radii at 30° intervals were generated, dividing the short-axis image into 12 approximately equal LV cavity and LV wall segments. Segments 1 to 4 correspond approximately to the ventricular septum, 5 to 8 to the anterolateral, and 9 to 12 to the posterior LV wall.

4. For each short-axis image, systolic thickening of each wall segment along each radius and systolic decrease in each LV cavity segment area were calculated and expressed as percent change from end-diastole. Our algorithms for these measurements were all tested on tracings of various geometric shapes to validate their accuracy.

5. The average percent cavity segment area change and percent wall thickening were calculated for *all* segments and radii studied, and standard deviations computed.

6. The range of cavity segment area change or wall thickening *per subject* was noted (that is, the difference between the highest and lowest cavity segment area change and percent wall thickening at each ventricular level in each individual subject).

Analysis for Sources of Variability

1. *To determine whether the pattern of contraction varied systematically at different levels of the ventricle*, the average cavity segment area change and wall thickening at individual ventricular levels were calculated for all subjects. The specific levels chosen were mitral, chordal, and papillary muscle levels. Mean values and standard deviations were calculated and the significance of differences between levels assessed by analysis of variance.

2. *To determine whether the heterogeneity of contraction varied systematically in different segments at a given level of the ventricle*, the average percent ventricular cavity segment area change and percent wall thickening were calculated for each of the 12 myocardial segments at each level for all subjects; standard deviations were calculated. The significance of differences found was tested using analysis of variance. To further assess segment-to-segment variability, the relation between contraction of pairs of adjacent segments at each ventricular level was assessed. That is, the contraction of segment 1 was compared with that of segment 2, segment 2 with 3, segment 3 with 4, and so forth, including segment 12 compared with segment 1 (Fig. 1). A correlation coefficient was calculated for each of these segment pairs, in all subjects, at mitral, chordal, and papillary muscle levels, for both segmental wall thickening and cavity segment area change.

3. *To determine the effect of cardiac rotation and translational motion*, end-systolic and end-diastolic images were entered into the image-processing system. The diameter and center of the end-systolic images were determined in the same way as that used for the end-diastolic images. The amount of

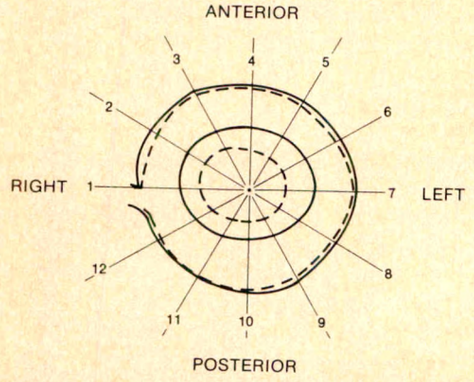

FIGURE 1. Method used for analysis of regional left ventricular contraction in a schematic of a short-axis 2-dimensional echocardiographic image. The junction between the posterior right ventricular free wall endocardium and right ventricular septal endocardium was chosen as a landmark, and a line drawn to the farthest point on the lateral left ventricular wall epicardium. This line (line 1-7) was designated as a cavity diameter and bisected to identify the cavity center. Twelve equidistant radii were drawn to separate the image into 12 cavity and wall segments. Percent area change of each cavity segment and percent thickening of the wall along each radius during systole were calculated. **Solid lines** represent end-diastole, and **interrupted lines** end-systole.

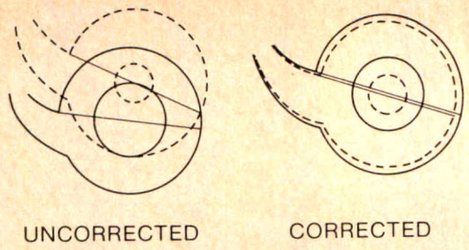

FIGURE 2. Correction for cardiac rotation and motion. The previously determined left ventricular landmark and diameter were used to realign the systolic onto the diastolic image. **Left,** schematic end-diastolic (**solid lines**) and end-systolic (**interrupted lines**) short-axis 2-dimensional echocardiographic endocardial and epicardial borders before correction. **Right,** the 2-dimensional echocardiographic borders after realignment.

systolic rotation of the LV diameter about the cavity center (in degrees) and the intrathoracic motion of the center and diameter (in mm) between end-diastole and end-systole were calculated. The center and diameter of the end-systolic image were then realigned onto those of the end-diastolic image. Data were analyzed both with and without this realignment (Fig. 2). That is, the overall values for wall segment thickening and cavity segment area change were calculated for the images with and without realignment to assess the effect of "correcting" the images for cardiac rotation and translation during contraction. The significance of differences found in left ventricular contraction indexes derived by the 2 methods was assessed by analysis of variance.

4. *To assess the contribution of temporal asynergy of contraction to variability*, end-diastolic outlines were traced at the peak of the electrocardiographic R wave, and end-systolic frames were initially traced at an arbitrary point of apparent minimum cavity area, as described earlier. To delineate the pattern of contraction at other points in the cardiac cycle, additional images were traced 33 ms (1 videotape frame) and 66 ms (2 frames) before and after the previously determined "end-systolic" frame. The average cavity segment area change and wall thickening were calculated using the *maximum percent cavity segment area change* and *maximum segmental wall thickening* found for each segment at any point in the cardiac cycle, no matter which of the 5 "end-systolic" frames showed this maximum contraction of a particular segment. This analysis was carried out in 5 of our subjects, using chordal level images. Differences between left ventricular contraction indexes calculated by the 2 methods (the "maximum contraction" method versus our earlier method using a single "end-systole"), that is, methods with and without correction for temporal asynergy, were assessed by analysis of variance.

5. *To assess the effects of interexamination variability*, the same observer, using the original videotape, traced end-diastolic and end-systolic outlines at chordal level on 2 different occasions, 6 months apart, for each of 5 of our subjects. The observer attempted to identify the same ventricular level and the same points in the cardiac cycle, but was not necessarily tracing from the same frame on both occasions. The initial, single "end-systolic" method was used for this portion of the study. The average differences between segmental area change and segmental thickening, as determined on the 2 occasions, as well as the range of differences per segment were calculated.

Results

Four hundred fifty-six ventricular cavity and wall segments were analyzed: (1) 12 segments at each of 2 levels (chordal and papillary muscle) for each of the 12 subjects (288 segments); (2) 12 segments at mitral level for each of 11 subjects (1 subject yielding technically inadequate mitral level images) (132 segments); and (3) 12 segments at apical level for each of 3 subjects (36 segments). In the other 9 subjects, apical level images of adequate technical quality were not obtained.

Overall data: Figure 3 shows, in graphic form, our data for cavity segment area change and wall thickening for all segments at all levels of all subjects. The average segment area change was 54.4% with a range of 0 to

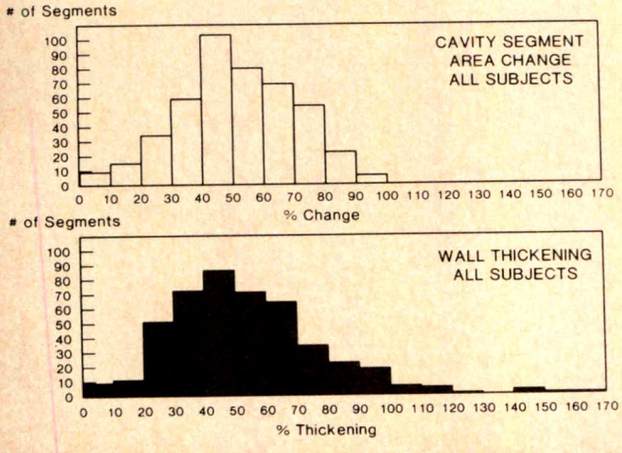

FIGURE 3. Overall distributions of cavity segment area change and wall thickening in all subjects studied, at all levels (456 segments). **Above,** percent cavity segment area change. **Below,** percent segmental wall thickening.

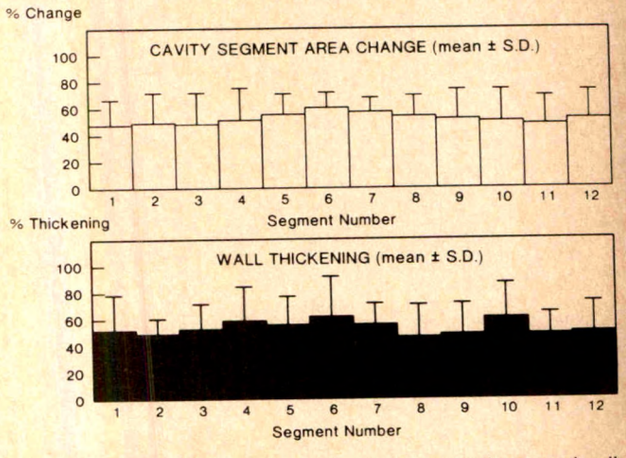

FIGURE 4. Regional variation in cavity segment area change and wall thickening. These data show left ventricular contraction indexes in all subjects at papillary muscle level. **Above,** cavity segment area change for each of the 12 segments at papillary muscle level. **Below,** percent wall thickening along each of the 12 radii at papillary muscle level. No significant differences in mean segmental contraction were found. S.D. = standard deviation.

TABLE I Intersubject Variability of Left Ventricular Contraction at Different Ventricular Levels*

Subject	Percent Cavity Segment Area Change Levels			Percent Wall Segment Thickening Levels		
	Mitral	Chordal	Papillary Muscle	Mitral	Chordal	Papillary Muscle
1	†	54 (16–87)	51 (20–75)	†	68 (43–97)	56 (29–97)

Overall average ± SD	44 ± 17	49 ± 19	53 ± 18	52 ± 27	53 ± 23	53 ± 24

* Values for each subject include the mean contraction of the 12 segments at a given level, followed by the range of contraction at that level (that is, lowest-to-highest segmental contraction).
† Technically inadequate for evaluation.
SD = standard deviation.

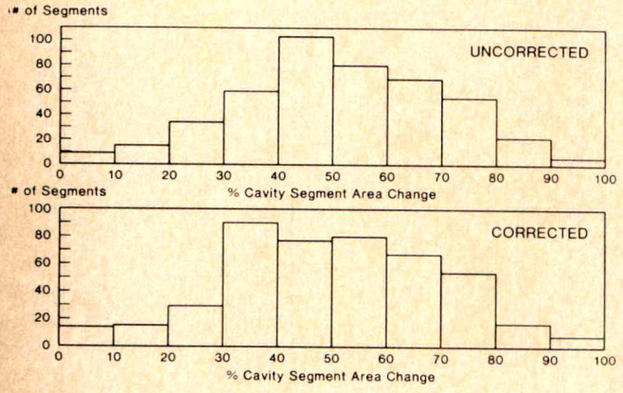

FIGURE 5. Cavity segment area change before and after correction for cardiac rotation and motion. No significant changes were found in mean contraction or in the range of contraction after realignment of the systolic and diastolic images.

100%. The average segmental wall thickening was 54.0% with a range of 0 to 150%. Systolic thinning was observed in 1 of 456 segments and systolic increase in cavity segment area was observed in 3 of 456 segments (<1% in each case). We presumed this systolic thinning and cavity expansion to be artifactual in these normal subjects, possibly due to either echocardiographic dropout or inaccuracies in tracing, or both; these segments were excluded from further analysis.

No consistent differences in average contraction of the major ventricular regions were found. That is, segments of the ventricular septum, anterolateral wall, and posterior wall did not exhibit differences in mean cavity segment area change or mean segmental wall thickening (Fig. 4). Similarly, no significant differences in average contraction were found among the 3 ventricular levels studied (that is, mitral, chordal, and papillary muscle) (Table I). The apical level results were not compared

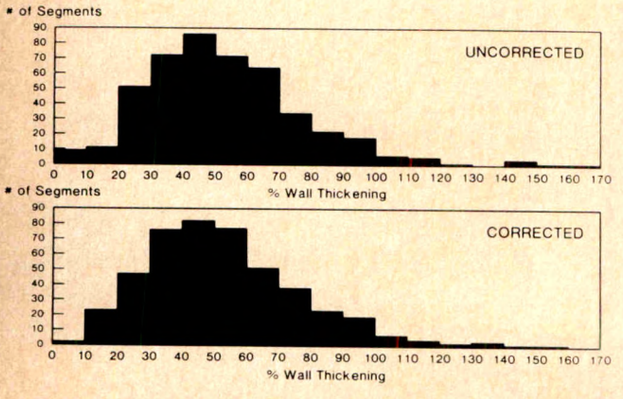

FIGURE 6. Wall segment thickening before and after correction for cardiac rotation and motion. Mean contraction and the range of contraction did not change after realignment of images.

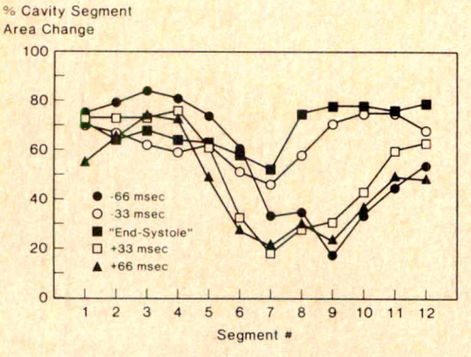

FIGURE 7. Temporal asynergy of cavity segment area change in 1 subject. The cavity segment area change for each of the 12 segments is plotted separately for each of 5 points around end-systole: 66 ms before end-systole, 33 ms before end-systole, end-systole, 33 ms after end-systole, and 66 ms after end-systole. Segments of the ventricular septum (1 to 4) reach peak contraction before other ventricular regions.

with those at the other levels, because of the small number of segments that could be analyzed. However, the data in Table I show the significant subject-to-subject differences that were found in both mean cavity segment area change ($p = 0.0001$) and mean segmental wall thickening ($p = 0.00001$).

The analysis of correlations between thickening of adjacent pairs of segments revealed a range of correlation coefficients from $r = 0.14$ to $r = 0.86$ with an average of $r = 0.58 \pm 0.18$. For area change of adjacent pairs of cavity segments, correlation coefficients ranged from $r = 0.54$ to $r = 0.95$ with an average of $r = 0.85 \pm 0.09$. The correlation coefficients indicate the degree of segment-to-segment variability in our data, more marked for segment thickening than for cavity segment area change. This intersegment variability of contraction is also demonstrated by the wide range of contraction noted in individual levels in each subject (Table I).

Intrathoracic cardiac rotation and motion: The average systolic cardiac rotation was $1.0 \pm 7.6°$ counterclockwise. The average systolic intrathoracic translational motion was 1.7 ± 21.4 mm to the right and 6.7 ± 37 mm anteriorly. We did not find a consistent direction of rotation, some subjects exhibiting clockwise and some counterclockwise rotation during systole. Similar subject-to-subject variability was found in the anteroposterior and right-left motion vectors.

Correction for intrathoracic systolic rotation and motion (that is, realignment of end-systolic and end-diastolic centers and diameters) did not significantly alter the mean values for segment area change or wall thickening nor the wide range of contraction (Fig. 5 and 6).

Temporal asynergy of contraction: Substantial temporal variability of the pattern of contraction was found for both cavity segment area change and wall thickening. That is, different segments of the ventricle reached peak contraction at different points in the cardiac cycle, and the pattern varied from subject-to-subject. For example, in some subjects, segments of the ventricular septum reached their peak cavity segment area change or peak wall thickening earlier than did segments of the anterolateral or posterior wall (Fig. 7). In other subjects, the pattern was reversed or other patterns were noted.

The degree of variability (that is, the range) of left ventricular cavity segment area change decreased somewhat after "correction" for temporal asynergy. Using the maximum cavity area change for each segment at any point in the cardiac cycle (of the 5 points studied near "end-systole") yielded a narrower distribution of this contraction index (Fig. 8). This narrowing of the distribution was due to relatively fewer low values for segment area change. This change in distribution caused a significant increase in mean segmental area change (from $58.8 \pm 19.6\%$ to $66.2 \pm 16.4\%$, $p < 0.001$). A significant increase in mean segmental thickening (from $58.1 \pm 29.4\%$ to $71.1 \pm 34.2\%$, $p < 0.01$) was also found, but the range of segment thickening remained wide (Fig. 9).

Interexamination variability: The average difference in cavity segment area change between the 2 tracing sessions was 20.4% with differences per segment ranging from 0 to 85%. The average difference in segmental wall thickening was 29.4%, with differences per segment ranging from 0 to 103%.

Discussion

The major finding of our investigation was that normal human LV contraction, as depicted in 2-D echocardiograms, is characterized by substantial intersegmental and intersubject heterogeneity. How do our results compare with those of other investigators who have studied the pattern of LV contraction using ultrasound as well as other imaging techniques? What biologic and technical factors may have contributed to the variability found in the present study?

Previous studies of regional LV contraction: The contraction patterns of human and canine left ventricles have been studied extensively by several techniques, including single and biplane contrast ventriculography,[11,14–16] cinefluorography,[17] coronary cineangiography,[8] biplane videometry,[18] implanted radioopaque markers,[14,19] implanted sonomicrometers,[9,20] radio-

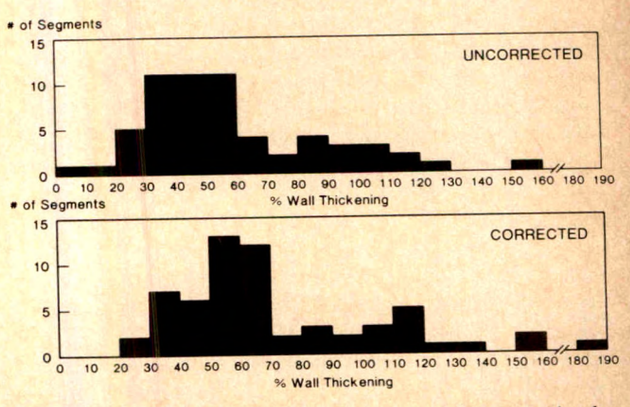

FIGURE 9. Wall segment thickening before and after correction for temporal asynergy. Average contraction increased significantly after this correction.

isotope ventriculography,[21] and echocardiography.[10,12,13,22,23] The general consensus is that LV ejection is accomplished by symmetric contraction of the ventricle, chiefly by circumferential fiber shortening.[24] However, regional differences in wall excursion have previously been demonstrated, with the LV free wall having a larger excursion than the ventricular septum.[8,25] Similarly, LeWinter et al,[9] using implanted sonomicrometers in dogs, showed an increase in shortening of hoop-oriented fibers at the ventricular apex compared with the mid-LV level. In these previous studies, information was gathered largely using techniques capable of evaluating only a limited portion of the LV cavity, and usually measuring endocardial excursion and not regional wall thickening. Discrepancies were found between regional endocardial excursion as displayed on contrast angiographic versus implanted marker studies, possibly due to the effects of infolding of endocardium in the contrast angiographic studies.[17]

Echocardiography is uniquely suited to the study of LV contraction, because of the ability to display both endocardial excursion and wall thickening of a portion of the left ventricle in real time. Initially, M-mode echocardiography was used to establish relatively narrow normal ranges of LV contraction, with excursion and thickening of the posterior wall being larger than those of the ventricular septum.[1] Recent 2-dimensional echocardiographic studies of regional LV contraction revealed a regional variability more substantial than that suggested by studies using other techniques.[12,13] Franklin et al[12] measured the motion of endocardium at radial separations of 10° around the short-axis circumference in 2-D echocardiograms, and found a 5-fold variation in maximum movement of individual endocardial targets toward a mean centroid. Greater than 25% variation was found in regional wall thickening along individual radii. Folland et al[13] observed more modest variability in a 2-D echocardiographic evaluation of endocardial motion. They found that a cavity segment area analysis technique (as an analog of endocardial excursion) revealed less variability than did measuring endocardial motion along a radius. Finally, Likoff et al,[26] using an echocardiographic crystal placed on the epicardium of open-chest human subjects, revealed marked heterogeneity of myocardial function in areas without known infarction or abnormality on angiogram. Thus, regional variability of contraction appears to be a feature of normal left ventricles.

Factors contributing to variability of ventricular contraction seen in 2-D echocardiograms: Several factors may have contributed to the contractile variability demonstrated in our study. Not all of these factors are unique to echocardiography; they influence other imaging techniques as well.[27] A summary of factors contributing to variability in our study is found in Table II.

Biologic contributors to variability may include regional differences in myocardial perfusion, previously demonstrated by Falsetti et al,[28] and variable LV fiber architecture.[29] In addition, temporal asynergy of contraction is an important factor to consider. All normal

TABLE II Factors Contributing to Regional Variability in Left Ventricular Contraction on 2-Dimensional Echocardiograms

I. Biologic factors
   A. Regional myocardial perfusion
   B. Variable muscle fiber architecture
   C. Temporal asynergy of contraction
II. Technical factors
   A. Frame of reference (correction for cardiac rotation and motion)
   B. Identification of endocardium and epicardium
   C. Gain dependence of image appearance

LV segments do not reach peak contraction simultaneously.[30] Therefore, any technique that arbitrarily evaluates LV wall motion at only 2 points in the cardiac cycle (end-diastole and end-systole) might show artifactual regional differences in contraction. In the present study, temporal asynergy of contraction was a modest contributor to the regional variability we found. When we used the *maximum* contraction of each segment, no matter when in the cardiac cycle it occurred, the overall heterogeneity of segmental area change decreased. Therefore, accurate characterization of regional LV function will require the evaluation of several points in the cardiac cycle.

Several important technical limitations of 2-D echocardiography may have contributed to the variability found in this study. The presence of intrathoracic cardiac rotation and motion was confirmed in our study, but the absolute amount of motion was small. Furthermore, when we corrected for this motion, significant regional variability was still apparent. This finding confirms previous work by Moynihan et al[23] who found that the use of a fixed or "floating" frame of reference made little difference in the analysis of regional left ventricular function.[23]

An important prerequisite for accurately depicting regional wall motion and thickening using echocardiography is the accurate definition of endocardial and epicardial boundaries. Some recent evidence suggests that definition of the endocardium may be difficult on 2-D echocardiograms.[31] Furthermore, measurements of cavity dimensions and wall thickness taken from 2-D echocardiograms may be less reproducible than M-mode measurements, and may correlate poorly with those obtained using M-mode techniques.[32,33] These problems stem in part from several technical limitations of image generation in current 2-D ultrasound systems, such as the dependence of structure appearance on gain or amplification settings.[34]

One manifestation of indistinct target identification in the present study may be the large interexamination variability we found. In our study, we did not examine interexamination or interobserver variability in tracing borders from the same frame. Instead, we attempted to evaluate the variability inherent in measuring regional cardiac contraction on 2 occasions from the same study, attempting to identify comparable frames at the same ventricular level. We believe that this type of interexamination variability has clinical relevance specifically for following up patients with serial echocardiographic

examinations. Parallax may have been an additional problem in our tracings, and newer image analyzers may decrease variability, because some of these systems superimpose a marker or cursor directly on the video image during tracing. The observer in our study may also have had difficulty in identifying the same ventricular level on 2 successive viewings of the videotape. Precise, reproducible landmarks may be difficult to locate in the closed-chest subject, and the patient's position and the transducer orientation may vary between examinations and during an examination. These factors may decrease reproducibility.

The variability demonstrated in the present study precludes the use of simple, qualitative assessment of the symmetry of contraction as a method of identifying segmental ventricular dysfunction. The wide range of normal contraction makes it difficult to identify the contraction of a given segment as abnormally decreased based simply on a comparison with the contraction of adjacent segments. Thus, echocardiographic "hypokinesia" is nonspecific and may be a normal variant that does not necessarily indicate segmental ventricular dysfunction. However, because our study, as well as those of others,[3,35] indicate that wall thinning and dyskinesia are rare findings in normal subjects, these abnormalities may be reliable indicators of abnormal regional LV contraction.

Cardiac Function in Sickle Cell Anemia

BARRY S. DENENBERG, MD, GERARD CRINER, MD, RICHARD JONES, MD, and JAMES F. SPANN, MD

Although ventricular dysfunction is suspected to underlie congestive heart failure in sickle cell anemia (SCA), ejection indexes of left ventricular (LV) pump performance have been found to be normal. The increased preload and decreased afterload of SCA increases the ejection phase indexes and might obscure true LV dysfunction. Therefore, the preload and afterload independent end-systolic stress-volume index was compared in 11 patients with SCA and in 11 normal volunteers. End-systolic pressure and echocardiographic LV dimensions were determined during rest, leg raise, hand-grip and amyl nitrite inhalation. Systemic vascular resistance (afterload) was decreased to 1,033 ± 314 dynes s cm^{-5} (mean ± standard deviation) in SCA from 1,701 ± 314 dynes s cm^{-5} in normal subjects. End-diastolic volume index (preload) was increased to 102 ± 24 ml/m^2 in SCA from 66 ± 10 ml/m^2 in normal subjects. Cardiac index was increased to 4.7 ± 1.1 liters/min/m^2 in SCA from 2.8 ± 0.8 liters/min/m^2 in normal subjects. Ejection fractions were similar: 0.59 ± 0.09 in SCA versus 0.62 ± 0.07 in normal subjects. However, in patients with SCA, the ratio of resting end-systolic stress-volume index was decreased (1.5 ± 0.5 in SCA versus 2.8 ± 0.6 in normal subjects) and the slope of the end-systolic stress versus end-systolic volume index relation was decreased (2.7 ± 1.3 in SCA versus 4.4 ± 1.8 in normal subjects), suggesting LV dysfunction in those patients. Thus, LV muscle contractile performance is depressed in SCA. Increased preload and decreased afterload compensate for the LV dysfunction and maintain a normal ejection fraction and high cardiac output.

Symptoms of congestive heart failure are frequent in patients with sickle cell anemia (SCA),[1–3] raising the possibility of depressed cardiac muscle function.[4] Previous studies suggest that the heart is normal in SCA.[5,6] However, these studies, measured myocardial function by ejection phase indexes that may not detect abnormalities of myocardial function under altered loading conditions.[7] Both preload and afterload are altered in SCA. In severe anemia, cardiac output and stroke volume increase because of both cardiac dilatation and decreased peripheral vascular resistance.[8,9] Cardiac dilatation increases preload and decreased peripheral resistance reduces afterload. Increased preload and decreased afterload result in increased ejection phase indexes, possibly obscuring abnormalities of cardiac muscle function.[7]

To study cardiac muscle function in SCA, indexes of myocardial performance that are independent of loading conditions must be used. The relation between pressure and volume at end-systole is an index of myocardial performance independent of preload and a linear function of afterload.[10–13] This index can be obtained reliably by echocardiography and external pressure recordings.[14] We used the end-systolic stress-volume relation to measure myocardial performance in patients with SCA.

Methods

Patient groups: There were 11 normal volunteers matched for age and 11 patients with SCA. These 2 groups were further subdivided by age, that is, 7 normal adults (aged 28 ± 7 years) were compared with 6 adult patients with SCA (aged 31 ± 7 years). Four normal children (10 ± 4 years) were compared with 5 children with SCA (aged 12 ± 4 years). Patients with SCA were typical clinically and homozygous for hemoglobin-S. SCA was severe in all patients, the hemoglobin averaging 7.9 g/100 ml; all patients had cardiac enlargement on chest roentgenograms, and 3 adults had a history of congestive heart

failure. No child with SCA had symptoms of congestive heart failure. No patient was studied during sickle cell crisis. Patients with renal failure, systemic hypertension, cor pulmonale, valvular heart disease, clinical, electrocardiographic, or echocardiographic evidence of pericardial disease, or diabetes were excluded. No history or electrocardiographic evidence of angina or myocardial infarction and no M-mode or 2-dimensional (2-D) echocardiographic evidence of regional wall disease was present.

Procedures and methods of study: Echocardiographic studies in adults were performed with a phased array (Varian 3000) echocardiogram machine and a 2.25 MHz transducer. Echocardiographic studies in children were performed with a mechanical sector scan (ATL) echocardiogram machine with a 3.5 MHz transducer. Two-dimensional echocardiography was performed in each individual at rest to exclude regional wall disease. M-mode echocardiograms were performed with the M-mode cursor angled through the center of the left ventricular (LV) cavity just below the mitral leaflets. Blood pressure was recorded from the arm by sphygmomanometer. After resting measurements, simultaneous M-mode echocardiography and blood pressure measurements were performed during supine leg raising, after submaximal hand-grip exercise and immediately after amyl nitrite inhalation. Left ventricular end-systolic and end-diastolic dimensions and end-diastolic posterior wall thickness were measured. End-systolic measurement was taken at the point of maximal excursion of the ventricular septum. End-diastolic dimension was measured at the R wave of the electrocardiogram. Posterior end-diastolic wall thickness was measured from leading edge to leading edge in the standard fashion.[15]

End-systolic pressure was determined from sphygmomanometric measurements of systolic pressure by use of a regression equation. The regression equation was derived from 29 normal patients at cardiac catheterization; end-systolic pressure derived from the intraarterial recording was compared with simultaneously obtained peak-systolic pressure by sphygmomanometer. Dicrotic notch pressures were taken as end-systolic pressures. The equation used was: $Y = 0.66x + 13.55$, where x is the peak systolic pressure by cuff and Y is the calculated end-systolic pressure. The correlation coefficient was 0.88. Ventricular volumes were calculated by the formula of Teicholtz et al.[16] Volumes were converted to volume index by dividing by body surface area. Cardiac output was determined by multiplying echocardiographic stroke volume by heart rate. Systemic vascular resistance was calculated by dividing mean blood pressure by cardiac output. Mean blood pressure was calculated by the following equation: Mean pressure = [systolic pressure + 2 (diastolic pressure)] 3.

Left ventricular end-systolic wall thickness was determined by a modification of the method of Hugenholz et al,[17] which assumes a constant LV mass throughout the cardiac cycle. First, LV mass (A) is calculated by the method of Troy et al[18] from end-diastolic LV dimension (B) and end-diastolic wall thickness (C), as follows: $A = 1.05[(B + 2D)^3 - (B)^3]$, where D = mean muscle thickness (with the assumption that C = D).

To calculate posterior wall thickness at end-systole (E), then: $1.05[(B + 2C)^3 - (B)^3] = 1.05[(F + 2E) - (F)^3]$ and, $E = 1/2[([B + 2C]^3 - [B]^3 + [F]^3)^{1/3}] - 1/2$ (F), where E = end-systolic posterior wall thickness and F is the measured echocardiographic LV end-systolic dimension.

Wall stresses were then determined at end-systole using a static thick-walled sphere model of the ventricle. Integrating pressure-generated force vectors perpendicular to the equatorial plane over the hemispheric surface of this model in spherical coordinates, the following relation can be shown: $S = PD/[4h(1 + h/D)]$, where S = equatorial wall stress, P = LV pressure, D = LV internal diameter, and h = LV posterior wall thickness. The stress was converted from millimeters of mercury to grams per centimeter by multiplying by 1.35. This figure was then converted to 10^3 dynes/cm^2 by multiplying by the gravitational constant 0.981×10^3 dynes/cm^2.[14,19]

Each patient had 4 total points, 1 at each of the 4 loading conditions plotted on a graph of end-systolic stress versus end-systolic volume index. Linear regression analysis by the least-squares method was done in each patient to determine the relation of end-systolic wall stress (independent variable) versus end-systolic volume index (dependent variable). Statistical analysis was done by analysis of variance performed on the data of the 4 groups with a modified nonpaired *t* test by the Bonferoni method.[20]

TABLE I Summary of Data in Adults

	Normal Subjects (n = 7)	Patients With SCA (n = 6)
Age (yr)	28 ± 7	31 ± 7
SVR	1,741 ± 343	856 ± 270*
EDVI	62 ± 8	106 ± 19*
CI	2.5 ± 0.5	5.0 ± 1.4*
EF	0.63 ± 0.07	0.59 ± 0.08
ESS/ESVI	2.8 ± 0.6	1.5 ± 0.4*
Slope of SI	3.3 ± 1.4	1.7 ± 0.6*

* $p < 0.05$.
Values are mean ± standard deviation.
CI = cardiac index; EDVI = end-diastolic volume index; EF = ejection fraction; ESS/ESVI = resting end-systolic stress/end-systolic volume index ratio; SCA = sickle cell anemia; slope of SI = slope of Sagawa index derived from the linear regression of ESS/ESVI points from the 4 loading conditions; SVR = systemic vascular resistance.

Results

Loading conditions: The systemic vascular resistance was significantly lower in patients with SCA (Fig. 1, left). This value was 1,033 ± 314 dynes s cm^{-5} in patients with sickle cell anemia compared with 1,701 ± 314 dynes s cm^{-5} in normal patients ($p < 0.001$). When the data were examined by age, systemic vascular resistance in adult patients with SCA was significantly reduced to 856 ± 270 dynes s cm^{-5} compared with 1,741 ± 343 dynes s cm^{-5} in the control group (Table I) ($p < 0.05$). In children there were similar reductions in systemic vascular resistance with a value of 1,247 ± 216 dynes s cm^{-5} in patients with SCA compared with 1,663 ± 297 dynes s cm^{-5} (Table II) in the control group.

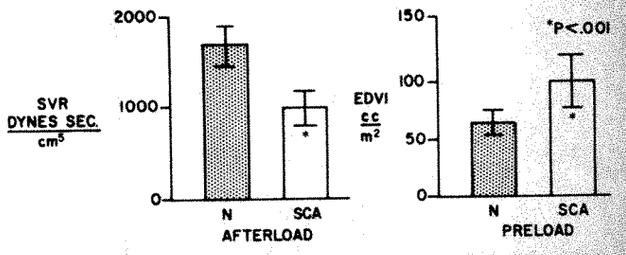

FIGURE 1. Loading conditions in 11 patients with sickle cell anemia (SCA) and 11 normal subjects (N). Afterload (**left**) as indicated by systemic vascular resistance (SVR) was significantly decreased in patients with SCA. Preload (**right**) as indicated by end-diastolic volume index (EDVI) was significantly increased in patients with SCA.

TABLE II Summary of Data in Children

	Normal Subjects (n = 4)	Patients With SCA (n = 5)
Age (yr)	10 ± 4	12 ± 4
SVR	1,663 ± 297	1,247 ± 216
EDVI	73 ± 10	96 ± 33
CI	3.6 ± 0.7	4.6 ± 0.8
EF	0.67 ± 0.07	0.59 ± 12
ESS/ESVI	2.5 ± 1.1	1.6 ± 0.8
Slope of SI	3.2 ± 1.1	2.0 ± 0.6

Values are mean ± standard deviation.
Abbreviations as in Table I.

Preload as indicated by end-diastolic volume was significantly increased to approximately twice the normal value in patients with SCA (Fig. 1, right). End-diastolic volume was increased to 102 ± 24 ml/m^2 in patients with SCA compared with 66 ± 10 ml/m^2 in control subjects ($p < 0.001$). In adult patients with SCA the end-diastolic volume index was 106 ± 19 ml/m^2 compared with 62 ± 8 ml/m^2 (Table I) ($p < 0.05$). In children with SCA similar results were noted, with the end-diastolic volume index being 96 ± 33 ml/m^2 compared with 73 ± 10 ml/m^2 in control subjects (Table II).

Ejection performance: Cardiac index was significantly increased in patients with SCA (Fig. 2, left), with a value of 4.7 ± 1.1 liters/min/m^2 compared with 2.8 ± 0.8 liters/min/m^2 in control subjects ($p < 0.001$). In adults the cardiac index was significantly increased to twice the normal value in patients with SCA, with a value of 5.0 ± 1.4 liters/min/m^2 compared with 2.5 ± 0.5 liters/min/m^2 in control subjects (Table I) ($p < 0.05$). In children similar results were again noted in patients with SCA, with the value of 4.6 ± −0.8 liters/min/m^2 compared with 3.6 ± 0.7 liters/min/m^2 in control subjects.

Ejection fractions were similar in the 2 groups (Fig. 2, right), with a value of 0.59 ± 0.09 in patients with SCA compared with 0.62 ± 0.07 in control subjects. In adults (Table I) and children (Table II) no significant differences in ejection fraction were noted between patients with SCA and control subjects.

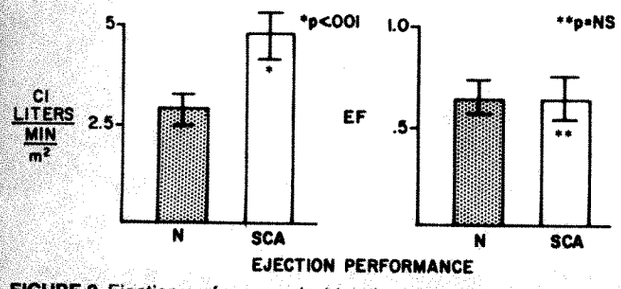

FIGURE 2. Ejection performance in 11 patients with sickle cell anemia (SCA) and 11 normal subjects (N). Cardiac index (CI) was significantly increased in patients with SCA. Ejection fraction (EF) was not significantly different in the 2 groups. NS = not significant.

Myocardial function: The ratio of resting end-systolic stress to end-systolic volume index was significantly reduced in patients with SCA (Fig. 3, left) to 1.5 ± 0.5 compared with 2.8 ± 0.6 in control subjects ($p < 0.001$). In adults with SCA the resting ratio of end-systolic stress to end-systolic volume index was 1.5 ± 0.4 compared with 2.8 ± 0.6 in adult control subjects (Table I) ($p < 0.05$). In children with SCA, again similar results were noted with a value of 1.6 ± 0.8 compared with 2.5 ± 1.1 in control children.

The average slope of the end-systolic stress versus end-systolic volume index relation derived from loading conditions in patients with SCA and control subjects is shown in Figure 3, right. The slope in patients with SCA was significantly reduced to 2.7 ± 1.3 compared with 4.4 ± 1.8 in control subjects ($p < 0.025$). In adults with SCA, the slope of the end-systolic stress-volume line was significantly reduced to 1.7 ± 0.6 compared with 3.3 ± 4.4 in normal adults (Table I) ($p < 0.05$). In children with SCA this slope was similarly reduced to 2.0 ± 0.6 compared with 3.2 ± 1.1 in control children (Table II).

Discussion

Our data suggest a significant depression of LV muscle contractile performance in SCA. This impaired myocardial function is independent of the duration of disease, because it is present in both children and adults. Increased preload and decreased afterload in patients with SCA may explain the normal ejection indexes of cardiac performance observed in this and previous studies.[6,21]

Symptoms of congestive heart failure were described in 85% of patients with SCA.[1] Although symptoms of heart failure led to the suspicion that myocardial contractile function was depressed in SCA,[4] symptoms and findings of congestive failure can be caused by circulatory congestion alone without depressed cardiac muscle function.[22–24] Knowledge of whether heart failure symptoms are due to circulatory congestion alone or to myocardial depression is of clinical importance. Vigorous infusion of fluids is recommended therapy in SCA.[25] Such therapy may lead to pulmonary edema.

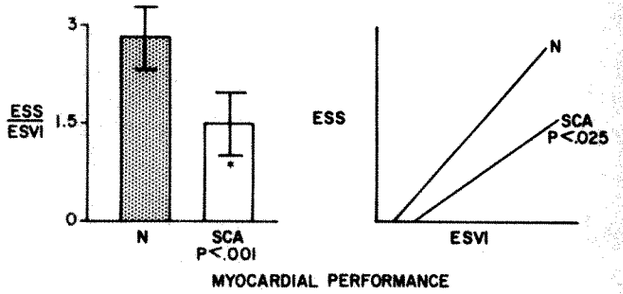

FIGURE 3. Myocardial performance in 11 patients with sickle cell anemia (SCA) and 11 normal subjects (N). **Left,** resting end-systolic stress/end-systolic volume index ratio (ESS/ESVI) was significantly decreased in patients with SCA. **Right,** the slope of the Sagawa line, derived from the linear regression of ESS/ESVI points from the 4 loading conditions, is significantly reduced in patients with SCA. The decrease in resting ESS/ESVI and in the slope of the Sagawa line suggests left ventricular dysfunction in patients with SCA.

Understanding the pathophysiology underlying the heart failure symptoms might form the basis of a more rational approach to the use of digitalis, diuretics, or vasodilators.

There have been 2 previous studies of ventricular performance in patients with SCA. Gerry et al[6] studied ejection phase indexes in 23 patients. They found the mean velocity of circumferential fiber shortening, ejection fraction, and systolic time intervals to be normal and concluded that SCA did not produce myocardial dysfunction.[6] Val-Mejias et al[21] also found that ejection fraction and systolic time intervals were normal in patients <23 years between sickle cell crises. In patients >23 years, the ejection fraction (0.66) was normal although significantly reduced from the control value (0.77). Systolic time intervals were prolonged in the older patients. They concluded that the chronic hemolytic process of SCA has a cumulative detrimental effect on myocardial function.[21]

Recent information on the effect of alterations in loading conditions on the ejection performance of the heart[9,12–16,21] indicates not surprisingly that studies using ejection indexes have not detected LV dysfunction in SCA. Ejection phase indexes are increased by decreases in afterload and increases in preload.[9,12,15,16,21] A decrease in afterload, systemic vascular resistance, and an increase in preload, end-diastolic volume index, were present in previous studies and in our patients with SCA (Fig. 1). Severe anemia can cause such changes.[8,9]

The end-systolic stress-volume relation proposed by Sagawa et al[26] is an index of contractile function independent of preload and a linear function of afterload, with the potential accurately to gauge contractile function in SCA despite the altered loading conditions. The Sagawa index was recently extended to man by Grossman et al[10] and Weisfelt et al.[27] Marsh et al[14] demonstrated that the end-systolic stress-volume relation can be determined in man by echocardiography.

We found the resting end-systolic stress end-systolic volume index and the slope of the Sagawa index decreased in our patients with SCA (Fig. 3). These findings suggest an intrinsic dysfunction of myocardial contractile function performance. We observed, as have others,[6,21] that load-dependent ejection phase indexes were normal or high; the indexes failed to detect myocardial dysfunction. As previously noted herein, myocardial dysfunction was independent of age. Consequently, dysfunction is probably not due to myocardial iron deposition, a process that would increase with age as the number of transfusions increased.

As cardiac muscle function is depressed in patients with SCA, positive inotropic drugs may have some value in patients with heart failure. Because a decrease in peripheral vascular resistance already exists, arterial vasodilators may not be helpful. Vigorous volume loading, the standard treatment for sickle cell crisis, in patients who already have an increased intracardiac volume and a decreased myocardial contractile function must be undertaken with caution.

The techniques we used have limitations. We employed M-mode echocardiography, in which only a single dimensional measure is used, to calculate ventricular volume. However, in subjects without dysnergic wall motion, echocardiography was found to provide accurate measurements of ventricular volume.[16] We have excluded ventricular wall dysnergy by 2-D echocardiography. Further, we calculated end-systolic pressure from peak-systolic pressure. Simultaneous intraarterial pressures and cuff pressures were recorded in 29 other patients and revealed a high degree of correlation between calculated end-systolic pressure and peak-systolic pressure measured by cuff. Finally, hand-grip exercise and amyl nitrite inhalation might have initiated baroreceptor reflexes, changing sympathetic stimulation to the heart, thus interfering with accurate assessment of contractile function. However, the lack of change in heart rate after our intervention and before our measurements indicates that this is unlikely.

The end-systolic volume/end-systolic pressure relation needs further validation as an independent index of contractility in the chronically volume- or pressure-overloaded heart, but several studies have found this index to correlate with other indicators of myocardial dysfunction in patients with chronic pressure and volume overload. In chronic volume overload due to aortic regurgitation[28] and in chronic pressure overload due to aortic stenosis,[29] the slope of the group end-systolic pressure relation was significantly reduced in patients with congestive heart failure compared with normal subjects or patients with severe aortic regurgitation or stenosis but no heart failure. Preoperative end-systolic volume was a predictor of postoperative LV performance in aortic regurgitation.[30] The preoperative end-systolic volume pressure relation was significantly depressed in patients who either died or continued to have heart failure after mitral valve replacement.[31]

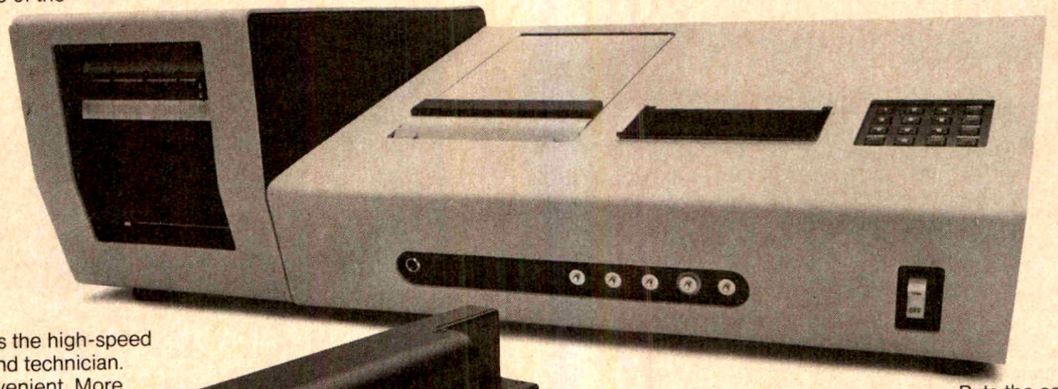
Clinical evaluation of various systems for analysis of ambulatory ECG records has been difficult to implement due to the variety of approaches to recording data, the operator-dependence of traditional recording and interpretation systems, and the subjective clinical judgements necessary in using the final results. One manufacturer can now report data utilizing a real-time approach to ambulatory monitoring that compares clinical accuracy to hand-counted data as a standard.[1]

In Holter studies, AEGIS™ gives you results in minutes... right in your office... without a specially trained operator.

›vides the same clinical rmation as a scanning ice—with none of the ›backs.

• Fits easily into any office.

• System validates itself—no need for repeat studies due to "lost" data or faulty equipment.



• Replaces the high-speed scanner and technician. More convenient. More efficient.

• Puts the control of evaluating Holter studies directly into your hands. Provides time-stamped rhythm strip and summary report for your confirmation.

• Analyzes each heartbeat as it occurs; counts and categorizes arrhythmias in real time.

For a 15-minute, no obligation demonstration, call toll-free: 800-257-5750.

For **every** professional with an interest in Exercise and the Heart.

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

Yorke Medical Books
Box C-757, Brooklyn, New York 11205 AJCF3

Please send me a copy of EXERCISE in Cardiovascular Health and Disease for 30 days free examination and use. If I decide to keep it, your invoice will be honored ($42.50 plus shipping cost). Otherwise, the book will be returned for full refund or credit.

☐ Full payment enclosed, publisher pays shipping.
☐ Please bill me, plus cost of shipping.
☐ Charge my credit card: ☐ MasterCard ☐ Visa.

CONFERENCE ON

"The Clinical Pharmacology of Cardiac Antiarrhythmic Drugs: *A Clinical Appraisal*"

Barbizon Plaza Hotel
New York, New York
October 3-5, 1983

The conference is sponsored by The New York Academy of Sciences. The conference co-chairmen are Oscar Garfein (Columbia University) and Charles Pippenger, The Cleveland Clinic.

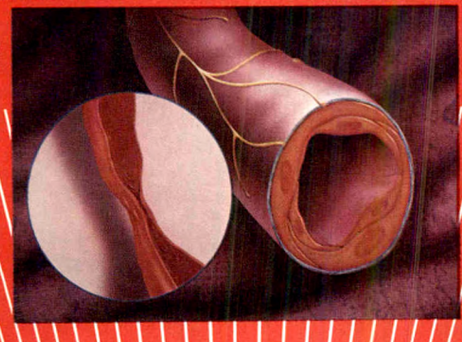
This conference will critically appraise the current status of this field on a fundamental level. Classical concepts and facts will be reviewed in the light of newer concepts and techniques of drug concentration measurement and arrhythmia detection and analysis, and with a fuller understanding of the cellular basis of arrhythmogenesis. Detailed discussions of classical as well as experimental antiarrhythmic agents will be presented, along with data on specific arrhythmias and their treatment. Thirty two papers will be presented.

Inquiries should be addressed to: Conference Director, The New York Academy of Sciences, 2 East 63rd Street, New York, New York 10021.

An educational program on new dimensions in the treatment of angina.*

CARDIZEM™ (diltiazem HCl): Calcium Channel Blockade in the Treatment of Coronary Heart Disease.

The CARDIZEM™ (diltiazem HCl) Educational Program will include a 30-minute film, with animated highlights depicting major aspects of the new class of drugs known as calcium channel blockers. To facilitate understanding of the use of calcium antagonists, a full monograph/self-test will accompany the film. Authorities in the fields of cardiology, pharmacology, and medicine will discuss the impact calcium channel blockers can make in the treatment of angina.



Please complete and mail this coupon for information.

Gentlemen:

I would like to arrange a showing of *CARDIZEM™ (diltiazem HCl): Calcium Channe Blockade in the Treatment of Coronary Hear Disease.*

Please cut along dotted line.
Mail to: Continuing Professional Education,
625 N. Michigan Avenue, Chicago, Illinois 60611.

The new PASS™ echocardiography system from General Electric expands the advantages of phased array ultrasound...and delivers a difference in M-mode and 2D images beyond your expectations.

More accurate clinical information, faster

Only GE applies baseband signal processing to phased array echocardiography and couples it with superior transducer design. Your clinical studies reap the benefits of this exclusive combination.

Specifically, baseband processing, with its greater signal timing accuracy, significantly improves image resolution and penetration. And baseband processing eliminates artifacts and other types of electronic noise. A continuous focusing ability provides a focused view of the heart from the near field to the deepest penetration; an important improvement over the zone focusing of other systems. As a result, you can image structures as fine as 1 mm; see better edge definition; and can differentiate soft tissue more precisely. Also, advanced phased array display capability permits time-efficient simultaneous viewing of M-mode and 2D images. Two M-mode images or two 2D images allow accurate quantification and diagnostic flexibility.

Image a wider range of patients with more transducer options

From premature neonate to obese adult, the PASS system widens the range of scannable patients. For neonatal and pediatric studies, the PASS system offers the first clinically proven 5 MHz phased array image without near field noise. Average size adults can be imaged at 3.3 MHz for optimal resolution. Obese adults can be imaged at 2.5 MHz for maximum penetration. And because PASS is a phased array system, its small, lightweight transducers offer better acoustic access compared to mechanical sector systems.

More options for future capability

Best of all, you can build on today's PASS system capability for tomorrow's imaging requirements. Because upgradeability is designed-in, you'll soon be able to add doppler; plus other technological advances as they are developed. In addition, self-diagnostic features facilitate servicing and help keep the system on the job.

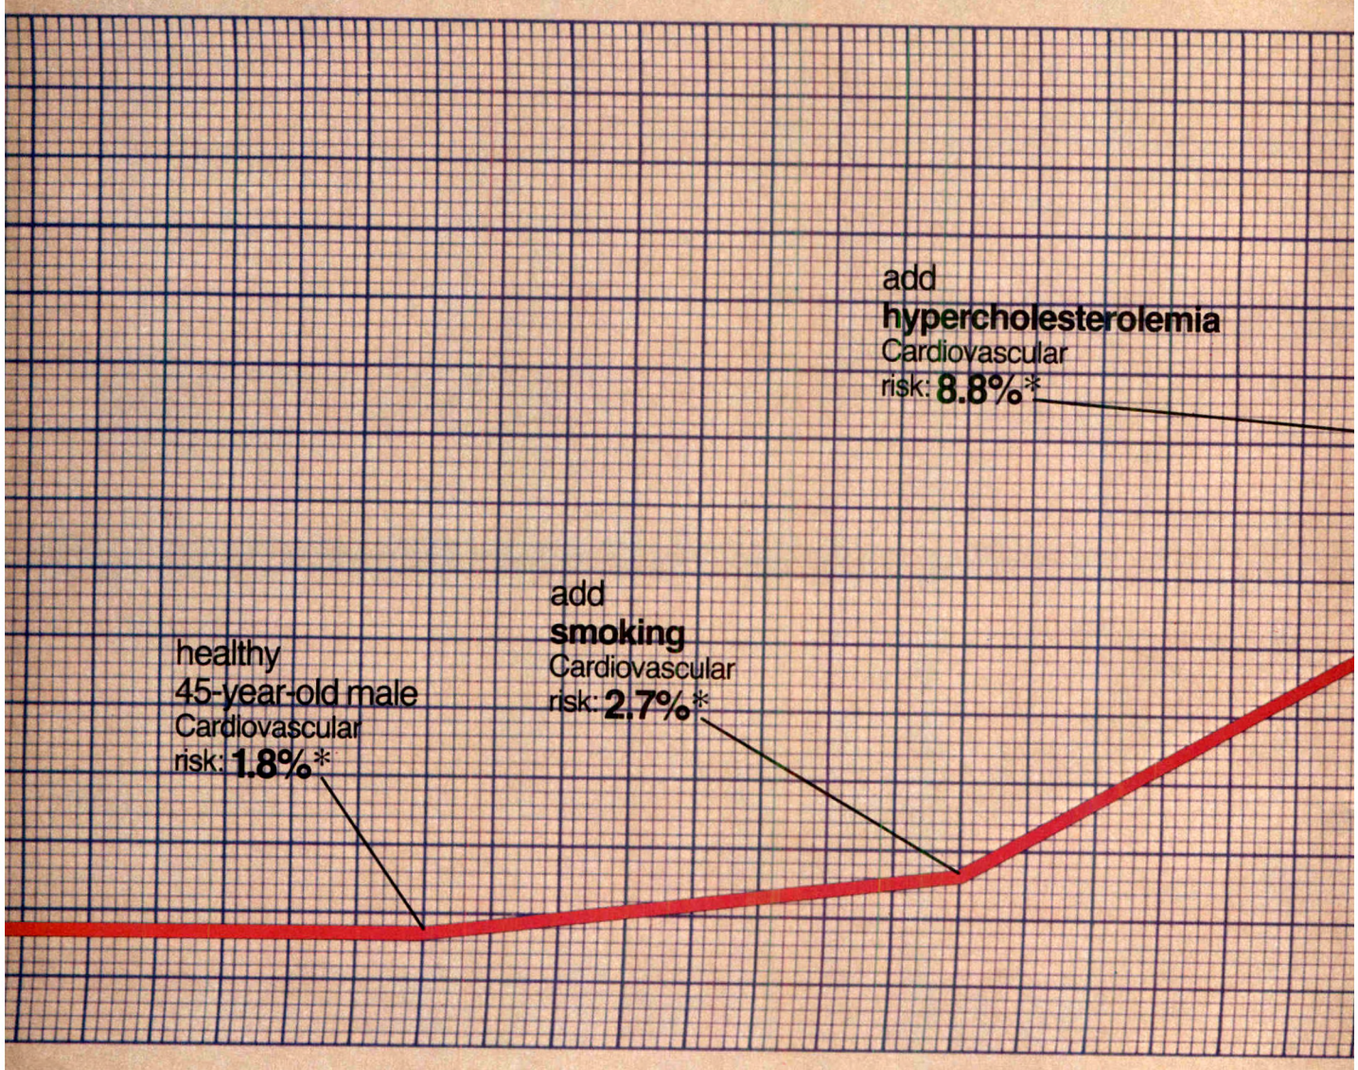
See the difference the PASS system can make in your clinical studies. Contact your GE representative.

...clinical studies you can trust.

We bring good things to life.

GENERAL ELECTRIC

In hypertensive patients:

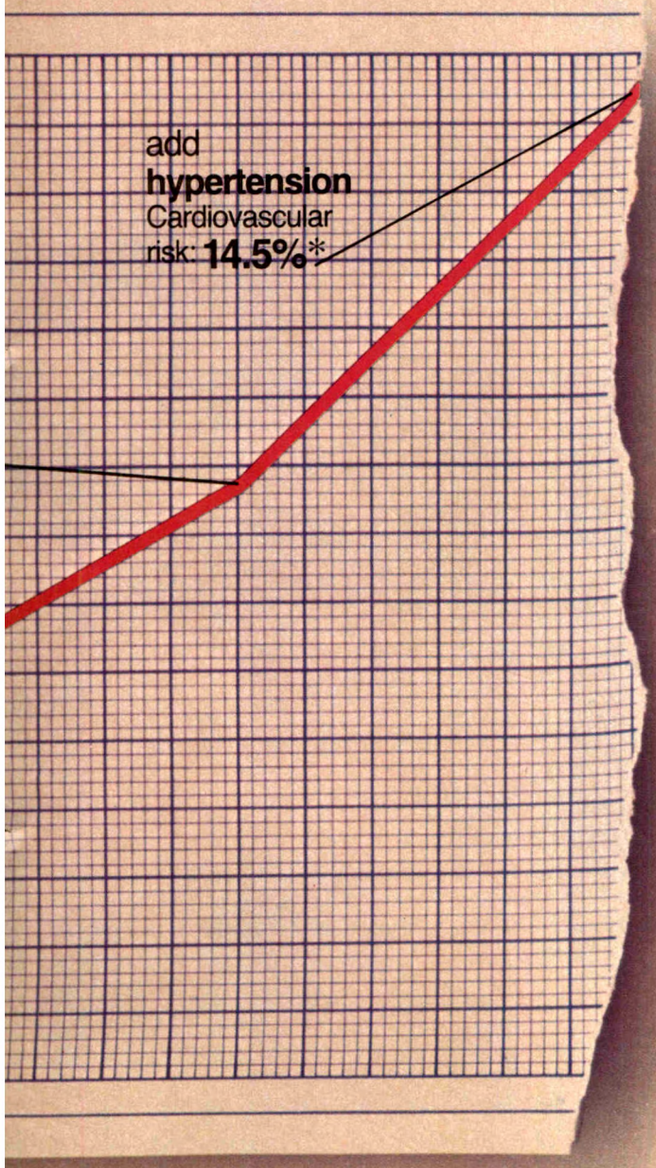


Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

Consider the Risks



▪ When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

▪ Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

▪ Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

Please see Minipress brief summary on following page.

BRIEF SUMMARY

MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*

INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings.)

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

Rheumatology

A Primary Care Approach

Written by:

Bruce M. Rothschild, MD

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8 $39.50
430 pp., illus., November 1982,

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Table of contents

Section 1 - Investigative Techniques, Chapter 1 - The Rheumatologic History and Physical Examination, Chapter 2 - Arthrocentesis and Joint Fluid Evaluation, Chapter 3 - Laboratory Studies, Chapter 4 - Radiology of Joint Disease, **Section 2 - Patterns of Disease,** Chapter 5 - Infectious Agent Arthritis, Chapter 6 - Arthritis of Mechanical Derivation, Chapter 7 - Crystalline Arthritis, Chapter 8 - Rheumatoid Arthritis, Chapter 9 - Juvenile Rheumatoid Arthritis, Chapter 10 - Ankylosing Spondylitis, Chapter 11 - Reiter's Syndrome and Psoriatic Arthritis, Chapter 12 - Arthritis Associated with Gastrointestinal Disease, Chapter 13 - Endocrine, Metabolic, and Deposition Disease, Chapter 14 - Arthritis Associated with Hematologic Disease, Chapter 15 - Miscellaneous Causes of Arthritis, Chapter 16 - Nonarticular Rheumatism, Chapter 17 - Systemic Lupus Erythematosus, Polymyositis, and Sjogren's Syndrome, Chapter 18 - Scleroderma, Chapter 19 - Vasculitis/Vasculopathy, **Section 3 - Management,** Chapter 20 - Approach to Diagnosis, Chapter 21 - Compliance and Quackery, Chapter 22 - Salicylate Pharmacodynamics, Chapter 23 - Medication Therapy, Chapter 24 - Rehabilitation Therapy, Chapter 25 - Surgical Intervention

Now the CMS™ 6000 is more flexible than ever.

Flexibility is key to giving more patients better care. That's why Physio-Control has designed flexibility into every feature of the CMS 6000 monitoring system.

It works with our well-known LIFEPAK® 6 monitor, our VSM®1 vital signs monitor and our TR1 telemetry system.

The PS1 patient selector lets you dial through eight patients for a quick look, and then select any four for continuous monitoring.

It's reliable, simple and best of all, it's a monitor from Physio-Control, a leader in medical instrumentation.

Manufacturers of the LIFEPAK family of defibrillator/monitors.

Dynamic Evaluation of Prognosis From Time-Dependent Variables in Acute Myocardial Infarction

ERLING BIRK MADSEN, MD, PHILIP HOUGAARD, MS, and ELIZABETH GILPIN, MS

For predicting the 3 endpoints death, cardiac arrest, and cardiogenic shock within 44 days after admission for acute myocardial infarction (MI), a competing risk variant of the Cox multivariate model was developed. The population consisted of 1,140 patients with definite MI admitted within 24 hours of onset of symptoms. Prognostic variables from the entire hospitalization period were assessed. The time-dependent variables (occurrence of complications) were evaluated with occurrence up through the day before the actual prediction period started. The important prognostic variables for the endpoint death were ventricular fibrillation, age, congestive heart failure, and asystole. Variables for the endpoint cardiac arrest were congestive heart failure, ventricular premature beats, supraventricular tachycardia, extension of MI, and age. Variables for the endpoint cardiogenic shock were cardiac arrest, age, congestive heart failure, previous MI, and nodal rhythm. By using a hazard function for each endpoint and the coefficients for the variables entered, it is possible to estimate a total risk of death, cardiac arrest, or cardiogenic shock for the individual patient. This prediction can be updated during the course of hospitalization according to the occurrence of the new complications. The model can be directly utilized to assess risk.

Many factors have been found to have predictive value for short-term prognosis in patients with acute myocardial infarction (MI). Complications that can occur at any time during hospitalization have been incorporated if they occurred before a certain fixed day,[1–15] but dynamic treatment of these variables as time-dependent has been rare.[16] Because many variables are involved in prognostic evaluation after MI sometimes with strong interrelations, the utilization of multivariate methods such as discriminant function analysis,[2,4,7,11,13,15] multiple regression,[5,10] or Cox analysis[8,12] is essential. This study describes a new prognostic model in which information from time-dependent variables during the entire hospitalization period is evaluated dynamically for different endpoints.

Material and Methods

Patients: The study population consisted of 1,140 consecutive patients with a definite MI admitted to our Coronary Care Unit during a 3-year period in 1977 to 1980. Their ages ranged from 23 to 92 years (mean 63) and 72% were men. All patients had MI <24 hours old at admission. For 813 patients with known time until admission the mean delay was 4.5 hours. A definite MI was diagnosed when at least 2 of the following criteria were present: typical severe chest pain, typical evolving electrocardiographic changes (Q waves or S-T segment/T-wave changes, or both), and elevated level of creatine kinase. Patients who died soon after the admission were included. The patients were routinely treated without prophylactic antiarrhythmic treatment, and beta-blocking agents were not given routinely. Cardiogenic shock was treated with pressor agents, and balloon counterpulsation was not available to us. No patient underwent coronary bypass surgery during the study period.

Prognostic variables: The following non–time-dependent variables were recorded: age, sex, previous MI (number), localization of MI (anterior [Q waves or S-T segment changes in any precordial lead] or other location), maximum creatine kinase (CK), and maximum CK-MB isoenzyme levels, measured at 6-hour intervals during the first 48 hours. The time-dependent variables analyzed were congestive heart failure (definite clinical signs of congestive heart failure [persistent pulmonary rales or enlarged neck veins or peripheral edema] or pulmonary vascular congestion from an x-ray in the upright position, or both), acute pulmonary edema, cardiogenic shock (systolic blood pressure <80 mm Hg or clinical signs of shock, or both), cardiac arrest (primary ventricular fibrillation or

* Occurrence of time-dependent variables (complications) within first 5 days.

For age, CK, and CK-MB, the mean (in units for enzymes) for survivors is indicated in total column.

CK = creatine kinase; CK-MB = creatine kinase isoenzyme; MI = myocardial infarction.

asystole of >10 seconds' duration), ventricular or supraventricular tachycardia (≥10 successive premature beats), ventricular premature beats (≥10% through more than 1 minute), atrioventricular block of second or third degree, nodal rhythm, sinus bradycardia (frequency <50 beats/min), atrial fibrillation or flutter, ventricular rhythm, and extension of MI (≥2 new of the 3 diagnostic criteria). For these variables the time of the first occurrence was noted and data from the entire hospitalization (usually about 18 days) were used for the analyses.

Prediction period: All patients were followed up for up to 44 days after admission. This period was chosen because our goal was to evaluate prognosis up to 14 days after discharge, which occurred at the latest around day 30. The time and cause of death were known for all patients who died. All deaths took place at the hospital or were witnessed and described as sudden death. Autopsy was performed in 90% of patients.

Statistical methods: As a preliminary step, all variables occurring before day 5 were tested univariately for association with mortality within 44 days after admission. Patients who did not survive until day 5 (183) were excluded from this analysis because prognostic variables in these patients are not relevant for the later outcome.

The multivariate analysis was the regression model proposed by Cox[17] describing the time to an endpoint (that is, death). The model was modified to a competing risks model with 3 endpoints within 44 days after admission[18]: death (i = 1), cardiac arrest (i = 2), and cardiogenic shock (i = 3). If more than 1 endpoint occurred the same day, the order was defined as cardiac arrest, cardiogenic shock, and death. The model for the hazard of endpoint i is $\lambda_z^i(t) = \lambda_0^i(t)e^{\beta_1^i Z_1(t)+\ldots+\beta_p^i Z_p(t)}$, where $\lambda_0(t)$ is an unspecified function common to all patients and $Z_1(t), \ldots, Z_p(t)$ are the covariates or prognostic factors (that is, age or complications). The values of $Z_1(t), \ldots, Z_p(t)$ have to be known at time t.

The regression coefficients (β_j^i) were estimated by a maximum partial likelihood method[19] and the integrated hazard functions ($\Lambda_0^i(t)$) by Breslow's method.[20] Only the significant

TABLE II Cox Analysis of the Most Important Univariate Variables for the Endpoint Death Within 44 days After Admission

	With Shock		Without Shock	
Variables	Coefficient	p	Coefficient	p
Age	0.041	<0.0001	0.077	<0.0001
VF	0.9	<0.0001	2.3	<0.0001
Heart failure	2.8	<0.0001	2.6	0.0001
Short-term shock	3.5	<0.0001	. . .	. . .
Late shock	1.0	0.003	. . .	. . .

The variable cardiogenic shock not included in the right portion because the patients were censored at the time of cardiogenic shock.

Late = risk beyond 5 days after the shock; p = p value from likelihood test; shock = cardiogenic shock; short-term = risk within 4 days after the occurrence of shock; VF = ventricular fibrillation.

variables were retained in the final model. To test the hypothesis that the regression coefficients were equal to zero (no prognostic importance), a likelihood ratio test statistic was used. Because of the overwhelming prognostic importance of cardiogenic shock, the survival after this complication was not described in the final model. The patients were censored after cardiogenic shock for all 3 endpoints and after cardiac arrest for the endpoint cardiac arrest only.

To assess prognosis, the risk (P_e) of at least 1 of the events (death, cardiac arrest, or cardiogenic shock) in the time period from day t to day 44 is as follows:

$$P_e = 1 - \exp\left(-\Sigma_{i=1}^{3}(e^{p_1^i Z_1(t)+\ldots+\beta_p^i Z_p(t)}(\Lambda_0^i[44] - \Lambda_0^i[t\text{-}1])\right).$$

For each endpoint (i) the difference in hazard rate (between day 44 and the day before day t) is multiplied by the exponential function of the score (sum of products $\beta_p Z_p$), given the assumption that the time-dependent covariates stay fixed. These 3 products are then added before the exponential function of the negative value of the sum gives the total risk.

To evaluate the importance of the last day in the observation period 2 analyses were performed. First, we included information on the occurrence of time-dependent variables (complications) through the day when the prediction period began (time t). We repeated the analyses with the time-dependent variables included only up to the day before prediction commenced (time t-1). This approach allowed evaluation of any connection between the timing of some variables and the endpoints.

Results

Univariate results for endpoint death: The univariate importance of the prognostic variables occurring during the first 5 days for the 957 patients who survived day 5 is shown in Table I. The most important variables (smallest p values) were congestive heart failure, cardiogenic shock, ventricular fibrillation, age, and ventricular premature beats. Twelve variables were univariately significant.

Multivariate results for endpoint death: In our first analysis we included only the most important univariate variables (congestive heart failure, cardiogenic shock, ventricular fibrillation, and age) in the Cox model. The left part of Table II shows the regression coefficients for these variables. The largest coefficient belonged to cardiogenic shock, which implied an especially high risk of death in the first 4 days after shock ($e^{3.5}$ = 33 times greater risk compared with patients

TABLE III Coefficients for Other Variables When Entered Into The Cox Analysis

Variable	Coefficient	SD	p
Asystole	1.1	0.3	0.0001

Age	0.010	0.007	0.12
Constant	−0.6	. . .	. . .
Cardiogenic Shock			
Cardiac arrest	1.2	0.17	<0.0001
Age	0.028	0.007	<0.0001
Congestive heart failure	3.3	1.0	0.001
Previous MI	0.22	0.07	0.003
Nodal rhythm	0.8	0.3	0.01
Constant	−1.7	. . .	. . .

Abbreviations as in Tables I and III.

without shock). Beyond the first 5 days after shock, the risk diminished to about 3 times that of patients without shock. The coefficients for the other variables indicated 16 times increased risk if congestive heart failure occurred and 2.5 times increased risk if ventricular fibrillation occurred.

The repeated analysis when cardiogenic shock was not included as a variable showed that age and ventricular fibrillation had increased coefficients, indicating the greater prognostic importance of these variables (Table II, right portion).

Next, all the remaining variables were entered in the analysis one at a time in addition to the important variables excluding cardiogenic shock. The coefficients for the added variables ordered according to the p value are presented in Table III. Only asystole, infarct localization, and atrioventricular block were significant and could contribute prognostic information to the ones already selected. Some of the univariately significant variables were not significant in the Cox analysis because of interrelations with variables that were better predictors. Pulmonary edema, ventricular premature beats, extension of MI, and ventricular tachycardia all had negative coefficients. However, these coefficients were all near zero.

When asystole, localization, and atrioventricular block were included in the model, only asystole retained significance. Table IV (top) shows the final model for the endpoint death. Only 4 variables were retained: ventricular fibrillation, age, congestive heart failure, and asystole.

Endpoint cardiac arrest: The left part of Table V shows the variables selected for the endpoint cardiac arrest when occurrence of the time-dependent variables were included through the day beginning the prediction period. For example, if prediction was for day 7 to day 44, the variables could occur from day 1 through day 7. The most significant variables for this endpoint were ventricular tachycardia, congestive heart failure, and ventricular premature beats.

The right portion of Table V shows the results when the variables were included only up to the day before the

TABLE V Variables Selected for Endpoint Cardiac Arrest

Abbreviations as in Tables I and V.

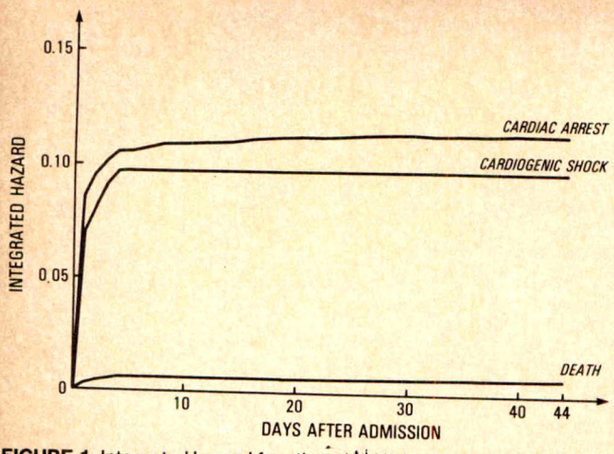

FIGURE 1. Integrated hazard functions ($\Lambda_0^1(t)$) for the endpoints death, cardiac arrest, and cardiogenic shock within 44 days after admission.

start of the prediction period. For this example the variables could occur from day 1 through day 6. This modification was associated with major changes in coefficients and p values for some of the variables. Ventricular tachycardia and atrioventricular block lost significance. Supraventricular tachycardia increased in importance. Therefore, ventricular tachycardia was indicative of a cardiac arrest during the day starting the prediction interval but not for a later cardiac arrest.

The final model for the endpoint cardiac arrest after deletion of the nonsignificant variables for the analysis up to but not including the start of the prediction interval is presented in Table IV (middle). Only 5 variables were retained. Age was retained even though it was not significant.

Endpoint cardiogenic shock: Table VI presents in the same manner as Table V the analyses for the endpoint cardiogenic shock. The most significant variables in the first analysis were pulmonary edema, cardiac arrest, and atrioventricular block. When only variables up to the day before the beginning of the prediction interval were included, pulmonary edema, atrioventricular block, and ventricular tachycardia lost their importance altogether. This indicates that these complications often occurred earlier on the same day as cardiogenic shock and were not prognostically important for later shock. The importance of cardiac arrest increased, while the coefficients and p values for the other variables were relatively unchanged.

The final model for the endpoint cardiogenic shock (Table IV, lower part) shows that only 5 variables were retained. Here age was significant, and the most important other variables were cardiac arrest and congestive heart failure.

Risk estimation: The integrated hazard functions for each endpoint (death, cardiac arrest, and cardiogenic shock) are illustrated in Figure 1. After steep increases in the first few days after the admission, the rate of increase slowed. By using the coefficients from Table IV on data for the individual patient according to the occurrence of the relevant variables, it is possible to compute an estimate of the risk for the 3 endpoints up to day 44 after admission. This risk assessment can be updated dynamically according to changes in the important variables and in the hazard functions.

For a 60-year-old patient surviving day 5 without any complications $e^{\beta_1^1 Z_1 + \ldots + \beta_p^1 Z_p} = e^0 = 1$ and the integrated hazard difference from day 5 to day 44 (Fig. 1) is 0.009 for cardiac arrest, 0.005 for cardiogenic shock, and 0.001 for death. The risk of an event from day 5 to day 44 is $1 - \exp[-(0.009 + 0.005 + 0.001)] = 1.5\%$. The computation can be accomplished by an appropriately programmed calculator.

Discussion

How to deal with time-dependent variables is an important question in the evaluation of prognosis after MI. This model incorporated the most important prognostic variables for 3 competing endpoints (death, cardiac arrest, and cardiogenic shock) (Table IV) with changing risk of each endpoint as indicated by the integrated hazard function (Fig. 1). The risk could be updated during the hospitalization according to the occurrence of new complications.

Multivariate importance: Only 4 of 12 univariately significant variables for the endpoint death (Table I) were found to be important independent predictors in the multivariate Cox analysis. This confirms the importance of using multivariate methods.[2,4,5,7,10–13,15] The Cox model as used previously for short-term prognostic evaluation[8,12] utilizes the observation time to the endpoints in the prediction period and directly provides a computed estimate of the risk of events.

The historical variables age, sex, and previous MI were univariately important, but only age was selected in the Cox analyses. Therefore, the dynamic prognostic variables incorporates prognostic information from the historical variables that are not independently important. It is not necessary to include the historical variables in a prognostic scheme if the dynamic variables are taken into account.

Time-dependence: Previous studies have mostly used a fixed point in time for prognostic evaluation such as day 1,[6,9,11,13,14] day 2,[10,15] day 5,[12] or discharge from the hospital.[2,3,5,7,8] Only 1 report tried to evaluate the prognosis in a simple dynamic way by calculating a risk score each day.[16]

The period of time in which the variables are included influences which variables are selected by the analysis, particularly if certain variables precede endpoints on the same day. In this material this occurred with ventricular tachycardia and atrioventricular block for the endpoint cardiac arrest (Table V) and with pulmonary edema, ventricular tachycardia, and atrioventricular block for the endpoint cardiogenic shock (Table VI). It is probably most feasible and practical clinically if the variables are evaluated only up to the day before the beginning of the prediction interval.

Endpoints: No previous study of prognosis after MI has reported using endpoints other than death with separate hazard functions for each. Our analysis indicated that a different set of variables and coefficients were of prognostic importance for the 3 competing endpoints. The endpoint death alone is not sufficient

for the prognostic evaluation. Identification of patients at high risk of cardiac arrest is especially important when early discharge is being considered.

Comparison with previous studies: It is difficult to compare our findings with those of previous studies because of their different statistical methods and approaches. The only comparisons feasible are for the important prognostic variables in the different studies.

For the endpoint death, our prognostic variables have had prognostic importance in several previous studies. Despite definition differences, congestive heart failure has been a consistent prognostic finding.[1–4,6–8,10–12,15,16] Cardiac arrest was important in 5 previous studies.[7,11,21–23] Age was an important variable in studies without restriction according to age.[7,8,12]

Congestive heart failure,[24,25] supraventricular tachycardia,[24] ventricular premature beats,[24,25] and extension of MI[24] have all been well documented to be indicative of later cardiac arrest. In contrast to previous studies,[24,25] ventricular tachycardia was not selected for the endpoint cardiac arrest in the final model in our study, but it was indicative of a cardiac arrest occurring later the same day (Table V).

A previous univariate study[26] confirmed that age, heart failure, cardiac arrest, and nodal rhythm were indicative for the later development of cardiogenic shock.

Prevalence and Prognosis After a First Nontransmural Myocardial Infarction

SANTIAGO COLL, MD, ANGEL CASTAÑER, MD, GINES SANZ, MD, EULALIA ROIG, MD, JORGE MAGRIÑA, MD, FRANCISCO NAVARRO-LOPEZ, MD, and AMADEO BETRIU, MD

Prevalence, prognosis, and coronary anatomy associated with nontransmural myocardial infarction (MI) were prospectively assessed in 458 consecutive men admitted to our coronary care unit with a first MI. Cardiac catheterization was performed in 402 of the 436 survivors within 1 month of the acute event. Mean follow-up was 33 months (range 5 to 72). Nontransmural MI was diagnosed in 28 patients (6%). These patients were younger (46 ± 10 versus 51 ± 7 years, p <0.001) and had lower peak creatine kinase values (601 ± 319 versus 1,141 ± 923 U, p <0.01) and better ejection fraction (63 ± 8 versus 46 ± 14, p <0.001) than did their counterparts. Survivors of nontransmural MI also had fewer affected arteries (p <0.001) and a lower prevalence of total or subtotal occlusion (>90%) in the involved artery (p <0.01). Mortality in the acute phase and long-term survival at 4 years (Kaplan-Meier) in patients with nontransmural MI (94%) were similar to those in patients with transmural MI (90%). The occurrence of new nonfatal coronary events was also similar in both groups of MI survivors. Thus, in the absence of symptoms, more aggressive management to improve survival does not seem warranted after nontransmural MI.

Despite extensive investigation, the prognostic significance of nontransmural myocardial infarction (MI) remains controversial.[1–10] Although some studies report a lower in-hospital mortality in patients with nontransmural MI than in those with transmural MI,[6,7] others found the same mortality in both forms of MI.[3,4,11] Similarly, the long-term mortality of patients with nontransmural MI has been either comparable to[3,6] or greater than[4] that of patients with transmural MI. Discrepancies among series available for review may be due to the criteria used to select patients for study. In particular, the inclusion of patients with healed MI[3,4,6,9–11] is misleading because the electrocardiogram is a poor predictor of transmural involvement in the presence of scar tissue.[12–14] Because left ventricular and coronary angiography were not performed routinely, previous studies failed to characterize baseline variables that appear to be important predictors of survival after MI.[2,15–19]

This investigation elucidates the prognostic significance of a first nontransmural MI. A series of 402 consecutive patients with proven MI were catheterized within 1 month of the acute event; 24 of these patients had nontransmural MI and are the subject of this report.

Methods

Patient population: From December 1975 to September 1981, 458 men aged ≤60 years were admitted to our Coronary Care Unit with a first MI. A detailed description of the prospective protocol, the University of Barcelona Myocardial Infarction Research Project, appears elsewhere.[15,20]

Criteria for diagnosis of MI: Acute MI was diagnosed when ≥2 of the following criteria were present: ischemic chest pain lasting >20 minutes, a typical increase and decrease in enzyme levels (total creatine kinase, lactic dehydrogenase [LDH], and LDH isoenzymes) and evolving Q-wave abnormalities with acute ST-T wave changes on the electrocardiogram. Previous MI was diagnosed in the presence of a hospital admission for documented MI or Q waves in the electrocardiographic diagnosis of an old infarct.

Nontransmural MI was diagnosed when a normal QRS persisted throughout the hospital stay (according to the

0	7 (29%)	21 (6%)	0.001
1	9 (37%)	138 (36%)	NS
2	4 (17%)	129 (34%)	NS
3	4 (17%)	90 (24%)	NS

CCU = coronary care unit; CHF = congestive heart failure; LVEDP = left ventricular end-diastolic pressure; NS = not significant.

Minnesota Code[21]) and peak enzyme levels were at least twice the baseline.

Clinical evaluation: On admission all patients underwent careful investigation of their risk factors. Each patient was questioned to determine a history of coronary artery disease and the use of cigarettes. Diabetes mellitus was considered present if the patient was being treated for this condition or if the fasting blood sugar was >120 mg/100 ml (6.7 mmol/liter). Similarly, hypertension was diagnosed if the patient was already receiving antihypertensive drugs or if the blood pressure was >155/95 mm Hg. Serum cholesterol and triglyceride levels were measured after a 12-hour fast in all patients; if either was elevated, hyperlipidemia was diagnosed. Obesity was defined as a weight ≥15% above that considered ideal for a given height.

Catheterization and angiographic procedures: Within 4 weeks of MI, coronary angiography was performed in 402 of the 436 survivors. The remaining 34 patients (4 with nontransmural infarct) were excluded because of their refusal to undergo catheterization (23 patients), coexistence of a disease with decreased life expectancy (2 patients had cancer, 3 cerebrovascular accidents, and 4 severe cor pulmonale), or dye allergy.[1] Informed consent was obtained in all patients before catheterization.

Left ventricular volumes and ejection fraction were determined using the area-length method modified for single-plane calculations.[22] To assess regional wall motion, 5 areas of interest, anterobasal, anterolateral, apical, diaphragmatic, and posterobasal, were constructed by drawing a longitudinal axis from the midpoint of the aortic valve to the apex and trisecting it by 2 equidistant chords. The 2 apical areas were combined and treated as a single region. The systolic change for each region was measured as the segmental ejection fraction.[23]

All angiograms were assessed by 2 independent observers that coded the degree and location of coronary arterial lesions. Discrepancies were resolved by caliper measurement of percent reduction of luminal diameter in the projection showing maximal stenosis. Lesions <50% were considered nonobstructive. Each patient was classified as having 1-, 2-, or 3-vessel coronary artery disease. Obstruction of diagonal or marginal branches was considered a lesion of the left anterior descending or circumflex artery, respectively. Collaterals were judged to be well developed when the diameter of the receiving artery measured >1 mm and the sending vessel showed nonobstructive lesions.[20]

Follow-up: Patients were seen monthly during the first 3 months and every 3 months thereafter. Clinical status, results of physical examination, and a resting electrocardiogram were recorded at each visit. The mean follow-up was 33 months (range 5 to 72). Follow-up was completed in 372 of the 402 patients who had angiograms; the other patients were lost to follow-up. Although no attempt was made to standardize medical treatment, all patients were kept on a low-cholesterol diet and moderate exercise was recommended. Surgical treatment was reserved for intractable angina or lesions of the left main coronary artery.

Statistical analysis: A total of 12 variables were identified in each patient from the clinical history and cardiac catheterization and angiographic data. These variables were age, history of hypertension, dyslipemia, diabetes, peak creatine kinase value, peak LDH, infarct location, severe congestive heart failure (Killip's class III or IV) complicating the acute phase of the infarct, left ventricular end-diastolic pressure, ejection fraction, number of abnormally contracting segments, and the number of involved vessels. Differences between patients with transmural and nontransmural MI were analyzed using the Statistical Package for Social Sciences, applying Student's *t* test, Fisher's exact test, or chi-square when appropriate. Occurrence of new coronary events was compared between patients with and without nontransmural MI by constructing Kaplan-Meier actuarial curves for the 2 groups. Statistical differences were assessed by the log-rank test. A p value <0.05 was considered significant. Patients not accepting coronary angiography were excluded from survival analysis.

Results

Prevalence: Of the 458 patients admitted to our Coronary Care Unit with a first infarction, 28 had nontransmural MI according to our criteria. Therefore, subendocardial infarct was prevalent in 6% of patients in the present series.

Clinical findings: None of the 28 patients with subendocardial infarct and 22 with transmural necrosis died in the acute phase, the difference being not statistically significant. Nonsurvivors were older and had higher peak creatine kinase values and a higher prevalence of severe congestive heart failure (Table I).

Patients with nontransmural MI were younger (46 ± 10 versus 51 ± 7 years, p <0.001) and had lower creatine kinase levels (601 ± 319 versus 1,141 ± 923 U, p <0.01)

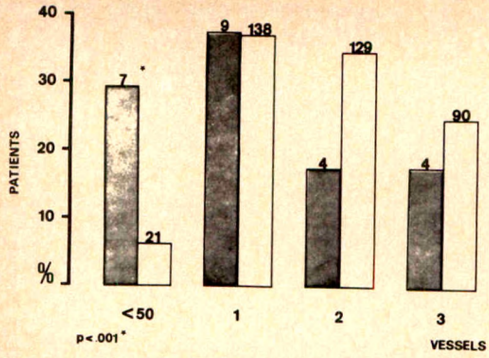

FIGURE 1. Percentage distribution of the number of affected vessels (≥50% stenosis) in patients with transmural infarcts (**open bars**) and those with nontransmural necrosis (**shaded bars**). As shown, nonobstructive disease was more prevalent among the latter group, and multivessel disease (2 and 3 vessels) in the former ($p < 0.01$).

in the acute phase than did patients with transmural involvement. Although no differences were found in the prevalence of a history of hypertension, diabetes, or cigarette consumption, the absence of all risk factors was more common among patients with nontransmural MI ($p < 0.05$) (Table II). Of the 436 acute-phase survivors, 402 (378 with transmural and 24 with nontransmural MI) underwent cardiac catheterization within 1 month of the onset of symptoms.

Hemodynamic and angiographic findings: Left ventricular end-diastolic pressure was lower (10 ± 5 versus 14 ± 7 mm Hg, $p < 0.01$) and ejection fraction higher (64 ± 8 versus 46 ± 14%, $p < 0.001$) in patients with nontransmural MI. No patient in this group was found to have an ejection fraction lower than 50%. Regional wall motion analysis showed that patients with subendocardial infarction had fewer abnormally contracting segments (0.73 ± 0.93 versus 2.29 ± 1.43, $p < 0.001$) and a higher prevalence of normal left ventricular angiograms (50 versus 9%, $p < 0.001$) than did survivors of transmural infarction.

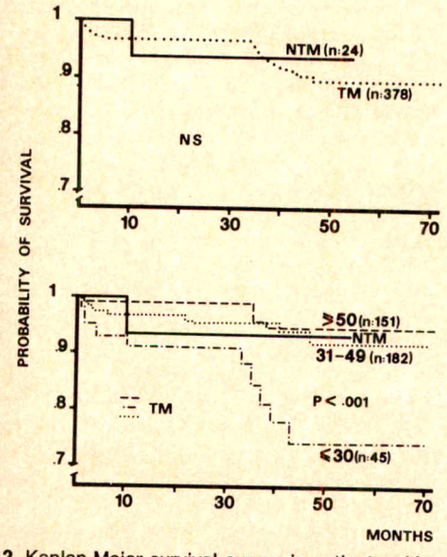

FIGURE 2. Kaplan-Meier survival curves in patients with transmural and nontransmural myocardial infarction. The **upper panel** shows similar long-term survival in both populations (90 and 94% at 4 years, respectively). The **lower panel** shows that the probability of survival after a first nontransmural myocardial infarction (all patients having an ejection fraction of 50%) is similar to that in patients with comparable degrees of left ventricular dysfunction after a first transmural infarction (4-year survival in the latter group was 95% for those with an ejection fraction of 50%, 92% for those with an ejection fraction between 31 and 49%, and 75% for those with an ejection fraction <30%).

TABLE III Location of Total or Subtotal Coronary Arterial Narrowings in Patients With Nontransmural and Transmural Myocardial Infarction

Coronary Artery	Nontransmural (n = 10 [41%])	Transmural (n = 285 [76%])	p Value
Left main	0	2	NS
LAD (proximal-mid)	3	125	NS
LC (proximal)	1	17	NS
Right (proximal-mid)	1	86	NS
Distal LAD, LC, right, diagonal, or marginal	5	55	0.05

LAD = left anterior descending; LC = left circumflex; NS = not significant.

Figure 1 shows the number of involved arteries (stenosis ≥50%) in both groups of infarct survivors. Patients with nontransmural MI had a higher prevalence of nonobstructive disease (29 versus 6%, $p < 0.001$), 4 of them having strictly normal coronary angiograms. Multivessel disease was prevalent among survivors of a transmural infarct (59 versus 33%, $p < 0.05$). The presence of total or subtotal (>90%) stenosis in ≥1 coronary arteries was also more common among the latter (76 versus 41%, $p < 0.01$). In 5 of 10 patients with nontransmural MI and stenosis >90% in the corresponding artery, the lesion was located in either a marginal or diagonal branch or the distal segment of a major artery (Table III). No differences were found in the prevalence of well-developed collaterals between the 2 groups.

Follow-up: No patient surviving a nontransmural MI and 20 in the group with transmural infarct had a nonfatal reinfarction, a statistically nonsignificant difference. The incidence of new onset of angina was also similar in both groups (42 and 37%, respectively). In no patient in the group with subendocardial infarction and in 46 with transmural infarcts did congestive heart failure develop during follow-up, a nonsignificant difference ($p = 0.06$).

Figure 2 shows Kaplan-Meier actuarial curves in survivors of transmural and nontransmural infarcts (4-year survival was 90 and 94%, respectively). No differences were found when both populations were compared (upper panel). When survival curves were constructed according to ejection fraction subsets in patients with transmural infarct, survivors of subendocardial infarct behaved like their counterparts with transmural necrosis and mild or moderate left ventricular dysfunction (lower panel).

TABLE IV Representative Studies on Long-Term Follow-Up After Nontransmural Myocardial Infarction (MI)

Discussion

Prevalence: It is now well recognized that minor degrees of myocardial necrosis can occur in a subset of patients with unstable angina pectoris.[24–28] Because differentiation between nontransmural infarct and unstable angina relies on the sensitivity of the test used for diagnosis, the wide discrepancies in survival patterns found in the literature are expected. If our criteria for the diagnosis of MI had been less stringent or if more sophisticated techniques (such as technetium scanning) had been used, our series would have included many patients now diagnosed and treated in this institution as having unstable angina pectoris.

Our data indicate that only 6% of patients with a first MI will fulfill the electrocardiographic and enzymatic criteria of nontransmural infarct. This figure is at variance with previous data reporting the prevalence of nontransmural infarct to be higher. Szklo et al,[6] in a retrospective multicentric study, found an incidence of 29%, whereas higher figures (up to 40%) have been reported in other studies dealing with selected population samples.[4,7] A source of error in estimating the prevalence of nontransmural MI may stem from the inclusion of patients with a previous MI. As in Table IV, most series include large percentages of patients with previous MI. Indeed, pathologic studies show that a new transmural MI may fail to produce diagnostic Q waves in the presence of an old scar.[12,29] Interestingly enough, Mahony et al[10] in the only study excluding patients with previous MI found that 4% of patients with acute MI failed to develop significant QRS abnormalities.

Results in prospective studies may vary depending on the population, the age and sex of the patients, and the selection criteria. Although we chose an age limit of 60 years to increase the likelihood of long-term follow-up, our series included 70% of all patients hospitalized with MI. Female subjects were excluded to increase the uniformity of the sample, as infarction in women is still uncommon in this country. In fact, only 23 women <60 years of age were hospitalized with acute MI during the study (male/female ratio 19:1). However, the incidence of symptomatic arterial disease in women parallels that in men, with a time lag of 8 to 10 years.[29,30] Thus, our results should not be seriously distorted by the exclusion of women.

Clinical and angiographic characterization of nontransmural MI: We found that patients with nontransmural infarcts were younger ($p < 0.001$) and had a higher ejection fraction ($p < 0.001$) and fewer affected ventricular segments ($p < 0.001$) than did patients with transmural infarcts. These data and the finding of a lower peak creatine kinase value in the former group suggest that the infarct is smaller in nontransmural MI. This hypothesis is in contrast to previous reports[1–3] in which no differences were found in the severity of left ventricular dysfunction between the 2 groups. Again, the exclusion of patients with previous infarction (which represents as much as 30% of all cases in some series[6]) might account for the observed differences.

Marmor et al[9] recently reported a wide prevalence of early reinfarction in patients with subendocardial infarcts (43 versus 8% in patients with transmural necrosis). In that study, serial plasma MB-CK isoenzyme activity was determined for 14 days and recurrences were elegantly demonstrated by secondary plasma MB-CK peaks. Nevertheless, repeat chest pain and new ST-T wave changes were found to be sensitive markers of early reinfarction (90 and 80% sensitivity, respectively). Accordingly, recurrent necrosis is unlikely to be missed in the present series despite the fact that we did not routinely assess plasma enzyme activity for a longer interval than clinically required. Thus, the discrepancies found between our data and those of Marmor et al[9] might be ascribed to differences in criteria of patient selection, as suggested by the finding that recurrences were more common in women than in men.

The prospective design of our study allows estimation of the coronary anatomy associated with nontransmural MI. We found nonobstructive disease in 7 of these patients (29%), a significantly higher incidence than that found among survivors of transmural infarcts (6%). The prevalence of total or subtotal occlusion of the involved artery was lower in patients with nontransmural MI. In addition, in 5 of the 10 patients with nontransmural infarction showing total or subtotal occlusion of a coronary artery, the lesion was located in a marginal or diagonal branch or in the distal segment of a major coronary artery. We recently found[20] that patients with stenosis of ≤90% in the artery corresponding to a MI showed better ejection fraction and regional wall motion than did patients presenting with tighter stenosis and no collaterals; this suggests that early reperfusion either by anterograde recanalization or through collaterals could limit infarct size. Because the prevalence of well-developed collaterals was similar in transmural and nontransmural MI, the factors responsible for the smaller infarct size in the latter appear to be either a

lower prevalence of total or subtotal occlusion or involvement of smaller branches.

Prognosis: Multivariate analysis[15–19,31–33] identified left ventricular ejection fraction, the number of narrowed arteries, severe congestive heart failure in the acute phase, and a previous history of MI as the main determinants of prognosis in patients with coronary artery disease. Series analyzing long-term survival after nontransmural infarction[4–10] are heterogeneous as they include patients with wide differences in age, degree of left ventricular dysfunction, and prevalence of previous MI. The present report is the first prospective study on the long-term prognosis of patients surviving first nontransmural MI that includes angiographic information. This group of patients had better left ventricular function and a higher prevalence of either nonobstructive coronary artery disease or distally located obstructive lesions than did those presenting with transmural involvement.

Free Your Angina Patient...
from some constraints of
beta-blocker therapy

Calan® TABLETS
80 mg and 120 mg
(verapamil HCl)

A Freer Life-style For Your Angina Patients

Unsurpassed by propranolol in the treatment of angina

- The efficacy of Calan was unsurpassed by that of propranolol in well-controlled comparative studies involving patients with chronic stable angina.[1-4]
- Calan is very effective in unstable[5] and variant angina,[6] where spasm factors may preclude the use of propranolol.[7]

Low incidence of unwanted effects

- Serious adverse reactions are rare with Calan at recommended doses; the single most common unwanted effect is constipation (6.3%). The therapy continuation rate was 94.5% in clinical studies.[8]
- Unlike beta-blockers, Calan rarely causes extreme fatigue or mental depression.

Benefits even for patients who can't take propranolol

- Calan, unlike propranolol, can be used without added caution in angina patients who also have asthma, chronic obstructive pulmonary disease (COPD), or diabetes.

The only non-nitrate indicated for initial therapy for all types of angina

Calan®
(verapamil HCl)
TABLETS
80 mg and 120 mg

A Freer Life-style For Your Angina Patients

▪ Efficacy unsurpassed by propranolol

Calan is effective and, unlike propranolol, is indicated as initial therapy both for stable effort angina and for vasospastic angina.

▪ Therapeutic considerations similar to propranolol

Calan and propranolol have similar cardiovascular contraindications and many of the same cardiovascular adverse reactions (e.g., hypotension, reduction of myocardial contractility, and intensification of AV block).[8,9]

▪ An easy-to-titrate dosage schedule

Initial dosage: 80 mg t.i.d.

Titrate to optimal response: usually 120 mg t.i.d. or q.i.d.

Calan® (verapamil HCl) TABLETS
80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings),* hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Occasional elevations of liver enzymes have been reported; patients receiving verapamil should have liver enzyme levels monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil. **Precautions:** Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, and spotty menstruation. Overall continuation rate was 94.5% in 1,166 patients. **How Supplied:** Calan (verapamil HCl) is supplied in 80-mg and 120-mg sugar-coated tablets.

Symptomatic, Electrocardiographic, Metabolic, and Hemodynamic Alterations During Pacing-Induced Myocardial Ischemia

ROY V. MARKHAM, Jr., MD, MICHAEL D. WINNIFORD, MD, BRIAN G. FIRTH, MD, DPHIL, PASCAL NICOD, MD, GREGORY J. DEHMER, MD, SAMUEL E. LEWIS, MD, and L. DAVID HILLIS, MD

Atrial pacing has been used to assess the physiologic impact of coronary artery disease (CAD). Several variables have served as markers of pacing-induced myocardial ischemia, but their specificities and sensitivities are unknown. Accordingly, in 28 patients, incremental atrial pacing was performed. Of the 28, 10 had no CAD. The left ventricular ejection fraction (LVEF) (by gated equilibrium blood pool scintigraphy) increased in this group (0.60 ± 0.11 [mean ± standard deviation] before pacing to 0.67 ± 0.13 at peak-pacing, p = 0.002). In no patient did left ventricular end-diastolic pressure increase by >5 mm Hg. No patient had lactate production, and 2 (20%) had electrocardiographic S-T segment depression ≥0.1 mV. Four (40%) had chest pain with atrial pacing. In the remaining 18 patients with CAD, atrial pacing caused a decrease in LVEF ≥0.05 (0.46 ± 0.10 to 0.33 ± 0.09, p <0.001) and new segmental wall motion abnormalities in all, indicating pacing-induced myocardial ischemia. Only 8 (44%) had an increase in left ventricular end-diastolic pressure of >5 mm Hg, and only 9 (50%) had lactate production. Ten (56%) had ischemic electrocardiographic changes, and 12 (67%) had chest pain. Thus, the electrocardiographic, metabolic, and hemodynamic alterations that may accompany pacing-induced ischemia are specific but relatively insensitive markers of ischemia. In contrast, chest pain during atrial pacing is a nonspecific occurrence, appearing with similar frequency in normal subjects and patients with CAD and pacing-induced ischemia.

Rapid atrial pacing has been used in the catheterization laboratory as a controlled and reproducible method of producing myocardial ischemia in patients with underlying coronary artery disease (CAD).[1–3] In these individuals, pacing has been shown to induce angina-like chest pain,[4–9] electrocardiographic S-T segment depression,[4–7,9–11] myocardial lactate production,[4,11–14] and increases in left ventricular (LV) filling pressure.[4,10,11,15–18] However, the frequency with which each of these variables occurs in patients with pacing-induced ischemia varies substantially among these reports. In addition, few studies have examined these variables in persons without CAD. Therefore, this study examines the sensitivities and specificities of the symptomatic, electrocardiographic, metabolic, and hemodynamic alterations caused by rapid atrial pacing.

From the Department of Internal Medicine (Cardiovascular Division) and Radiology (Nuclear Medicine), the University of Texas Health Science Center, Dallas, Texas. This study was supported in part by Ischemic SCOR Grant HL 17669 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland, and the Harry S. Moss Heart Fund, Dallas, Texas. Manuscript received December 7, 1982; revised manuscript received February 14, 1983, accepted February 15, 1983.

Address for reprints: L. David Hillis, MD, Room L5. 134, University of Texas Health Science Center, 5323 Harry Hines Boulevard, Dallas, Texas 75235.

Methods

Patient population: The study was performed in 41 persons (28 men, 13 women, mean age 53 years) without valvular, congenital, pericardial, or primary myocardial disease referred for catheterization for the evaluation of chest pain. All patients were in sinus rhythm and had normal ventricular activation. No cardiac medications were administered within 8 hours of the study. In all patients, the entire protocol was performed before the introduction of radiographic contrast material. Based on the results of coronary arteriography and pacing-induced alterations in the left ventricular ejection fraction (LVEF), the patients were assigned to 1 of 3 groups.

Control group: Ten persons (5 men, 5 women, mean age 51 years) had no angiographic evidence of CAD. At the time of catheterization, all 10 were taking oral isosorbide dinitrate,

2 were taking propranolol, 2 were receiving nifedipine, and 1 was receiving digoxin.

Ischemic group: In 18 patients (13 men, 5 women, mean age 54 years) with CAD (defined as ≥70% luminal diameter narrowing of 1 or more major epicardial coronary arteries), myocardial ischemia was induced by rapid atrial pacing, as evidenced by a decrease in LVEF of ≥0.05 and new segmental wall motion abnormalities, both assessed by equilibrium gated blood pool scintigraphy. Of these 18, 11 were taking long-acting nitrates, 10 were receiving propranolol, 4 were receiving nifedipine, and 4 were taking digoxin.

Nonischemic group: In 13 patients (10 men, 3 women, mean age 53 years) with CAD, rapid atrial pacing did not induce a decrease in LVEF of ≥0.05 or segmental wall motion abnormalities. Since these persons did not have pacing-induced ischemia, they were excluded from further analysis.

Study protocol: In each patient, a 7 or 8Fr Gorlin catheter was advanced from the right basilic vein to a position approximately 2 cm into the coronary sinus; its location was confirmed fluoroscopically and oximetrically. A 9Fr polyurethane sheath was introduced percutaneously into the femoral artery, and its side-arm was connected to a pressure transducer for the monitoring of femoral arterial pressure and the acquisition of blood samples. Through this sheath, an 8Fr micromanometer-tipped pigtail catheter (Millar Instruments, Houston, Texas) was advanced to the left ventricle. Before pacing, arterial and coronary sinus blood samples were obtained for quantitation of lactate and oxygen content. In addition, a 12-lead electrocardiogram, a radionuclide ventriculogram, heart rate, femoral arterial pressure, and LV end-diastolic pressure were recorded. Subsequently, continuous atrial pacing was begun at 100 beats/min and increased every 4 minutes by 20 beats/min until chest pain or atrioventricular block occurred or until a heart rate of 140 beats/min was achieved. After 1 minute at the peak pacing rate, acquisition of another radionuclide ventriculogram was initiated. During the 15 seconds before the termination of pacing, arterial and coronary sinus blood samples again were obtained for measurement of lactate and oxygen content, and a 12-lead electrocardiogram was recorded during the 10 seconds after pacing was discontinued. LV end-diastolic pressure was recorded for 30 seconds after the abrupt termination of pacing.

Electrocardiographic and metabolic assessments: Ischemic electrocardiographic alterations were defined as at least 1 mm (0.1 mV) of horizontal or downsloping S-T segment depression 0.08 second after the J point in comparison to the baseline tracing.[19] Blood samples for lactate determination were immediately deproteinated in iced perchloric acid, centrifuged, decanted, and stored frozen. Lactate concentrations were assayed enzymatically with a commercial kit (Sigma Chemical, St Louis, Missouri). For each pair of blood samples, the percent myocardial lactate extraction was calculated using the formula $100 \times (A\text{-}CS)/A$, where A represents the arterial lactate concentration and CS the coronary sinus lactate concentration. Using this formula, a value less than zero is indicative of myocardial lactate production.[20] Finally, arterial and coronary sinus oxygen contents were determined with a Lex-O_2-Con analyzer (Lexington Instruments, Lexington, Massachusetts). These data were used to confirm that the coronary sinus catheter had not become inadvertently dislodged during rapid atrial pacing.

Hemodynamic assessments: Before pacing, LV end-diastolic pressure was measured coincident with the peak of the electrocardiographic R-wave; in each patient, 10 consecutive beats were averaged. To obtain the postpacing end-diastolic pressure, 10 consecutive beats again were averaged, beginning with the sixth beat after pacing was abruptly discontinued, as previously described.[21] For the purposes of this study, an increase in LV end-diastolic pressure from before to immediately after pacing of >5 mm Hg was considered abnormal.[10]

Radionuclide ventriculography: Red blood cells were labeled with radioisotope using a technique combining features of in vitro and in vivo labeling.[22] Scintigraphic data collection was performed with a portable gamma scintillation camera (Series Sigma 420, Ohio Nuclear, Solon, Ohio) equipped with an all-purpose parallel hole collimator and interfaced with a dedicated on-line computer system (Series 550). Equilibrium gated blood pool scintigrams were obtained in a modified left anterior oblique projection adjusted to allow the clearest septal visualization and left ventricular isolation. All studies were gated for 32 frames per cardiac cycle and collected for 100% of the cardiac cycle. The scintigraphic images were acquired for a predetermined number of cardiac cycles so that the total acquisition time of the study was 3 minutes. This procedure resulted in a minimum of 100,000 counts per frame of the study. All data were stored on magnetic disks for subsequent analysis.

LVEF was determined from the time-activity LV curve by constructing a region of interest over the left ventricle in the end-diastolic (ED) and end-systolic (ES) frames. After correcting for background activity, LVEF was calculated using the formula: LVEF = (ED counts − ES counts)/ED counts. This method has been shown to correlate well with results obtained by contrast angiography.[23] In this study, a decrease in LVEF of ≥0.05 (the accepted limit of observer error)[24] was considered abnormal.

A subjective analysis of regional wall motion also was performed. The image border in the left anterior oblique projection was divided into 5 equal segments identified as the basal-lateral, apical-lateral, apical, apical-septal, and basal-septal.[25] Wall motion was graded according to the following scale: 3 = normokinesia, 2 = mild hypokinesia, 1 = severe hypokinesia, 0 = akinesia, and −1 = dyskinesia. Changes in wall motion of 1 or more units were considered abnormal.

Statistical analysis: All results are reported as mean ± 1 standard deviation. For the analysis of the heart rate-systolic arterial pressure "double product," LVEF, and end-diastolic pressure within each group of patients, baseline values were compared with peak or after pacing values with a paired *t* test. For the comparison of these values between groups, an unpaired *t* test was employed. The change in LV end-diastolic pressure induced by pacing was compared with the pacing-induced alteration of LVEF by a 2-variable linear regression analysis. Finally, the sensitivities and specificities of each variable in each of the 2 patient groups were compared with a chi-square analysis.[26,27] For all analyses, a p value <0.05 was considered significant.

Results

Control group (n = 10) (Table I): In those without CAD, double product (heart rate × systolic arterial pressure) was 10.1 ± 2.4 × 10^3 units at rest and increased to 18.5 ± 2.1 × 10^3 units at peak pacing ($p < 0.001$). Pacing was accomplished at 140 beats/min in 8 of the 10 persons; in the remaining 2, it could not be performed above 120 beats/min because of atrioventricular block. Resting LVEF averaged 0.60 ± 0.11. At peak-pacing, it increased to 0.67 ± 0.13 ($p = 0.002$), and no patient had regional wall motion abnormalities. Of the 10 patients, 4 had their usual chest pain at peak-pacing, 2 had S-T segment alterations compatible with ischemia, and none had myocardial lactate production or an increase in LV end-diastolic pressure >5 mm Hg.

TABLE I Symptomatic, Electrocardiographic, Metabolic, and Hemodynamic Responses to Rapid Atrial Pacing in Patients With Normal Coronary Arteries (Control Group)

Patient	Age (yr) & Sex	Peak Pacing HR (beats/min)	Double Product × 10^3 Units		Chest Pain	S-T Depression	LVEDP (mm Hg)		LVEF	
			Pre	Peak			Pre	Post	Pre	Peak
1	42M	120	6	17	0	0	17	18	0.61	0.71
2	35M	140	9	15	0	0	12	12	0.59	0.71

Mean 51		...	10 ± 2	19 ± 2	...	...	15.1 ± 4.5	15.7 ± 4.6	0.60 ± 0.11	0.67 ± 0.13
SD		...	...	...	...	...				
			p <0.001				NS		p = 0.002	

HR = heart rate; LVEDP = left ventricular end-diastolic pressure; LVEF = left ventricular ejection fraction; SD = standard deviation.

For the 10 patients, left ventricular end-diastolic pressure averaged 15.1 ± 4.5 mm Hg at baseline and 15.7 ± 4.6 mm Hg immediately after pacing (not significant).

Ischemic group (n = 18) (Table II): All patients had angiographic evidence of CAD (1-vessel in 5, 2-vessel in 7, and 3-vessel in 6). At rest, double product was 9.0 ± 2.3 × 10^3 units, increasing to 17.8 ± 4.8 × 10^3 units at peak pacing ($p < 0.001$). The resting LVEF was 0.46 ± 0.10. With pacing, it decreased by ≥0.05 in all patients, so that at peak pacing it was 0.33 ± 0.09 ($p < 0.001$). All 18 had new wall motion abnormalities at peak-pacing. Of the 18 patients, 12 (67%) had their usual chest discomfort, 10 (56%) had postpacing S-T segment depression, 9 (50%) had myocardial lactate production, and 8 (44%) had an increase in LV end-diastolic pressure of >5 mm Hg. There was no correlation between the increase in end-diastolic pressure and the decrease in LVEF with pacing (r = 0.13, Fig. 1).

Of the 18 patients with CAD and pacing-induced LV dysfunction, 13 had a decrease in LVEF of ≥0.10. Of these 13 persons with an especially prominent pacing-induced functional change, 10 (77%) had chest discomfort, 7 (54%) had postpacing S-T segment depression ≥0.1 mV, 7 (54%) had myocardial lactate production, and 7 (54%) had an increase in LV end-diastolic pressure of >5 mm Hg. No variable occurred more frequently in these 13 patients than in the entire group of 18.

Finally, 8 of the 18 patients with CAD and pacing-induced LV dysfunction had a LVEF ≥0.50 during the baseline study, whereas the resting ejection fraction in the remaining 10 was <0.50. Of these 8 patients, 6 (75%) had pacing-induced chest pain, 6 (75%) had ischemic S-T segment alterations, 5 (63%) had lactate production, and 5 (63%) had a substantial (>5 mm Hg) increase in postpacing LV end-diastolic pressure. Ten of the 18 individuals with CAD and a pacing-induced decrease in the LVEF had a prepacing LV end-diastolic pressure ≤16 mm Hg. Of these, 6 (60%) had pacing-induced chest pain, 5 (50%) had ischemic S-T segment depression, and 4 (40%) had myocardial lactate production.

Discussion

Previous studies have demonstrated that rapid atrial pacing may induce chest pain,[4–9] electrocardiographic S-T segment depression,[4–7,9–11] myocardial lactate production,[4,11–14] and an increase in LV end-diastolic pressure[4,10,11,15–18] in persons with CAD, but the relative sensitivities and specificities of these variables have not been assessed. Therefore, this study was performed to examine each of these variables in normal subjects (persons with chest pain and angiographically normal coronary arteries) and those with pacing-induced ischemia, as reflected by a deterioration in LVEF and the appearance of new segmental wall motion abnormalities. The data provided in this study indicate that postpacing S-T segment depression, peak-pacing

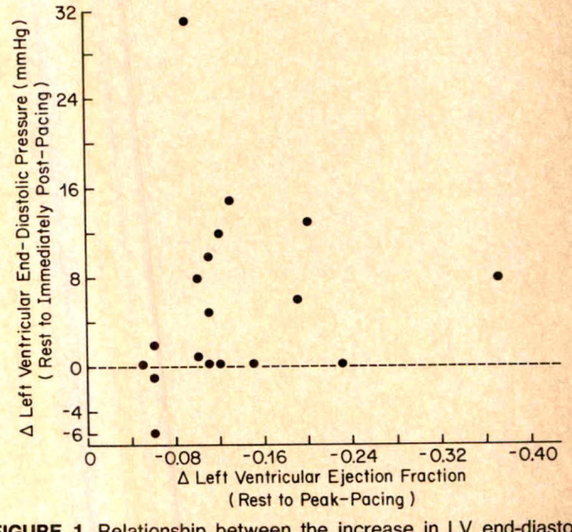

FIGURE 1. Relationship between the increase in LV end-diastolic pressure (in mm Hg) from rest to postpacing (**vertical axis**) and the decrease in LVEF from rest to peak-pacing (**horizontal axis**) for the 18 patients with CAD and pacing-induced ischemia. Each dot represents the data from 1 patient. There is no correlation between these 2 variables (r = 0.13, p = 0.60).

TABLE II Symptomatic, Electrocardiographic, Metabolic, and Hemodynamic Responses to Rapid Atrial Pacing in Patients With Coronary Artery Disease and Pacing-Induced Left Ventricular Systolic Dysfunction (Ischemic Group)

Pt	Age (yr) & Sex	Peak Pacing HR (beats/min)	Double Product × 10^3 Units		Chest Pain	S-T Depression	Lactate Production	LVEDP (mm Hg)		LVEF		Percent Diameter Narrowing of Coronary Arteries

myocardial lactate production, and postpacing increases in LV end-diastolic pressure are specific but relatively insensitive markers of pacing-induced ischemia. At the same time, pacing-induced chest pain is a relatively nonspecific occurrence, appearing with similar frequency in normal persons and those with underlying CAD and pacing-induced ischemia.

Pacing-induced chest pain: Several studies have indicated that pacing-induced chest pain is a highly sensitive and specific marker for underlying CAD.[4–9] In fact, in some studies[4,10,11,15–18] chest discomfort has served as the variable to which all other (such as lactate production and increases in LV end-diastolic pressure) are compared. In our experience, however, chest pain during pacing is an unreliable reflector of ischemia, since some patients cannot differentiate between ischemic chest pain and the palpitations associated with atrial pacing. Indeed, in the present study, 4 (40%) of the 10 patients without CAD or scintigraphic evidence of ischemia had their usual chest pain during pacing.

Pacing-induced electrocardiographic S-T segment depression: Although some studies[5] have demonstrated an excellent relationship between pacing-induced chest pain and S-T segment depression *during* pacing, others[9] have shown that S-T depression during pacing is neither specific nor sensitive in the identification of persons with CAD. Since rapid atrial pacing, in itself, produces certain electrocardiographic abnormalities,[4,21] we assessed pacing-induced S-T segment alterations in the immediate *postpacing* period. Ten (56%) of the 18 patients with pacing-induced ischemia had ≥0.1 mV of S-T segment depression on the postpacing electrocardiogram, but 2 (20%) of the 10 normal subjects also had such S-T segment alterations. Thus, postpacing electrocardiographic S-T segment depression offers only modest specificity and sensitivity in the identification of pacing-induced ischemia.

Pacing-induced myocardial lactate production: Pacing-induced myocardial ischemia leads to anaerobic glycolysis in the ischemic tissue, resulting in the release of lactate into the coronary venous effluent.[4,12–14,28–30] At the same time, the systemic arterial lactate concentration is stable. Thus, the normally oxygenated and perfused myocardium extracts lactate, whereas the ischemic myocardium produces it. Previous studies[4,10,11,14] have shown that lactate production occurs in most patients with CAD during pacing-induced angina. Our data indicate that myocardial lactate production is specific for pacing-induced ischemia, in that none of the 10 normal subjects produced lactate during pacing. However, lactate production is not a sensitive marker of pacing-induced ischemia: of the 18 patients with pacing-induced LV dysfunction, only 9 (50%) had lactate production. Our data show no relationship between lactate production and the severity of pacing-induced LV dysfunction. The 9 patients with lactate production had a pacing-induced decrease in the LVEF of 0.12 ± 0.05, whereas the 9 persons without lactate production had an average decrease of 0.14 ± 0.10 (not significant in comparison to the 9 who produced lactate). It is conceivable that lactate production is not demonstrable in some patients during pacing-induced ischemia because (1) coronary sinus blood sampling is not performed at the precise time of greatest lactate efflux, or (2) the lactate produced by ischemic tissue is diluted in the coronary venous effluent by drainage from nonischemic areas.

Pacing-induced increases in LV filling pressure: An elevated LV end-diastolic pressure is a common occurrence during angina in patients with CAD.[2,5,15,31,32] When angina is induced by atrial pacing, LV end-diastolic pressure usually increases with the onset of angina and becomes maximally elevated in the immediate postpacing period.[4,10,11,15–18] Although several studies have assessed postpacing alterations in LV end-diastolic pressure in patients with CAD, there is disagreement as to the frequency with which such elevations occur.[10,16–18] As with the production of lactate, our data indicate that a substantial (>5 mm Hg) increase in postpacing LV end-diastolic pressure is a specific but relatively insensitive marker of pacing-induced ischemia. Such elevations did not occur in the 10 normal subjects, but they occurred in only 8 (44%) of the 18 with pacing-induced LV systolic dysfunction. Furthermore, although McKay et al[33] have demonstrated a good correlation between pacing-induced hemodynamic changes and LV segmental hypoperfusion (as assessed by thallium scintigraphy), our data show no relationship between the magnitude of change in LV end-diastolic pressure and that in LVEF with pacing (Fig. 1).

Use of alterations in LVEF and segmental wall motion as indexes of pacing-induced myocardial ischemia: In the present study we used a decrease in LVEF of ≥0.05 and the appearance of new segmental wall motion abnormalities during pacing as indicators of myocardial ischemia. The use of these functional markers is supported by numerous studies in experimental animals and man showing that ischemia impairs LV systolic performance.[34–40] In each patient with CAD, a decrease in LVEF of ≥0.05 from rest to peak-pacing was required, since Wackers et al[24] have shown that alterations in LVEF of smaller magnitude are within the accepted limits of observer variability with multigated equilibrium blood pool imaging.

Clinical implications: Although selective coronary arteriography allows identification of obstructive CAD, it gives no information about the physiologic importance of such disease. In most patients, this information can be obtained by exercise testing or atrial pacing at the time of cardiac catheterization. Previous studies have suggested that pacing-induced chest pain, electrocardiographic alterations, lactate production, and elevations of LV end-diastolic pressure are reliable markers of ischemia, but their sensitivities and specificities are unknown. The present study demonstrates (1) that chest pain during atrial pacing is a nonspecific occurrence, since it appears with similar frequency in normal persons (40%) and those with CAD and pacing-induced ischemia (67%) (not significant); (2) that postpacing electrocardiographic S-T segment depression ≥0.1 mV occurs in slightly more than half those with pacing-induced ischemia, but it also occurs on occasion in normal persons; and (3) and that both peak-pacing myocardial lactate production and post-

pacing elevations of LV end-diastolic pressure are highly specific but relatively insensitive reflectors of pacing-induced ischemia. It is possible that this relative insensitivity might improve if atrial pacing were performed more rapidly (>140 beats/min) or for a longer period of time (>4 minutes).

Effect of Oral Sustained-Release Nitroglycerin on Exercise Capacity in Angina Pectoris: Dose-Response Relation and Duration of Action During Double-Blind Crossover Randomized Acute Therapy

SERGE G. DEGRÉ, MD, GISÈLE M. STRAPPART, MS, JOHN C. SOBOLSKI, MD, GUY M. BERKENBOOM, MD, ERIC E. STOUPEL, MD, and POL P. VANDERMOTEN, MD

Ten men with documented coronary artery disease and stable exertional angina underwent a double-blind crossover study to examine the benefit and the duration of action on their symptom-limited exercise capacity of 2 doses (2.5 and 6.5 mg) of sustained-release nitroglycerin (SRNG). A multistage bicycle test was performed in the sitting position by steps of 30 W each 3 minutes until the onset of typical angina pectoris. It was performed 24 hours before the start of the study; 1 and 5 hours after administration of placebo, and repeated after 2.5 and 6.5 mg of SRNG administered in a double-blind crossover study according to a 4 successive days protocol. No differences appeared between administration of placebo (1 and 5 hours) and the results obtained at the first exercise test. The dose of 2.5 mg of SRNG was effective on the symptom-limited working capacity but only at 1 hour (+9%; $p < 0.01$). The dose of 6.5 mg was more effective both at 1 hour (+25%; $p < 0.001$) and at 5 hours (+27%; $p < 0.001$). All patients had angina at a higher heart rate (+5 to 8%; p = NS [not significant] and $p < 0.01$), whereas systolic blood pressure and double product tended to be slightly but insignificantly increased. S-T depression at the onset of angina was insignificantly changed with placebo, and 2.5 and 6.5 mg of SRNG. It is concluded that 6.5 mg of orally administered SRNG is effective during at least 5 hours, and that the magnitude of the benefit and its duration are dose-related.

Because the duration of action on sublingual nitroglycerin is relatively short, there has been a search for a pharmacologic agent that would have prolonged therapeutic effectiveness. Three basic approaches to a prolonged pharmacologic action of nitroglycerin have been evaluated by utilizing an ointment base, an organic nitrate compound (isosorbide dinitrate and pentaerythritol tetranitrate), and the formulation of timed disintegration granules with controlled and sustained release of a therapeutic dose of nitroglycerin. The investigation reported here evaluated the therapeutic effectiveness of 2 doses, 2.5 and 6.5 mg of a sustained-release nitroglycerin preparation (SRNG) (Nysconitrine®, 2.5 and 6.5 mg) orally administered to patients with angina pectoris. The efficacy of both dosages was evaluated in a double-blind crossover investigation of the SRNG preparation compared with an identically presenting placebo capsule, according to objective criteria (that is, symptom-limited maximal working capacity measured during a graded exercise test).

Methods

Patient group: Ten men, aged 48 to 70 years (mean, 61 ± 8) with stable grade II exertional angina pectoris were studied. Patients with symptoms or clinical evidence of congestive heart failure were excluded. During the study period, no other treatment (beta-blocking agents or calcium-channel inhibitors) was allowed.

The diagnosis of coronary artery disease was based on both a positive coronary angiogram (≥50% reduction in luminal diameter of at least 1 coronary artery) and a positive exercise thallium scan. Five patients had 1-vessel disease, 3 patients

TABLE I Comparison Between Maximal Values Obtained Before the Study and Under Placebo Conditions

BET = basic exercise test; D = maximal working capacity expressed in duration; HR = maximal heart rate; NS = not significant; p = probability; PRP = maximal pressure-rate product; SD = standard deviation; SPB = maximal systolic blood pressure; S-T↓ = maximal S-T segment depression; Val = absolute value; Δ = difference.

had 2-vessel disease and 2 patients 3-vessel disease. No patient had S-T segment depression on the resting electrocardiogram, but all had angina pectoris and S-T segment depression during exercise. No complications occurred as a result of the experimental procedure.

Protocol: The patients first performed a multistage bicycle exercise test in the sitting position: After an initial work load of 30 W during 3 minutes, the load was increased by 30 W every 3 minutes. Exercise was continued until the onset of typical angina pectoris. A 12-lead electrocardiogram was recorded every minute. Electrocardiographic leads V_3, V_4, V_5, and V_6 were continuously monitored on an oscilloscope. Lead V_5 was automatically analyzed. An exercise test was considered positive when the surface limited by the resting S-T level and the depressed S-T segment, 0.02 to 0.08 second from the top of the R wave, was ≥7.5 mV·s. All patients had a positive exercise test according to these criteria.

Twenty-four, 48, and 72 hours later, the same multistage graded exercise was performed 1 and 5 hours after administration of placebo and 2.5 or 6.5 mg of SRNG preparation, administered according to a double-blind crossover randomized protocol. Symptom-limited working capacity was expressed as the duration of the standardized exercise test. The experiments took place in an air conditioned room (temperature, 20°C to 23°C; humidity, 40 to 60%), all patients having already performed at least 1 exercise test before the present procedure. The following variables were measured or calculated: (1) maximal symptom-limited working capacity, expressed in minutes of duration of the progressive exercise test; (2) maximal heart rate; (3) maximal systolic blood pressure; (4) S-T segment depression in mm; and (5) double product (heart rate × systolic blood pressure).

Statistical analysis was performed by Student's paired *t* test.

Results

The various parameters, measured 1 and 5 hours after placebo administration, did not differ significantly from values measured during the basic exercise test (Table I). The mean values for symptom-limited maximal exercise capacity comparing placebo and SRNG (2.5 and 6.5 mg) are presented in Table II.

Symptom-limited maximal working capacity measured 1 hour after administration of 2.5 mg of SRNG compared with that 1 hour after placebo administration increased by 9% ($p < 0.01$), heart rate by 5% (NS), systolic blood pressure by 8% ($p < 0.05$), double product by 12% (NS), and S-T segment depression by 8% (NS).

Symptom-limited maximal working capacity measured 5 hours after administration of 2.5 mg of SRNG compared with that 5 hours after placebo administration remained unchanged (+1%; NS), heart rate increased by 2% (NS), systolic blood pressure by 6% ($p < 0.05$), double product by 7% (NS), and S-T segment depression was unchanged (−2%; NS).

Symptom-limited maximal working capacity measured 1 hour after administration of 6.5 mg of SRNG compared with that 1 hour after placebo administration improved by 25% ($p < 0.001$), heart rate increased by 8% ($p < 0.01$), systolic blood pressure was unchanged (+1%; NS), double product increased by 10% (NS), and S-T segment by 7% (NS).

Symptom-limited maximal working capacity measured 5 hours after administration of 6.5 mg of SRNG compared with that 5 hours after placebo administration remained significantly improved (+27%; $p < 0.001$). Heart rate increased by 5% (NS) and systolic blood pressure by 4% (NS). The double product was significantly higher (+8%; $p < 0.01$), whereas the S-T segment depression remained unchanged (+1%; NS).

Discussion

Our results demonstrate that orally administered SRNG was rapidly absorbed from the gastrointestinal tract and exerted an antianginal effect 1 hour after intake. The drug produced a dose-related increase in symptom-limited maximal working capacity (+9% and 25%, 1 hour after 2.5 and 6.5 mg of SRNG, respectively). We could also demonstrate a dose-related increase in the duration of action: Maximal symptom-limited exercise capacity was unaffected 5 hours after administration of 2.5 mg of SRNG, whereas a 27% increase was still present 5 hours after administration of 6.5 mg. The study involved 7 repeated exercise tests over 4 days. A training effect could have influenced the exercise performance of the patients. This was taken into account in designing the study: Each patient was studied after a double-blind crossover administration of placebo, and

Abbreviations as in Table I.

2.5 or 6.5 mg of SRNG. No statistically significant differences were observed between the basic exercise test values and the values observed during the tests performed on the first, second, or third day under placebo conditions.

Although sublingual nitroglycerin prolongs exercise tolerance in patients with angina pectoris,[1–4] the usefulness of SRNG or long-acting nitrates in angina pectoris was seriously questioned until recently.[5] The reasons for conflicting opinions about long-acting nitrates are varied: (1) Poor to no statistical method. When considering properly designed investigations, long-acting nitrates are usually found to be ineffective.[6] (2) The major difficulty in designing adequate clinical evaluations of antianginal therapy.[5,7,8] (3) The works of Needleman and Johnson[9] showing that orally administered nitrates are rapidly metabolized in the liver, allowing little or none of the active molecule to reach the systemic circulation. However, more recently, several well-designed studies have shown prolonged effects of long-acting nitrates in increasing exercise tolerance in patients with angina.[8,10,11] Three long-acting nitrate formulations have shown clear-cut effectiveness in recent studies: isosorbide dinitrate, oral sustained-action nitroglycerin, and nitroglycerin ointment.[12]

As far as SRNG is concerned, only 2 well-designed contemporary studies reported a sustained efficacy in patients with angina: Improved exercise tolerance was shown up to 4 hours after the last oral dose of 6.5 mg of nitroglycerin.[8,11]

In the present investigation, we evaluated the duration of action as well as the influence on symptom-limited exercise capacity and other exercise parameters of an orally administered SRNG at 2 different doses: 2.5 and 6.5 mg, administered randomly and in double-blind manner, compared with placebo. The 2.5 mg dose increased exercise duration by 9% at 1 hour, but was ineffective at 5 hours. In contrast, 6.5 mg of SNRG increased exercise capacity by 25% for 5 hours. All patients were stopped by angina at a higher level of heart rate (5 to 8%), whereas systolic blood pressure and double product tended to be slightly but insignificantly increased. However, double product was significantly increased 5 hours after administration of 6.5 mg of SRNG. S-T segment depression at the onset of angina remained unchanged with placebo and 2.5 or 6.5 mg of SRNG. These results were in agreement with earlier studies on SRNG or isosorbide dinitrate.[3,10]

Previous studies have shown a variable effect of nitrates on rate-pressure product.[11,13,14] Heart rate and systolic blood pressure are important determinants of myocardial oxygen requirement, but these 2 variables do not take into account the influence of ventricular volume and myocardial contractility. In our study, the effects of SRNG on these 2 parameters were not studied. Therefore, we cannot comment on the overall effects of different doses of SRNG on the myocardial oxygen supply and demand equation in the patients studied. It is nevertheless admitted that nitroglycerin improves maximal exercise tolerance mainly by a decrease in venous and arterial tone.

In conclusion, our results show that a single dose of 6.5 mg of SRNG is effective during at least 5 hours, as opposed to a single dose of 2.5 mg. Both the magnitude and the duration of the beneficial effect are dose-related.

Acknowledgment: We thank Biothera-Asperal, Brussels, Belgium, for the supply of identical tablets for the different doses of SRNG and placebo and the nursing staff of the Cardiology Laboratory for their cooperation throughout the study. The help of Pascale Naracci, Francine Pype, Agnès Minne, and Patricia Vandenberghe was particularly appreciated.

Prolonged Angina Pectoris and Persistent Negative T Waves In the Precordial Leads: Response to Atrial Pacing and to Methoxamine-Induced Hypertension

JAIME FIGUERAS, MD, JUAN CINCA, MD, LUIS GUTIERREZ, MD, ROSA SEGURA, ScD, and JORGE RIUS, MD

In 18 consecutive patients without a history of myocardial infarction (MI), prolonged angina pectoris with persistent negative T waves in the precordial leads was associated with a high frequency of in-hospital spontaneous angina (14 of 18, 78%), usually accompanied by S-T segment elevation, and occasionally in-hospital MI (4 of 18, 22%). Angina and MI always involved the electrocardiographic leads with negative T waves. Coronary arteriography, performed in 16 patients, revealed ≥90% proximal diameter reduction of the left anterior descending (LAD) coronary artery in 14 patients. No patient had severe narrowing of all 3 major coronary arteries, but the 3 who had 100% LAD occlusion lacked collateral circulation. The ejection fraction was ≥50% in 13 patients. Atrial pacing performed in 11 patients at an average rate of 142 beats/min produced a 1.0 mm S-T segment change in only 5 patients (45%), 3 of whom had an associated lactate production. Arterial systemic hypertension induced by methoxamine in 14 patients caused reversal of negative T waves without significant S-T segment shifts or chest pain and failed to elicit lactate extraction abnormalities in each of the 5 patients in whom it was determined. Thus, prolonged angina with persistent negative T waves in the precordial leads is almost invariably associated with a critical and proximal LAD obstruction, severe narrowing of 1 or 2 coronary arteries, and poor or absent collateral vessels. The relatively preserved coronary reserve in 55% of our patients suggests that negative T waves do not represent active myocardial ischemia. The study also suggests that transient "positivization" of the negative T waves may not necessarily relate to myocardial ischemia when associated with acute systemic hypertension.

Although it is known that prolonged angina may be associated with negative T waves in the precordial leads as the only electrocardiographic abnormality,[1–5] the clinical and coronary arteriographic characteristics of these patients are ill defined. Given their electrocardiographic similarities, it is forseeable that these patients also could share common angiographic features which therefore could be predicted from the electrocardiographic findings. Albeit no definite proof has been afforded, perhaps the most accepted hypothesis suggests that these negative T waves reflect subendocardial or transmural ischemia provided the enzyme profile is unaltered.[1,6,7] If this concept were to hold true, it would probably follow that modest increases in myocardial oxygen needs could easily magnify the extent of this ischemia.

Partial or complete T-wave "positivization" however, has been associated with angina and scintigraphic evidence of transmural ischemia,[7–9] but similar electrocardiographic changes during exercise stress testing have been interpreted as nonspecific.[10,11] We surmise that factors other than myocardial ischemia (MI), such as arterial hypertension or the sympathoadrenergic discharge during both spontaneous angina and exercise[12,13] may exert some influence on these changes in T-wave polarity irrespective of the presence of ischemia. The 3-fold purpose of this study is (1) to study the clinical and angiographic characteristics of patients with prolonged angina and negative T waves in the precordial leads, (2) to explore the possibility that these negative T waves could imply a marked reduction in the coronary reserve, and (3) to investigate the effects of arterial systemic hypertension on negative T waves and its correlation with possible symptoms or changes in myocardial metabolites.

AMI = acute myocardial infarction; AP = angina pectoris; CABG = coronary artery bypass grafting; d = days; DM = diabetes mellitus; In-H = in-hospital; MI = myocardial infarction; Pt = patient; SH = systemic hypertension; Tc = technetium pyrophosphate scintigram; y = years.

Methods

Patients: The 18 consecutive patients included in this study, 14 men and 4 women, mean age 53 years (range 40 to 72), were admitted within 12 hours of the onset of an episode of prolonged angina (>20 minutes) which was not relieved by sublingual nitroglycerin, 1.0 mg. In addition, they met the following criteria: (1) presence of negative T waves ≥3.0 mm in 2 or more precordial leads involving at least leads V_2 and V_3 or V_3 and V_4, which persisted for a minimum of 3 days; (2) absence of previous MI; (3) absence of acute MI based on the absence of Q waves and the lack of a significant increase in enzyme levels (greater than twice the normal values, 30 to 70 IU/liter); (4) absence of bundle branch block or atrioventricular block of second degree or greater; and (5) absence of valvular heart disease. Patients with variant angina with typical circadian rhythm, a high incidence of nocturnal attacks, and preserved exercise capacity were excluded. Also excluded were those treated with digitalis, amiodarone, or propranolol, those with hypocalcemia, and those with persistent atrial fibrillation.

Protocol: All patients were admitted to the coronary care unit and placed on bed rest. A standard 12-lead electrocardiogram was taken on admission, at least once each day thereafter, and during and after episodes of chest pain. No antianginal medication was administered except for sublingual nitroglycerin or intravenous analgesics. After documentation of the electrocardiographic and blood pressure changes during 1 or 2 episodes of angina, treatment was initiated with nifedipine, 40 to 80 mg/day, isosorbide dinitrate, 5 mg every 2 to 4 hours, or a combination of both drugs. Eventually, some patients also received diltiazem in doses up to 240 mg/day. Total creatinine phosphokinase and oxaloacetic transaminase were measured every 8 hours during the first 48 hours and in the 24 hours subsequent to an episode of angina >30 minutes.

A technetium-stannous pyrophosphate myocardial scintigram (Dynacamera 2C, Picker) was performed between the first and fifth days in 7 patients, using 20 mCi of technetium-99 pyrophosphate. Scans were taken the first and second hours after injection, and images were obtained in 3 different views: anteroposterior, left lateral, and left anterior 45° oblique. They were interpreted by 2 observers unaware of the patient's condition, as follows: 0 = absence of myocardial activity; 1+ = minimal cardiac activity; 2+ = definite myocardial activity but of lesser intensity than that of bone; 3+ = myocardial activity equal to that of bone; and 4+ = myocardial activity greater than that of bone.

Between the 5th and 10th days, and while the electrocardiogram still exhibited negative T waves, 11 patients underwent atrial pacing and methoxamine-induced arterial hypertension studies. Antianginal medication was discontinued at least 6 hours before these tests. After sedation with 5 to 10 mg of diazepam orally, right-heart catheterization was performed using a 7Fr Swan-Ganz catheter inserted percutaneously through the subclavian or femoral vein. An 18-gauge arterial cannula was inserted into a radial or femoral artery for pressure measurements and blood sampling. Pressure was measured through a pressure transducer (Hewlett-Packard, model 1280C). Values were taken at the end-expiratory point averaging 3 respiratory cycles and were recorded on a Hewlett-Packard 4-channel recorder, model 7754. The zero point was measured at the mid-chest level. Cardiac output was measured in triplicate by the thermodilution technique (Edwards Laboratory computer model 9510). In addition, a 7Fr Gorlin coronary sinus pacing catheter (USCI) was introduced into the left subclavian vein, also percutaneously, and advanced into the coronary sinus, placing the tip at the very

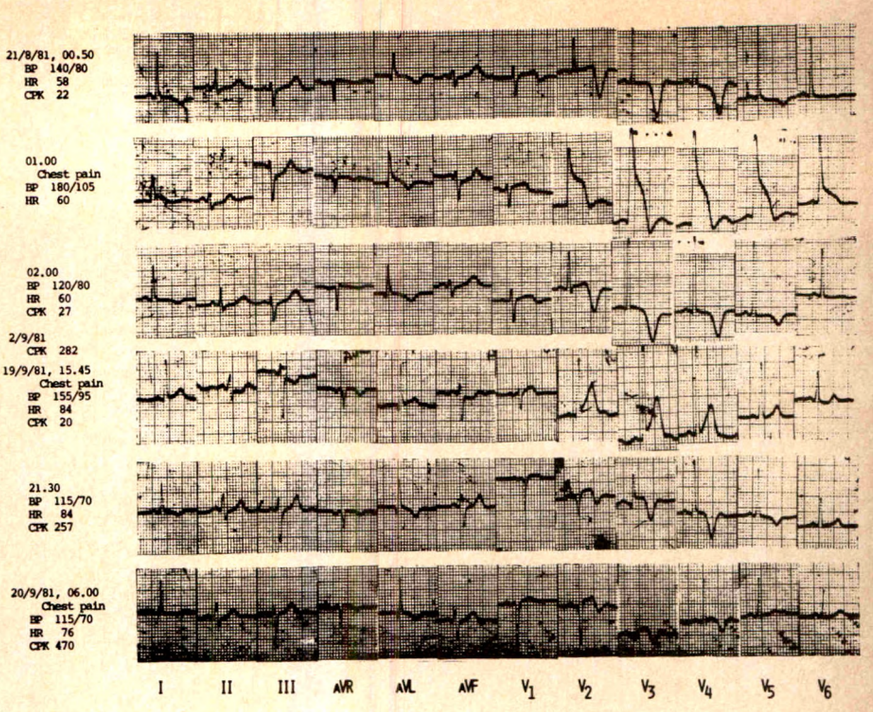

FIGURE 1. Sequential electrocardiograms in Case 15 illustrating changes during several episodes of spontaneous chest pain. Two were prolonged and were followed by QRS changes of transmural myocardial infarction and by an elevation in enzyme levels. The first of these 2 episodes (not shown) occurred on September 1, 1981 and had a peak creatinine phosphokinase of 282 IU/liter and the second, on September 19, had a peak creatinine phosphokinase of 470 IU/liter. BP = blood pressure; CPK = creatine phosphokinase; HR = heart rate.

origin of the coronary sinus to permit pacing as well as blood sampling. In the 7 patients in whom the pulmonary catheter was introduced through the subclavian vein, this catheter was removed before insertion of the Gorlin catheter.

The pacing study was then initiated by increasing the heart rate in steps of 10 beats, which were maintained for 2-minute periods, and stopping during the 10 to 15 beats after each step before going to the next to recognize possible ischemic changes. Pacing was discontinued whenever a 1.0 mm S-T segment shift was observed, a heart rate of 150 to 160 beats/min had been reached, or the patient experienced angina. Allowing a minimum of 20 minutes for recovery and once the possible electrocardiographic changes had fully reverted, an intravenous infusion of methoxamine was started at a rate of 2.0 mg/min with the purpose of increasing systolic blood pressure to a level 30% higher than the baseline value and to maintain it for a 5-minute period. Methoxamine was then discontinued, and 5 minutes later sublingual nitroglycerin, 1.0 mg, was given to accelerate the return of blood pressure to controls levels. Heart rate was kept at approximately the baseline value either spontaneously or by atrial pacing. In 10 patients (Patients 8 to 13, and 15 to 18), simultaneous blood samples were drawn from the arterial line and the coronary sinus catheter to analyze partial pressure of oxygen and carbon dioxide, pH, and plasma potassium at the following time intervals: (1) before pacing (first control), (2) just before stop-

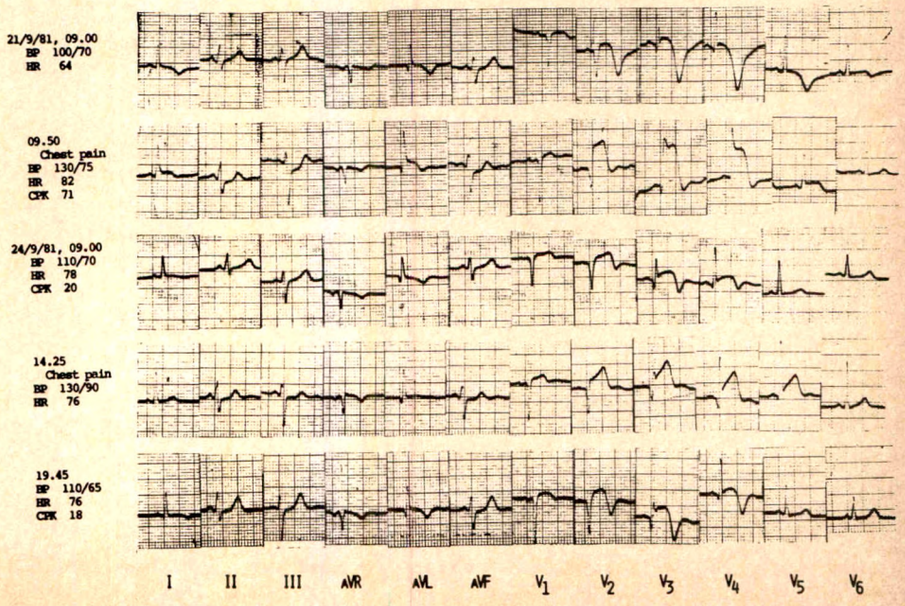

FIGURE 2. Sequential electrocardiograms also in Case 15 illustrating 2 anginal episodes that occurred after the infarction shown in Figure 1. As in previous ischemic episodes, the salient change was S-T segment elevation in the leads with resting negative T waves. Abbreviations as in Figure 1.

ping pacing at the highest rate, (3) before initiating the methoxamine drip (second control), (4) just before stopping methoxamine, and (5) 10 minutes later, after blood pressure had regained baseline values (third control). In 5 patients (Patients 8 to 10, 12, and 18), additional samples for lactate measurements were drawn at the same time intervals. In 6 other patients, only right-heart catheterization and the methoxamine test were carried out.

Blood gases were measured in an ABL-I acid-base laboratory automatic analyzer (Radiometer Copenhagen). Blood lactate was measured using an enzymatic technique.[14] Throughout the pacing and methoxamine studies, the electrocardiogram was continuously monitored on an 6-channel Elema-Mingograf ink jet recorder.

Coronary arteriography and left ventriculography were performed within 15 days of admission in 13 patients and within 30 days in 3 others. Statistical analysis was performed using Student's t test for paired samples.

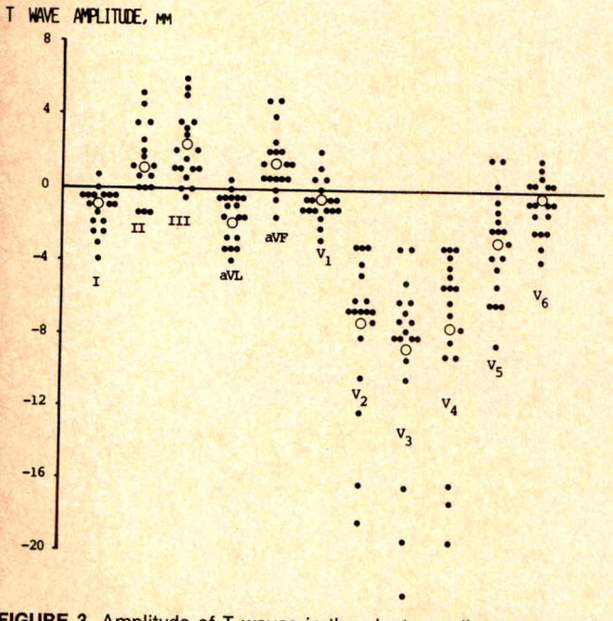

FIGURE 3. Amplitude of T waves in the electrocardiogram of each patient which evidenced the deepest T waves. **Open circles** represent mean values in each lead in the 18 patients, whereas **closed circles** represent individual values.

Results

Clinical features: Relevant clinical data are summarized in Table I. Most patients related a short history of effort or resting angina, or both. Four patients had a history of definite and 4 borderline systemic hypertension. While in the hospital, 14 patients had at least 1 episode of spontaneous angina associated with transient electrocardiographic changes. Myocardial scintigrams were not indicative of MI in the 7 patients in whom they were performed (0 or 1+). In 4 patients, transmural MI developed in the hospital, anterior and uncomplicated in all, and in none did the total creatinine phosphokinase reach 700 IU/liter. In patient 3, MI occurred shortly after coronary bypass grafting. Patients 15 and 16 had a second MI 18 and 7 days after the initial one, involving the same electrocardiographic leads (Fig. 1 and 2).

Electrocardiographic findings: The maximal amplitude of negative T waves, measured at least 12 hours after an eventual episode of rest angina, is shown for each patient in Figure 3. In all patients, leads V_2 to

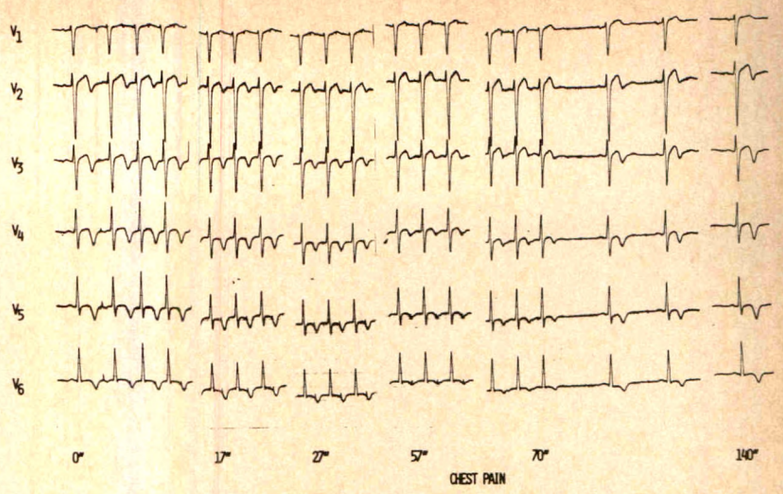

FIGURE 4. Effects of atrial pacing at a rate of 150 beats/min on negative T waves in Case 16. The progressive disappearance of negative T waves is probably indicative of ischemia which culminates in chest pain and a 2.0-mm S-T segment elevation in V_2 which already had a 1.0-mm elevation in the resting electrocardiogram. The changes reverted in <2 minutes and pain was immediately relieved on cessation of pacing. Disappearance of negative T waves is partly related to the superimposition of the P wave on the T wave during pacing.

V_4 had negative T waves. In 12 of them, negative T waves persisted >9 days, and in 5 they persisted ≥20 days. In each of the 14 patients who had ≥1 episodes of spontaneous angina, S-T segment elevation was present in leads with negative T waves in at least 1 crisis. In other anginal episodes, only complete or partial positivization of T waves was observed. Myocardial infarction and reinfarction involved leads with negative T waves. Only 3 patients had an electrocardiographic pattern of left ventricular hypertrophy in the resting electrocardiogram. All patients remained in sinus rhythm.

Coronary arteriographic findings: Fourteen of the 16 patients who underwent coronary angiography presented ≥90% diameter reduction of the proximal segment of the left anterior descending (LAD) coronary artery (Table II). Three had 100% occlusion, and 1 remaining patient had 50 to 60% proximal LAD stenosis and the other had 75% obstruction of the first diagonal branch as the only significant lesion. No patient had significant (≥70%) 3-vessel disease (LAD, left circumflex coronary artery, and right coronary artery). Collateral circulation was nonexistent in 13 patients and present in 3 who happened to have 100% LAD occlusion. However, in 2 of them this collateral supply was poor. In Patients 6 and 14, a second coronary arteriography was carried out 2 years later, revealing complete occlusion of the initially critical LAD stenosis, progression of the disease in other vessels, and the appearence of collateral vessels. Twelve patients had either a normal left ventriculogram or slight apical hypokinesia. Ejection fraction was ≥50% in 13 patients. One of the 2 patients without coronary angiograms (Patient 8) had an in-hospital MI and early postinfarction angina.

Pacing test: During right-sided cardiac catheterization, 6 patients had angina which reverted spontaneously or after sublingual nitroglycerin. In these patients, pacing and pressure measurements were not taken earlier than 30 minutes after relief of angina. Baseline right atrial and left ventricular filling pressures were normal (4.6 ± 0 and 8.9 ± 1 mm Hg, respectively; mean ± standard error of the mean). Cardiac index was

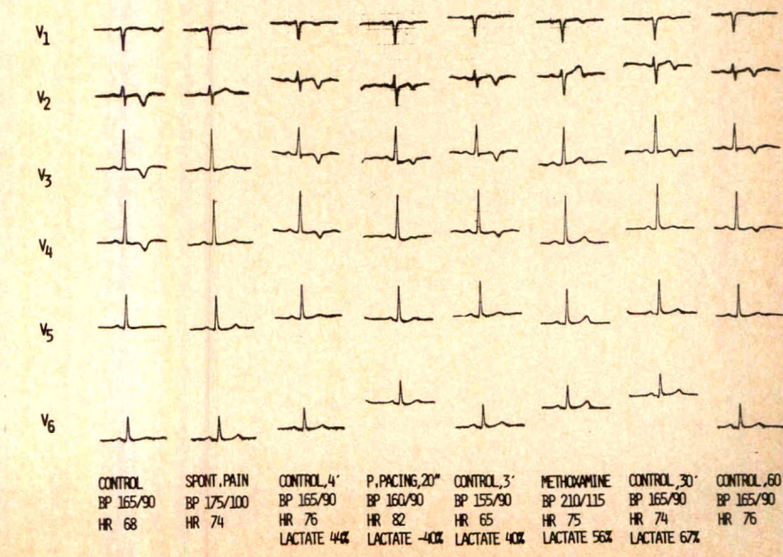

FIGURE 5. Changes in precordial leads, blood pressure (BP), and heart rate (HR) during spontaneous angina (Spont. pain) 20 seconds after pacing at 150 beats/min (P. Pacing, 20"), during methoxamine-induced hypertension, and during appropriate control measurements in Case 18. Results of lactate extraction measured at several of these steps are also shown. Right after pacing there is a reduction of negative T waves, a 1.0-mm S-T segment depression in leads V_3 and V_4, and an important lactate production, whereas during methoxamine there is an absence of significant S-T segment changes and of lactate production despite an indisputable T-wave positivization similar to that occurring during spontaneous angina. In this case, however, elevation of the J point does not permit some degree of ischemia to be ruled out. The electrocardiographic changes rapidly disappear after pacing ceases and after prompt relief of pain with nitroglycerin in spontaneous angina, whereas those related to methoxamine persisted through the first 30 minutes. An additional sample for lactate metabolism was drawn as soon as the electrocardiogram had returned to control after pacing (Control 3').

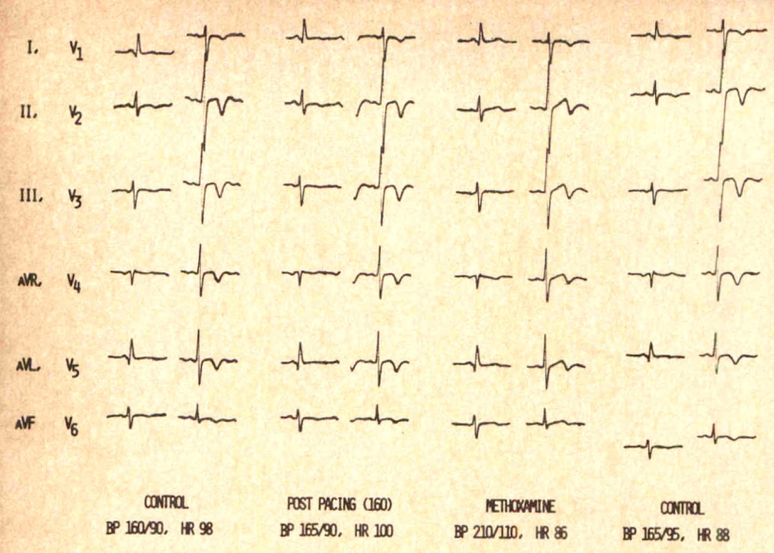

FIGURE 6. Changes in the 12-lead electrocardiogram in Case 13 a few seconds after maximum heart rate by pacing and during methoxamine infusion. This patient developed neither T-wave nor S-T segment changes during pacing. During hypertension, there were also no significant (≥1.0 mm) S-T segment changes or chest pain; T-wave changes, nevertheless, became apparent. Appreviations as in Figure 1.

also normal in most of the 12 patients in whom it was measured. During pacing, 1.0 mm S-T segment depression developed in 5 patients. One also developed a 1.0 mm S-T segment elevation. In Patient 12, pacing could not proceed beyond 100 beats/min because of Wenckebach atrioventricular block. Four patients had chest pain which disappeared after cessation of pacing. During pacing the magnitude of negative T waves tended to decrease particularly among those who developed S-T segment changes. (Fig. 4). The duration of all electrocardiographic changes did not exceed 15 minutes. Three patients (Patients 8, 9, and 18) of the 5 in whom lactate metabolism was studied, exhibited lactate production associated with significant S-T segment shifts (Fig. 5).

Methoxamine test: Administration of this drug produced substantial systemic hypertension: systolic blood pressure increased from 140 ± 5 to 208 ± 6 mm Hg and diastolic blood pressure from 74 ± 2 to 110 ± 3 mm Hg, and was not accompanied by chest pain or significant (≥1.0 mm) S-T segment changes. However, in 3 patients, it elicited an almost significant J point elevation in lead V_2. Total dose of methoxamine ranged from 15 to 30 mg. Three of 17 patients in whom the test was performed were excluded from the electrocardiographic analysis due to unacceptable recordings. In each of the remaining 14 patients the amplitude of negative T waves was reduced, and in several a definite T-wave positivization followed (Fig. 6). These changes persisted an average of 30 minutes (range 20 to 90) and were associated with an increase in T wave amplitude in other leads with initially flat or positive T waves. These changes differ from those observed during pacing, which

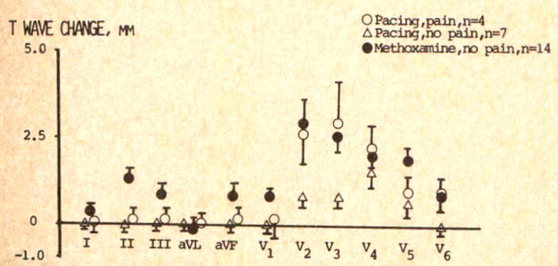

FIGURE 7. Mean (± standard error of the mean) changes in T-wave amplitude during pacing in patients who developed pain (**open circles**), in those who did not develop pain (**open triangles**), and during methoxamine-induced hypertension (**closed circles**) which did not cause pain. Because control precordial leads presented negative T waves, the increased amplitude actually represents a decrease in negativity, whereas in leads II, III, and aVF with control positive T waves, the change means a net increase in their amplitude. The tendency to become less negative or more positive during methoxamine is clear in most leads although it is more evident in leads V_2 through V_5. In contrast, during pacing, T-wave changes were limited to precordial leads and were of little magnitude, particularly in patients who did not present chest pain.

TABLE III Methoxamine and Pacing Studies: Metabolic Data (Mean ± SEM)

		Blood Gases (n = 10)			Lactate Extraction (%) (n = 5)
		PO_2 (mm Hg)	PCO_2 (mm Hg)	pH (Units)	
Control	A	72 ± 2	39 ± 1	7.38 ± 0.01	32 ± 14
	Cs	21 ± 1	51 ± 1	7.34 ± 0.01	
Pacing	A	79 ± 4	38 ± 2	7.40 ± 0.01	11 ± 23
	Cs	20 ± 1	51 ± 1	7.35 ± 0.01	
Control	A	70 ± 3	38 ± 1	7.39 ± 0.01	37 ± 12
	Cs	19 ± 1	49 ± 1	7.36 ± 0.01	
Methoxamine	A	75 ± 2	38 ± 1	7.41 ± 0.01	52 ± 5
	Cs	19 ± 1	52 ± 1	7.35 ± 0.01	
Control	A	71 ± 3	38 ± 1	7.41 ± 0.01	39 ± 9
	Cs	19 ± 4	49 ± 2	7.37 ± 0.01	

A = arterial; Cs = coronary sinus; PCO_2 = arterial carbon dioxide tension; PO_2 = arterial oxygen tension; SEM = standard error of the mean.

were confined to leads with negative T waves (Fig. 7). Positivization of T waves during methoxamine administration was not modified by the administration of sublingual nitroglycerin. Left ventricular filling pressure (pulmonary artery diastolic pressure) increased during hypertension in each of 9 patients in whom it was monitored (7.9 ± 1 to 17.4 ± 1 mm Hg) and returned to control levels on normalization of blood pressure. In Patient 17, pacing and methoxamine studies were performed once T waves had become upright. This patient had a slight increase in T wave amplitude and a 1.0 mm S-T segment shift localized in leads within negative T waves during pacing-induced angina, and generalized and persistent increases in T wave amplitude without pain or S-T segment changes during methoxamine perfusion.

In none of the 5 patients in whom lactate metabolism was studied were there abnormalities in lactate extraction during hypertension (Table III). In addition, no increases in plasma creatinine phosphokinase levels occurred during the ensuing 24 hours in the 5 patients in whom they were determined to rule out possible myocardial damage caused by methoxamine. In the 10 patients in whom coronary arteriovenous differences in the partial pressure of oxygen and carbon dioxide, pH, and potassium were examined, no significant differences were observed during pacing and methoxamine tests (Table III) with regard to control measurements. However, arterial partial pressure of oxygen and oxygen extraction tended to increase during both interventions, and coronary sinus partial pressure of carbon dioxide also tended to increase during hypertension. No complications occurred during either test.

Follow-up: During an average follow-up of 23 months (range 3 to 45) 1 patient had inferior MI and another died during coronary surgery (Table I). Ten patients had effort angina and 8 also had resting angina despite treatment with nitrates and calcium antagonists.

Discussion

Patients with coronary artery disease who have prolonged chest pain associated with persistent negative T waves in the precordial leads and normal enzymes have been included in the series of unstable angina without attempting to single out their possible clinical and angiographic characteristics.[15,16] Clinically, most of our patients had a short history of effort or rest angina, or both, and had episodes of spontaneous angina while in the hospital. Four patients developed acute, anterior, transmural, and uncomplicated MI during hospitalization. During an average follow-up of 23 months, 1 patient died, another had inferior MI, and 10 continued to have angina. With an overall 2-year mortality rate of 5% and a MI rate of 28%, these patients seemed to have a rather good long-term prognosis despite an initial unstable course. Gazes et al[3] pointed out the relative low risk in their 32 patients after a 10-year follow-up. Their MI and mortality rates were somewhat lower than ours, but they included patients with negative T waves in precordial as well as nonprecordial leads and patients who had negative T waves during resting angina. Earlier, Pruitt et al[1] commented that their 62 patients with negative T waves in the precordial leads presented recurring episodes of spontaneous angina, as did ours. Cutts et al,[2] in 69 patients comparable to ours, noted that prognosis was poor, reporting a 4-year mortality rate of 20%, half of their deaths occurring during the first year. None of the foregoing studies had arteriographic data.

Three of the 5 patients reported on herein who had an in-hospital MI had recurring episodes of resting angina before the acute MI. Therefore, their course was similar to that described by Madias[7] and Maseri et al[17] in a group of patients in whom MI eventually developed after several crises of spontaneous angina during hospitalization. Most of their patients also had negative T waves in the precordial leads before MI. These investigators attributed both resting angina and MI to coronary spasm,[7,17] a factor not ruled out in our patients.

Our angiographic observations constitute the first prospective report on this subject. These findings, which in essence indicated ≥90% proximal stenosis of the LAD, severe 1- or 2-vessel narrowing, absence of collaterals, and preserved left ventricular function, agree with those of Fisch et al,[5] who were the first to draw attention to isolated and severe LAD disease and to the lack of collaterals in 6 similar patients. Arteriographic data extracted from other series of patients with unstable angina, which included patients with negative T waves in the precordial leads, also bear out our observations.[18–20] Likewise, Batlle et al[4] reported the association of prolonged angina, negative T waves, proximal single- or double-vessel disease, and poor collateral vessels, although they failed to mention the localization of negative T waves and of the coronary lesions.

Although important and proximal LAD stenoses are also present in most patients who develop S-T segment elevation in the precordial leads during angina,[7,17,21] the degree of this LAD narrowing is not consistently as critical as it is in patients with negative T waves. This fact is infered from studies of patients with unstable angina who had resting electrocardiographic abnormalities other than negative T waves.[5,7,9] This close relation between negative T waves and severe LAD stenosis is further substantiated by the work of McMahon et al[21] who found negative T waves in the precordial leads in each patient in a restricted group selected on the basis of 95% proximal LAD obstruction, single-vessel disease, no collaterals, and the absence of previous MI.

Isolated negative T waves associated with elevated cardiac enzymes[22,23] or pathologic evidence of tissue necrosis[1,24] has been interpreted as a sign of subendocardial necrosis. However, in our patients it is somewhat difficult to consider such a diagnosis for they had no enzyme elevation and no positive scintigraphic findings, although scintigraphic data were only available in some cases.[25] When associated with prolonged angina and no evidence of MI, negative T waves are believed to indicate subendocardial or transmural ischemia.[1,6,7] If this were the case, slight or moderate increases in myocardial oxygen needs in these circumstances would readily in-

crease the severity of ischemia. Contrary to this hypothesis, however, we found that a considerable proportion of our patients were able to withstand pacing rates that commonly cause ischemia in other patients with unstable or even stable engina,[26,27] without exhibiting S-T segment changes or chest pain. This relatively high threshold for ischemia may question the validity of the ischemic nature of these negative T waves in at least some patients. In similar cases, absence of ischemic changes were found in biopsy studies of the myocardial tissue underlying the electrocardiographic leads with negative T waves.[28]

In 4 of the 5 patients in whom an electrocardiogram was recorded during prolonged angina, S-T segment elevation also was documented in the leads with subsequent negative T waves. In addition, S-T segment elevation also was observed during spontaneous angina in the leads with negative T waves in 12 patients. Madias[7] and Maseri et al[18] reported similar findings during pain in comparable patients. Therefore, negative T waves in the setting herein discussed may imply recent but not actual transmural ischemia.[1] Therefore, we submit that most episodes of prolonged angina are transient transmural ischemia.

In accordance with previous investigators,[7–9] we documented upright T waves as the sole electrocardiographic changes during some episodes of spontaneous angina which has also been shown to indicate transmural myocardial ischemia in scintigraphic studies.[19] However, interpretation of identical partial or complete positivization of negative T waves during symptomless exercise-stress test remains controversial.[10,11,29,30] Contrary to earlier opinions,[29,30] observers are currently inclined to confer no pathologic significance on to such transient electrocardiographic changes.[10,11] Because of this discrepancy, we examined the possibility whether this electrocardiographic change could be accounted for at least in part by the increases in blood pressure so often present during exercise and angina.[12,13] We found that hypertension did indeed produce a decrease in T-wave negativity and frequently a complete positivization. We doubt that this reversal of negative T waves by methoxamine in most patients signifies myocardial ischemia relative to the increase in myocardial oxygen demands due to hypertension, because it was not generally associated with significant S-T segment changes, chest pain, or lactate production whenever measured, and moreover was not modified by nitroglycerin. Previous studies have demonstrated that drug-induced hypertension cannot elicit myocardial ischemia in patients with angina and fixed coronary narrowings.[31,32] Whether the persistence of negative T waves implies a state of adrenergic imbalance with abnormal sympathetic activity that could in turn be responsible for recurrence of paroxysmal increases in coronary arterial tone and subsequent ischemia[33] is an attractive hypothesis that cannot be validated from our data. However, along with this theory is recent evidence of the existence of alpha-adrenergic receptors in the myocardium,[34] and recent work has attributed to methoxamine an alpha constrictor activity[35] and a capacity to increase contractility which can be completely prevented by alpha-adrenergic blockage.[34] These developments may allow speculation on the possible neurogenic nature of the negative T waves and on the likelihood that its reversal by methoxamine could have been due to a direct alpha-adrenergic effect perhaps also present during exercise or rest angina.

The rather preserved coronary reserve as suggested by the nonischemic response to pacing and hypertension in an appreciable number of patients may reflect certain improvement in the resting cardiac reserve afforded by the use of calcium antagonists or nitrates despite the fact that treatment was withheld 6 hours before these studies.

Increases in arterial partial pressure of oxygen and oxygen extraction were observed during pacing and during hypertension. These changes might possibly be ascribed to reflex hyperventilation secondary to mild lung congestion because of hampered left atrial emptying during pacing and to increases in left ventricular filling pressure during hypertension. More obscure is the interpretation of increases in coronary sinus partial pressure of carbon dioxide during methoxamine. A drug-linked reduction in coronary flow offers a possible explanation which could also account, at least in part, for the increases in oxygen extraction.

Clinical Evaluation of the Internal Automatic Cardioverter-Defibrillator in Survivors of Sudden Cardiac Death

PHILIP R. REID, MD, M. MIROWSKI, MD, MORTON M. MOWER, MD, EDWARD V. PLATIA, MD, LAWRENCE S. C. GRIFFITH, MD, LEVI WATKINS, Jr., MD, STANLEY M. BACH, Jr., MD, MIR IMRAN, BSEE, MS, and ANDRA THOMAS, RN

An R-wave synchronous implantable automatic cardioverter-defibrillator (IACD) was evaluated in 12 patients with repeated episodes of cardiac arrest who remained refractory to medical and surgical therapy. Seven men and 5 women, average age 61 years, surgically received a complete IACD system. Coronary artery disease was found in 11 and the prolonged Q-T syndrome in 1. The average ejection fraction was 34%, and 6 patients had severe congestive heart failure (New York Heart Association class III or IV).

The IACD is a completely implantable unit consisting of 2 bipolar lead systems. One system uses a lead in the superior vena cava and on the left ventricular apex through which the cardioverting pulse is delivered. The second system employs a close bipolar lead implanted in the ventricle for sensing rate. After the onset of ventricular tachycardia or fibrillation, the IACD automatically delivers approximately 25 J.

Postoperative electrophysiologic study in 10 and spontaneous ventricular tachycardia in 1 patient demonstrated appropriate IACD function and successful conversion in all with an average of 18 ± 4 seconds. The induced arrhythmias were ventricular tachycardia (160 to 300 beats/min) in 9 and ventricular fibrillation in 1.

These data demonstrate that ventricular tachycardia, not ventricular fibrillation, was the predominant rhythm induced during programmed ventricular stimulation in these survivors of cardiac arrest and that the IACD effectively responded to a wide range of ventricular tachycardia rates as well as ventricular fibrillation. Use of the IACD offers an effective means of therapy for some patients who otherwise may not have survived.

As originally conceived,[1] the implantable automatic defibrillator employed in animal studies,[2] and later modified for patient implants,[3] was for automatic conversion of ventricular fibrillation (VF). Both sensing and defibrillation was accomplished by electrodes positioned in the superior vena cava (SVC) and on the left ventricular (LV) apex. The determinant for detection of VF was satisfaction of a probability density function[4] which required the input signal to spend increased time away from a zero-potential baseline. VF, characterized by a sinusoidal pattern, spends relatively little time at the zero potential. With sinus rhythm the signal spends a relatively great amount of time at the zero potential (for example, P-R or T-P segments). As a practical consequence, ventricular tachycardia (VT) rates <240 to 250 beats/min were subject to rejection by the probability density function sensing circuitry since there was increased isoelectric time (the T-QRS segment). It became apparent,[5–8] however, that most survivors of cardiac arrest initially had hypotensive VT with rates <240 beats/min. VF was observed only at a later stage, if at all.

Therefore, extensive design modifications were undertaken to broaden the spectrum of ventricular tachyarrhythmias to which the defibrillator would respond. This was accomplished, in part, through the development of a reliable rate detector system using a bipolar ventricular lead which also served for R-wave synchronization. Thus, the modified defibrillator used the SVC-LV apex for probability density function detection and delivery of the cardioverting pulse, and the

ventricular bipolar lead permitted accurate counting of lower heart rates.

This report describes our initial clinical experience with the internal automatic cardioverter-defibrillator (IACD) (Intec Systems, Pittsburgh, Pennsylvania) in patients with refractory, life-threatening ventricular tachyarrhythymias.

Methods

Patient population: Each patient (Table I) considered for IACD implant had previously had failure with several antiarrhythmic agents (average 5.0) and continued to have episodes (average 3) of life-threatening ventricular arrhythmias requiring cardiopulmonary resuscitation. Informed consent was obtained separately for each of the invasive diagnostic procedures and a separate set of consent forms were used both for the surgery to be performed and for implantation of the IACD.

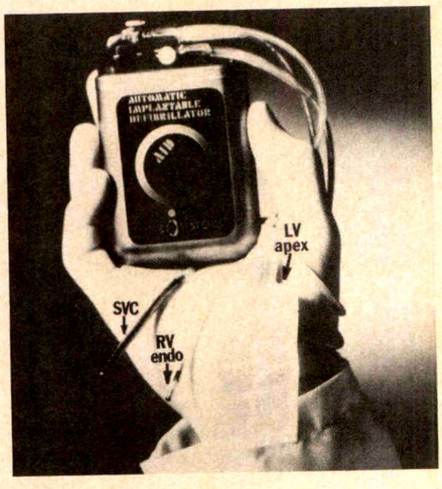

FIGURE 1. IACD pulse generator with the superior vena cava and left ventricular apex electrodes which constitute 1 bipolar system for sensing probability density function and delivery of the cardioverting pulse. The second bipolar lead (RV endo) is used for sensing ventricular rate and R-wave synchronization; this lead may be positioned in the right ventricular apex (as shown), or left ventricular intramural bipolar leads may be substituted.

The clinical features of the patients on whom this report is based are presented in Table I. The average age was 61 ± 8 (standard deviation) years, with 9 men and 5 women. Coronary artery disease was the major cardiac condition in all but 1 patient who had idiopathic prolongation of the Q-T interval (without deafness). The average ejection fraction was 34 ± 13% and significant congestive heart failure (New York Heart Association class III or IV) was present in 9 patients.

Five patients had previously undergone cardiac surgery consisting of aortocoronary artery bypass, aneurysmectomy, and LV subendocardial resection. Two patients (Patients 11 and 12) previously underwent exchange of the older defibrillator model because of battery depletion. A fractured SVC lead was replaced in 1 and a fractured apical lead was replaced in another.

Preoperative evaluation was undertaken in all IACD candidates. This included at least 72 hours of ambulatory electrocardiography, submaximal exercise testing and documentation of antiarrhythmic drug levels. All patients were required to have received conventional antiarrhythmic agents with continued life-threatening ventricular arrhythmias or to have sustained VT induced during programmed electrical stimulation. Propranolol and disopyramide were considered relatively contraindicated if the patient manifested New York Heart Association class III or IV congestive heart failure. Use of investigational antiarrhythmic agents did not preclude implantation of the IACD.

Programmed electrical stimulation was accomplished using a basic ventricular drive (n = 8) of 600, 500, and 450 ms with single and double ventricular premature stimuli of 1.0 ms pulse width at twice diastolic threshold until ventricular refractoriness was reached. Ventricular burst pacing (n = 10) was used at progressively shorter cycle lengths until 2:1 conduction was manifest or until the burst pacing cycle length reached 200 ms. If sustained VT or VF was not induced from the right ventricular apex, the pacing protocol was repeated with the catheter repositioned at the right ventricular outflow tract followed by 2 LV sites.

The internal automatic cardioverter-defibrillator (Fig. 1) is a device with external dimensions of 8.1 × 11.1 × 2.54 cm, weighing 290 g, and having an internal volume of 162 cm^3 with a specific gravity of 1.8. The case is constructed of titanium, is hermetically sealed, and contains a special lithium

battery capable of charging 2 capacitators to approximately 700 V in 7 to 9 seconds.

The IACD employs 2 bipolar electrode systems. One bipolar electrode system serves both for defibrillation and for sensing the probability density function: an intravascular catheter (anode) is positioned in the SVC near the right atrial junction with the cathode having the form of a flexible rectangular patch and placed over the LV apex. The other bipolar electrode system consists of either a right ventricular endocardial catheter (with 1 cm interelectrode spacing) or intramural electrodes which serve for rate detection and R-wave synchronization. Input signal compensation is provided for wide amplitude variations; however, the minimum voltage required for rate sensing is approximately 0.1 mV. When both the probability density function and rate criteria are satisfied, the device delivers a truncated exponential pulse of approximately 6 ms across the SVC and LV patch electrodes. The initial discharge is approximately 25 J, but the IACD can recycle 3 times with the strength of the final 3 pulses increased to 30 J. All discharges are synchronized to the onset of ventricular depolarization detected locally through the rate detector lead, whether this is VT or VF.

When compared with the earlier model,[3] the cardioverter-defibrillator provides several additional features which can be monitored noninvasively after implantation: (1) using a strong external magnet and detector (AIDcheck B®), the number of delivered pulses and capacitator charging time can be measured; (2) if the magnet is held in place above the implanted device, an audible beeping tone is emitted synchronous with the detected R wave, which permits a rapid check of the R-wave sensing function; (3) in addition, the magnet may be used to completely inactivate (or reactivate) the device; and (4) radiodense insignias are incorporated to permit easy identification. As in the previous model, when the IACD is magnetically activated, the pulse is delivered into an internal resistor rather than through the leads to the patient.

Implantation procedure: The surgical approach is dictated by clinical needs and has been previously described.[9] This remains the same except that the bipolar, rate-detector lead is implanted using closely spaced (1 cm) LV intramural electrodes if the patient requires either a median sternotomy or lateral thoracotomy. In those cases approached using a subxiphoid incision,[10] the right ventricular bipolar endocardial rate detector lead is implanted percutaneously in a fashion similar to transvenous pacemaker insertion. The choice of the surgical approach is dictated by the clinical needs. For example, if the patient had not had previous chest surgery and the procedure was only for IACD implantation, the subxiphoid incision was used. On the other hand, if additional surgery (for instance, coronary bypass) was needed or if the patient had previously had chest surgery, then either the lateral thoracotomy or median sternotomy was used. All leads are tunneled subcutaneously and connected to the IACD generator placed in a pocket developed in the periumbical area.

Postoperative evaluation includes general medical management and adjustment of antiarrhythmic therapy. Programmed stimulation was performed postoperatively in all but 2 patients in whom IACD function had been evaluated intraoperatively (Patient 9) or the device responded appropriately to a spontaneous arrhythmia (Patient 14). If programmed stimulation failed to induce a sustained ventricular tachyarrhythmia, it was reliably induced using a 1 to 5 second exposure to full-wave rectified alternating current.[11] These procedures permitted assessment of both the inducibility of the patient by programmed stimulation and the adequacy of IACD function.

Most patients had the implantation procedure performed in 2 stages: the leads were first surgically implanted in the operating room and, after postoperative recovery, the pulse generator was inserted under local anesthesia with testing in the electrophysiology laboratory. This permitted recording of IACD lead signals which were later replayed off-line through a bench model of the IACD. In this manner, the IACD could later be analyzed with respect to both probability density function and ventricular rate-counting accuracy in the individual patient during sinus rhythm and induced tachyarrhythmias.

Patient follow-up procedures required outpatient visits every 8 to 12 weeks for noninvasive testing of the pulse generator in order to reevaluate medical therapy and to assess residual battery life.

Results

Operative results: Three patients had the subxiphoid approach,[10] 4 patients had a left thoracotomy, and 7 patients had a median sternotomy for lead insertion. In 6 patients, aortocoronary artery bypass and aneurysmectomy were performed at the time of IACD lead placement (Table I).

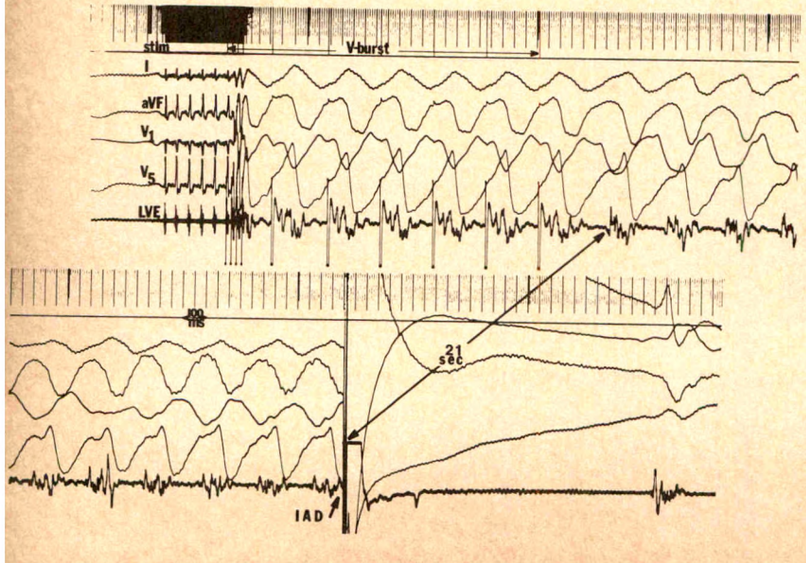

FIGURE 2. Postoperative IACD testing is illustrated with the induction of sustained ventricular tachycardia by programmed stimulation using 10 pulses (V burst; basic cycle length 230 ms). The pacing stimulus (stim) is illustrated with surface leads I, aVF, V_1, and V_5 and a left ventricular electrogram (LVE). From sinus rhythm (slower paper speed), V-burst results in a sustained ventricular tachycardia (240 ms = 250 beats/min) which is automatically terminated with an R-wave synchronous pulse (IAD) 21 seconds later. Within 1.5 seconds after IAD discharge, a perfusing rhythm was restored.

There were no intraoperative deaths. However, 3 patients died in the early postoperative period. Two of these patients (Patients 6 and 7) died in progressive low-output failure before implantation of the IACD pulse generator. The third patient (Patient 9) expired in cardiogenic shock associated with intractable VT during which time the IACD was observed to function appropriately. All 3 patients had severe heart failure preoperatively and postmortem examination revealed no evidence that the implanted leads contributed to these deaths. One patient (Patient 13) had a postoperative thrombosis of the subclavian vein in which the SVC electrode was located. There was complete resolution after heparin therapy.

Electrophysiologic testing: During the pre- and postoperative electrophysiologic studies, there were no complications. Programmed stimulation was performed in all 12 patients who received pulse generators except Patient 9, in whom appropriate spontaneous IACD function was observed. All patients except Patient 14 had VT, and not VF, induced during these studies. Patient 14 was documented to have VF associated with the idopathic prolonged Q-T syndrome, and VF was also induced during programmed stimulation. One patient (Patient 3) had a successful postoperative conversion while taking investigational drugs, and another (Patient 10) had negative programmed stimulation results after coronary artery bypass, aneurysmectomy, and LV subendocardial resection.[12] In those cases (Patients 3 and 10) having negative results by programmed stimulation, alternating current was used for arrhythmia induction to permit IACD testing and resulted in sustained VT. An example from 1 postoperative study is shown in Figure 2.

The IACD system successfully converted malignant ventricular tachyarrhythmias in all 12 patients who had received pulse generators: 1 patient had a spontaneous arrhythmia and 11 were induced. The average IACD charge time (7.5 ± 0.8 seconds) obtained during a magnet test agreed closely with the actual charge time of the IACD (7.3 ± 0.5 seconds) obtained during the electrophysiologic study (Table II). The magnet was initially held in place (which inactivated the IACD) approximately 5 seconds after arrhythmia induction to prevent false sensing during rapid ventricular pacing. Therefore, the total time to defibrillation, which averaged 17.9 ± 4.2 seconds, represents the period of time when the unit was not permitted to detect (that is, magnet in place), plus the requisite amount of time (5 to 7 seconds) for rhythm recognition and the charging time of the capacitators (7.3 ± 0.5 seconds).

Conversion to the patient's normal rhythm was accomplished with a single discharge in 9 of the 12 cases. In 3 cases (Patients 1, 2, and 8) the initial discharge did not convert the rhythm; however, the unit immediately recycled and the second pulse restored the preinduction rhythm. In Patient 8, the initial IACD implanted had a rate setting too high for the induced VT, necessitating replacement with a lower rate cutoff. The latter successfully converted the VT to sinus rhythm in 30 seconds by recycling when the initial discharge was unsuccessful. In none of these cases did the initial discharge cause degeneration to VF and, when the VT

persisted, it was at a cycle length similar to that which was initially induced. Examination of the tracings from each case demonstrated that all IACD discharges occurred during the R wave of the VT.

In 2 cases (Patients 1 and 8), the IACD discharged while the patients were partially conscious. Both patients reported the sensation of a "thud" in the chest accompanied by the fleeting visual perception of colored lights. In neither case was the description that of intense pain or of electric shock. In all cases, at the time of IACD discharge, there was a noticable slight jerking motion of the torso.

The signal from the IACD bipolar rate lead provided a clear ventricular signal which averaged 15 ± 6 mV during sinus rhythm without evidence of atrial activity. During induction of the arrhythmias, discrete signals were again obtained which averaged 22 ± 8 mV. These direct-current signals were also placed on an FM tape recorder and later replayed through a bench model of the IACD. Patient rhythms were recorded from both the SVC-LV apex bipolar lead (former rate detector system) and from the present IACD ventricular bipolar lead. A square wave signal was used to indicate detection during sinus rhythm (Fig. 3) or VT (Fig. 4). In comparing these 2 systems, the SVC-LV apex bipole demonstrated some inaccuracies during both sinus rhythm and VT, whereas the rate detected through the IACD bipolar lead was much more accurate.

Follow-up results: After the hospitalization, which averaged 39 ± 23 (standard deviation) days, patients were returned to their referring physicians or to the Sudden Death Prevention Program Arrhythmia Clinic for periodic reevaluation and magnet testing of the IACD. In October 1982, the average follow-up period was 4 ± 2 months, and during this short period there was no documented out-of-hospital cardioversion.

In 1 patient (Patient 2), during routine follow-up, a nonfunctional unit was discovered and successfully replaced. Two patients (Patients 3 and 8) had bipolar ventricular demand pacemarkers implanted in addition to the IACD without interference being noted between the 2 devices.

Discussion

These results demonstrate the IACD capable of performing as both an R-wave synchronous cardioverter for VT and a defibrillator for VF. As shown in Table II, it converted VT at rates ranging from 160 to 300 beats/min. Where the initial discharge was ineffective, the rhythm was appropriately managed when the IACD recycled.

The accuracy of the R-wave synchronized rate counter using the ventricular bipolar catheter is illustrated in Figures 3 and 4. Compared with our former system, which employed an SVC-LV apex bipolar circuit[3] for rate detection, the IACD demonstrated greater accuracy during both sinus rhythm and VT. Occasional spurious discharges occurred with the earlier model,[13] particularly in patients with bundle branch block. In the present series, this was not observed during the limited follow-up period despite the fact that 5 patients had bundle branch block with QRS duration ≥120 ms (Table II).

This population had severe LV dysfunction as well as severe arrhythmias. Unfortunately this was reemphasized in 3 patients who died from heart failure. All had had heart failure preoperatively and only 1 (Patient 9) had received the IACD pulse generator which functioned appropriately. These patients are quite similar to our earlier group[3,13] except for the absence of nonischemic cardiomyopathy, usually found in approximately 25%.[14]

Based on the results of electrophysiologic study, this study confirms and extends our earlier reports that VT appears to be the major tachyarrhythmia initiating hypotensive symptoms. In the present series, VT was observed or induced in all cases except 1. While many rapid ventricular rhythms can be modified by therapy, these results suggest that VT occupies a preeminent role in initiating cardiac arrest. Nevertheless, 1 of our patients did have VF. Thus, any device used to automatically convert ventricular tachyarrhythmias must include the ability to manage both VT and VF.

The hospitalization time for patients who received the complete IACD system, including leads and pulse generator, was 39 ± 23 days. However, an arbitrary 30-day postoperative recovery period, before pulse

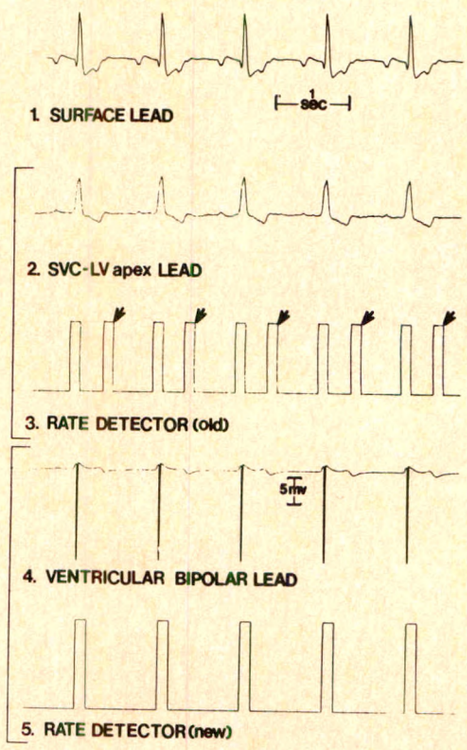

FIGURE 3. Recordings during sinus rhythm made at the time of IACD testing which show (**1**) surface lead V_1 with recordings from (**2**) the superior vena cava-left ventricular (SVC-LV) apex leads replayed through (**3**) the older (IAD) rate-detector circuit and recordings from (**4**) the ventricular bipolar lead replayed through (**5**) the present (IACD) rate detector circuit. Each detected signal and refractory period (panels 3 and 5) is represented by a square wave. The **arrows** (panel 3) demonstrate double rate-counting associated with voltage changes during the T wave (panel 2) when the older (superior vena cava-left ventricular apex) circuit is used. This counting error is avoided by using the ventricular bipolar signal (panel 4) and the new IACD rate circuitry (panel 5).

generator implant and testing, was required in any patient who underwent a ventriculotomy. This time should decrease as IACD surgery and pulse generator implantation can be performed as a single procedure.

The average follow-up period for the 11 patients was 4 ± 2 months. While all pulse generators were found to function properly during induced tachyarrhythmias and 1 spontaneous VT, there have been neither spontaneous out-of-hospital automatic conversions nor late deaths. Our longer experience (average 1.5 years) with the earlier defibrillator model has documented more than 75 automatic conversions and a significant increase in 1-year survival.[15]

Late hospital and follow-up complications appear to be relatively uncommon in these high-risk patients. One patient had a subclavian venous thrombosis, probably related to the SVC catheter (the first in 2.5 years) which completely resolved after heparin therapy. One patient had premature IACD battery depletion, which was replaced under local anesthesia. These events emphasize the importance of careful clinical follow-up after IACD implant.

While the IACD offers the potential for discontinuation of antiarrhythmic therapy, most patients appear to need some therapy to reduce the frequency of symptomatic events. Thus, the IACD is complementary to and supportive of other medical and surgical management. Two patients in this series required permanent (VVI) pacemakers. Both were bipolar and we were unable to demonstrate any interference with IACD performance. Nevertheless, pacemakers offer a potential source of interference: for example, rapid ventricular pacing beyond the IACD sensing period of 5 to 7 seconds or relatively large pacemaker pulses from atrioventricular sequential or unipolar systems which could lead to double rate counting.

The IACD offers several advantages over the earlier defibrillator. In addition to increased capability for management of VT, it permits noninvasive, audible verification of the R-wave sensing function, interrogation for the number of delivered pulses, and the ability to activate and deactivate the device. While it is easy to envision additional possibilities, such as programming and pacing, the IACD must not become so complex that effective use is precluded in a wide variety of clinical settings.

Acknowledgment: We express our gratitude to Jennifer Beeker, Sandra Waclawski, RN, Sarah Ord, BS, Mary Jo Bradley, BS, Joseph Wassil, Marguerite Sonneborn, Charles Bauer, and Sara Schmitt for technical support, and to Toni Haase for secretarial assistance. In addition, we are grateful for the nursing support provided by the staff of Osler 5 and the General Operating Room.

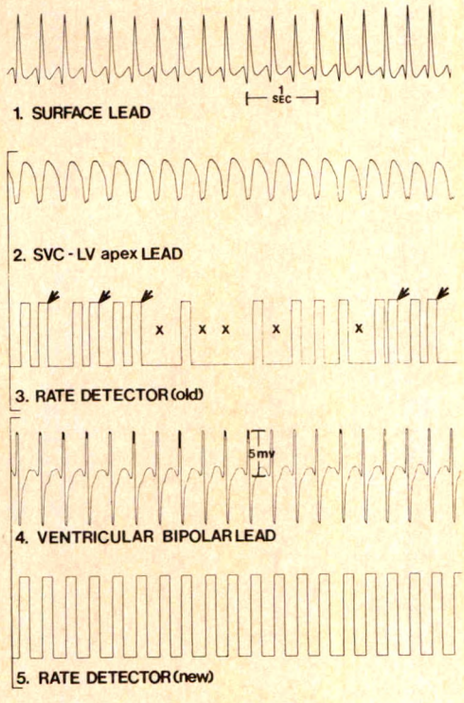

FIGURE 4. Recordings made during induced ventricular tachycardia at the time of IACD testing which show (**1**) surface lead V_1 with recordings from (**2**) the superior vena cava-left ventricular (SVC-LV) apex replayed through (**3**) the older (IAD) rate-detector circuitry and recordings from (**4**) the ventricular bipolar lead replayed through (**5**) the present (IACD) rate detector circuit. Each detected signal and refractory period (panels 3 and 4) is represented by a square wave. In panel 3 an **arrow** indicates double rate counting and an **X** indicates failure to detect a ventricular depolarization when the older (superior vena cava-left ventricular apex) circuit is used. These counting errors are avoided by using the ventricular bipolar signal (panel 4) and the new IACD rate circuit.

Addendum

Since submission of this manuscript we have documented 2 out-of-hospital IACD cardioversions in 2 different patients.

Efficacy of Verapamil in Chronic, Recurrent Ventricular Tachycardia

JAY W. MASON, MD, CHARLES D. SWERDLOW, MD, and L. BRENT MITCHELL, MD

Verapamil, 0.25 mg/kg, was given to 24 patients with chronic, recurrent ventricular tachycardia (VT) whose clinical tachyarrhythmias were reproduced at electrophysiologic study. Seven patients (29%) responded acutely to verapamil: VT was not inducible in 5 and spontaneously terminated within 5 seconds of induction in 2 patients in whom it was previously sustained. Four of the 7 responders had no identifiable structural heart disease, and 3 had coronary artery disease. Responders were younger and had better left ventricular function than did nonresponders. Long-term therapy with verapamil, attempted in 5 of the 7 responders, was effective in 3, ineffective in 1, and of uncertain efficacy in 1. Verapamil therapy was discontinued because of worsened congestive heart failure in 2 patients.

The short-term efficacy of verapamil in these patients compares favorably with the efficacy of other antiarrhythmic agents against VT induction in patients with long-term, recurrent, drug-refractory VT. The short-term efficacy of verapamil correlated with its long-term efficacy. These observations provide preliminary evidence that verapamil may be useful in the treatment of some patients with recurrent VT. When standard drugs are not effective, verapamil should be given a trial, especially in young patients with good left ventricular function.

Previous reports regarding the efficacy of verapamil in chronic, recurrent ventricular tachyarrhythmias have dealt with small numbers of patients and have not generally been encouraging.[1–6] Nevertheless, it is reasonable to suspect that calcium-dependent phenomena underlie ventricular tachyarrhythmias in some patients. Triggered automaticity, a calcium-dependent phenomenon, has been demonstrated in vitro in human and subhuman primate cardiac tissues.[7,8] Circumstantial clinical evidence has supported the possibility that ventricular tachycardia (VT) is due to triggered automaticity in patients.[6,9] Slowly rising action potentials, possibly generated by slow inward calcium currents, have been demonstrated in diseased human ventricular myocardium.[10] Furthermore, recent evidence suggests that ischemia-induced ventricular tachyarrhythmias are suppressed by calcium antagonists and by reduced extracellular calcium ion concentration.[11] Thus, we examined the efficacy of verapamil as therapy for chronic, recurrent VT.

Methods

Patients undergoing electrophysiologic study were consecutively selected to participate in this study if they had clinically recurrent VT, if their clinical arrhythmia was reproducibly inducible at electrophysiologic study, and if antiarrhythmic drugs, including beta-adrenergic antagonists, could be discontinued at least 24 hours before study. Patients were considered to have no structural heart disease when right and left heart pressure, left ventriculograms, coronary arteries, and 2-dimensional echocardiograms were normal.

VT was induced by ventricular extrastimulation according to a previously reported protocol.[12] VT was not inducible by rapid atrial pacing or atrial extrastimulation in any subject. Reliable inducibility of VT was established by reproduction 3 times of VT with rate, electrocardiographic QRS complex morphology, and duration similar to that of the clinical tachyarrhythmia. Repeated arrhythmia induction was not possible in the 3 patients who had continuous VT at the time of electrophysiologic study. Verapamil, 0.25 mg/kg, was then infused over a 15-minute period. Immediately at the end of infusion tachycardia induction was reattempted. After induction attempts were completed, blood was obtained through a femoral arterial catheter in 21 of the 24 patients for determination of the plasma concentrations of verapamil and norverapamil by a previously described liquid chromatographic technique.[13] If appropriate, long-term therapy with oral verapamil was instituted, and arrhythmia inducibility was again tested during stable oral therapy with verapamil.

Sustained and unsustained VT was defined as before.[12] Efficacy of verapamil was judged by the following criteria. At

TABLE I Characteristics of the Patients

Patients (n)	24
Age (yr)	56 ± 15
Male/female	22/2
Previous myocardial infarction (n)	16
Cardiomyopathy (n)	3
No structural heart disease	5
Cardiac index (liters/min/m^2)	2.5 ± 0.6
Left ventricular end-diastolic pressure (mm Hg)	14 ± 6
Sustained ventricular tachycardia (VT) (n)	18
Continuous VT (n)	3
Unsustained VT (n)	3
Continuous or >10 episodes of VT (n)	12
Two to 10 episodes of VT (n)	12
Previously ineffective drugs	3.5 ± 2.0

electrophysiologic study, the response to verapamil was considered complete if fewer than 6 ventricular repetitions could be induced after verapamil administration in patients with previously inducible sustained VT, or if fewer than 3 repetitions were induced in patients with previously unsustained VT. The response to verapamil at electrophysiologic study was partial if verapamil administration resulted in conversion of previously inducible sustained VT to inducible VT of less than 5 seconds' duration. Verapamil was considered effective during chronic oral therapy if a dose could be selected that resulted in absence of VT during electrocardiographic monitoring and absence of symptoms suggestive of VT recurrence. Therapy was initiated at 360 mg/day, and the dose was increased by 80 mg/day no more frequently than every 48 hours until tachyarrhythmia recurrence was prevented (Patients 1 and 2), a maximum safe dose was reached in subjects with heart failure (Patients 4 and 5), or a maximum dose of 8 mg/kg/day was reached (Patient 3). Each patient underwent at least 100 hours of electrocardiographic monitoring during chronic therapy with verapamil. Patients treated for longer than 6 weeks have undergone ambulatory monitoring every 3 months.

Means are expressed with standard deviations. Incidences were compared by 2 × 2 contingency table analysis with the significance of differences determined by a chi-square test with Yates' correction or by Fischer's exact test. Independent samples were compared by a 2-tailed unpaired *t* test or the Mann-Whitney rank-sum test.

Results

Twenty-four patients were studied (Table I). Although the majority of patients had coronary artery disease and previous myocardial infarction, 5 did not have structural heart disease identified by complete echocardiographic and angiographic studies. Eighteen patients had recurrent, sustained VT, 3 had continuous VT which persisted for days before electrophysiologic study, and 3 patients had recurrent, unsustained VT. VT was symptomatic in each patient, and each patient could accurately identify the presence of VT. Half of the patients had had more than 10 episodes or had continuous VT. On the average, each patient had failed to respond to 3.5 ± 2.0 individual antiarrhythmic drugs during clinical trial before electrophysiologic study because of recurrence of the clinical arrhythmia despite maximally tolerated doses.

At electrophysiologic study, 7 patients responded to verapamil, 2 of them having a partial response. Thus, verapamil prevented sustained arrhythmia induction in 29% of the patients. Characteristics of the responders are shown in Table II. None of them had received digitalis glycosides within 7 days of electrophysiologic study.

Responders were clinically different from nonresponders (Table III) in that they were younger and had better left ventricular function. Four patients without identifiable structural heart disease responded to verapamil and only 1 did not. There was no statistically significant difference between responders and nonresponders in the number of previously ineffective antiarrhythmic agents (2.9 ± 2.2 for responders, 3.7 ± 1.9 for nonresponders, $p > 0.4$), the nature of the VT (sustained, unsustained, or continuous), the rate of tachycardia, or the number of previous episodes. All 3 of the 7 responders to verapamil who received a clinical trial of propranolol failed to respond to it and an additional 1 still had inducible VT after receiving intravenous propranolol. The morphology of VT on 12-lead electrocardiography more frequently showed a pattern of right bundle branch block and left axis deviation in the responders (3 of 7 versus 3 of 17, $p = 0.36$).

Five patients received long-term oral therapy with verapamil (Table II). The 4 in whom stable maintenance therapy was achieved underwent repeat electrophysiologic study and remained classified as responders. Two patients (Patients 1 and 2) were young men without structural heart disease whose ventricular tachyarrhythmias have been effectively suppressed for more than 1 year. Patient 3, who also had no structural

TABLE II Characteristics of Responders and Results of Therapy

Patient	Age (yr) & Sex	Structural Heart Disease	Nature of VT	NYHA Class	Acute Response	Long-Term Therapy: Dose (mg)	Duration (mo)	Effective	Reason for Discontinuation
1	31M	0	Continuous	1	Complete	400	19	+	...

TABLE III Differences Between Responders and Nonresponders

	Responders	Non-responders	P Value
Patients (n)	7	17	...
Age (yr)	40 ± 15	62 ± 35	<0.001
Cardiac index (liters/min/m^2)	3.2 ± 0.4	2.3 ± 0.5	<0.001
LV end-diastolic pressure (mm Hg)	10 ± 4	15 ± 6	<0.001
Structural heart disease (n)	3	16	<0.018

LV = left ventricular.

heart disease, had recurrence of tachycardia on a maximum verapamil dose of 600 mg/day. In the last 2 patients (Patients 4 and 5), VT did not recur during maximal doses of verapamil, but the drug had to be discontinued in both because it significantly worsened preexisting congestive heart failure. In Patient 5 the duration of oral verapamil therapy was too short to assess its efficacy. Two responders (Patients 6 and 7) did not receive chronic oral therapy. One (Patient 7) had a partial response to verapamil, but ultimately had a complete response to imipramine at electrophysiologic study. The other underwent surgery for the arrhythmia.

Discussion

Verapamil is only rarely used to treat chronic, recurrent ventricular tachyarrhythmias because low efficacy rates have been reported in a few small series.[1–3] In these studies smaller doses (10 mg intravenously) than we used were given during ongoing VT. We are aware of only 1 study in which arrhythmia induction was included in the assessment of verapamil efficacy.[4] However, in that study, once again, only 10 mg were given to each of the 8 patients and only during established VT which was terminated by verapamil in only 1 patient. Our study differs from these in that a larger dose of verapamil was used (0.25 mg/kg, 18.5 ± 2.8 mg/patient), arrhythmia induction was used to test drug efficacy, and chronic therapy was attempted. McKenna et al[14] assessed chronic efficacy in 13 patients with hypertrophic cardiomyopathy and predominantly asymptomatic, unsustained VT (maximum duration 27 beats). Although verapamil did not appear effective, the patient population in that study is considerably different from ours.

The efficacy of verapamil in this study (29%) compares well with that of other individual antiarrhythmic agents assessed in our electrophysiology laboratory.[15] The most effective agents used in our laboratory, quinidine, procainamide, and propranolol, have completely or partially prevented VT induction, as defined herein, in 27 of 85 (32%), 17 of 52 (33%), and 5 of 17 (29%) trials, respectively. The overall incidence of individual antiarrhythmic drug efficacy in 405 trials in our laboratory is only 25%.[15] The mean age, indexes of left ventricular function, and incidence of normal heart structure of the 24 patients in this study do not differ from those of other patients evaluated in our laboratory.[15] Thus, our results suggest the possibility that verapamil is as effective as standard antiarrhythmic agents in the treatment of chronic, recurrent, medically refractory VT. This possibility requires confirmation in a larger group of patients. Patients who responded were younger, had better left ventricular function, and more frequently had no structural heart disease compared with nonresponders.

A previous case report[5] suggested the possibility that VT with a surface electrocardiographic pattern of right bundle branch block and left axis deviation occurring in patients without identifiable structural heart disease might represent a specific syndrome responsive to therapy with verapamil. Only 1 of our 7 responders had both no structural heart disease and this electrocardiographic pattern during VT. Absence of this electrocardiographic pattern and presence of structural cardiac disease did not preclude a response to verapamil.

Wu et al[6] reported on 3 patients without organic heart disease who had VT inducible by exercise but not by ventricular extrastimulation, and who responded to intravenous verapamil. They concluded that afterdepolarizations, which are dependent on or modulated by calcium ion, might be responsible for their patients' arrhythmias. Of course, a response of VT to verapamil cannot be taken alone as direct evidence for a specific mechanism of arrhythmia. Although verapamil is a potent inhibitor of the slow inward current, it has additional electrophysiologic and cardiovascular effects. Verapamil alters outward currents,[16] and its (+)-isomer blocks the myocardial sodium channel.[17] In addition, verapamil reduces left ventricular afterload and preload, reduces myocardial contractility, dilates coronary vessels, and promotes reflex autonomic adjustments to its hypotensive effects. Any of these additional actions conceivably could influence the inducibility and spontaneous occurrence of VT. Nevertheless, a response to verapamil provides circumstantial evidence that the affected arrhythmia resulted directly or indirectly from oscillatory afterpotentials or calcium-dependent, slow response action potentials.

The possibility that coronary artery spasm was responsible for tachyarrhythmias in these patients cannot be excluded conclusively because coronary arteriography, showing patent, normal vessels, was performed during VT in only 1 of the 7 responders (Patient 1). However, none of them had clinical evidence suggesting spasm. Although 2 responders had coronary artery disease, they did not have angina pectoris immediately before, during, or after episodes of tachycardia. None demonstrated S-T segment elevation before onset or after termination of VT. Furthermore, inducibility of tachycardia by extrastimulation in these patients makes coronary artery spasm an unlikely cause, because ventricular pacing is not known to induce coronary artery spasm and it is unlikely that spontaneous, asymptomatic spasm occurred coincidentally during attempts at VT induction.

Our protocol design may have been faulty, in that it did not compensate for a possible delay in peak effect of verapamil.[18] Also, we did not perform chronic trials of oral verapamil in patients with continued arrhythmia

inducibility after intravenous verapamil. We did not evaluate smaller doses of verapamil. The large intravenous and oral doses we used may have increased the incidence of heart failure. These design features may have reduced the potential efficacy of verapamil in this study.

We consider our findings on the efficacy of verapamil for treatment of VT preliminary because of the small number of patients in our study. In addition, only 2 of the original 24 subjects, both young and free of structural heart disease, continue on verapamil. However, until our findings can be confirmed or disaffirmed we recommend that verapamil be given a trial in patients for whom it is not contraindicated when other antiarrhythmic drugs have failed to control chronic, recurrent VT. Verapamil efficacy can be assessed at electrophysiologic study, as noninducibility of VT after intravenous verapamil correlated with arrhythmia nonrecurrence during chronic oral therapy. Our observations suggest that young patients with good left ventricular function and without identifiable structural heart disease are most likely to respond to verapamil.

Electrophysiologic Effects of Lorcainide on the Accessory Pathway in the Wolff-Parkinson-White Syndrome

WOLFGANG KASPER, MD, NORBERT TREESE, MD, THOMAS MEINERTZ, MD, EBERHARD JÄHNCHEN, MD, and TIBERIUS POP, MD

The electrophysiologic effects of lorcainide, a class I antiarrhythmic agent with local anesthetic properties, were studied in 20 patients with the Wolff-Parkinson-White syndrome. After intravenous administration of lorcainide (2 mg/kg), the sinus cycle length decreased in all patients from 705 ± 117 to 636 ± 94 ms ($p < 0.001$). The atrioventricular conduction time lengthened from 84 ± 22 to 94 ± 22 ms ($p < 0.01$) and the QRS duration increased from 92 ± 19 to 120 ± 29 ms ($p < 0.001$). The effective refractory period of the atrium increased from 230 ± 27 to 243 ± 35 ms ($p < 0.05$), whereas the ventricular refractoriness was unaffected. Retrograde conduction over the accessory pathway was blocked in 5 of 18 patients after lorcainide; in the remaining 13 patients a prolongation from 107 ± 32 to 162 ± 57 ms ($p < 0.001$) was found. Anterograde conduction over the accessory pathway was blocked in 6 patients, and in all other patients it increased considerably. Circus movement tachycardia could be induced in 14 patients before and in 10 patients after the drug. The shortest R-R interval during tachycardia lengthened from 326 ± 40 to 364 ± 67 ms ($p < 0.05$). The tachycardia zone was unaffected by lorcainide. In 15 patients atrial fibrillation was induced. After lorcainide anterograde conduction during atrial fibrillation was blocked ($n = 5$). The shortest R-R interval over the accessory pathway during induced atrial fibrillation increased from 228 ± 35 to 304 ± 103 ms ($p < 0.05$). Intravenous administration of lorcainide produced a pronounced negative dromotropic effect on the conduction properties of the accessory pathway. Lorcainide appears to be a promising new antiarrhythmic agent in patients with the Wolff-Parkinson-White syndrome.

Lorcainide, a class I antiarrhythmic agent with local anesthetic properties, was recently introduced into antiarrhythmic therapy in Europe and is currently under investigation in the United States.[1] In clinical studies the drug was found effective against premature ventricular contractions and ventricular tachycardia.[2–8] Lorcainide has a disappearance half-life of 7 to 9 hours and is well absorbed under chronic oral therapy with a saturable presystemic elimination.[9] Initial electrophysiologic studies showed the drug to be useful in patients with the Wolff-Parkinson-White (WPW) syndrome and circus movement tachycardia.[10–12] This study substantiates the electrophysiologic effects of this agent on the accessory pathway in patients with the WPW syndrome.

Material and Methods

Twenty patients (15 men and 5 women) aged 18 to 68 years (mean 39) were studied. Routine electrophysiologic investigations were performed because of unexplained supraventricular tachycardia in 4 patients and reciprocating tachycardias with known WPW syndrome in 14 patients. Two patients had a history of atrial fibrillation. Fourteen patients had electrocardiographic evidence of type A (Cases 1, 3, 7 to 10, 12 to 17, 19 and 20) and 4 patients type B WPW syndrome (Cases 2, 5, 6, and 18). In 2 patients a concealed left sided bypass tract was found, which conducted only in the retrograde direction (Cases 4 and 11). All studies were performed after informed written consent had been obtained. Cardioactive medications had been discontinued ≥72 hours before the beginning of the electrophysiologic study.

Electrophysiologic testing: Three quadripolar electrode catheters were usually introduced percutaneously through a left antecubital and right femoral vein and positioned under fluoroscopic control on the lateral wall of the high right atrium, into the apex of the right ventricle and in the region of the bundle of His. In those patients with a left-sided bypass tract, the high right atrial catheter was moved into the coronary

* Left bundle branch block.
† Blocked.
‡ Right bundle branch block.
§ Patient 14 was restudied under long-term oral lorcainide therapy.
Ante = anterograde; Atr = atrial; C = control; CL = cycle length; CL-CMT = cycle length of the circus movement tachycardia; ERP = effective refractory period; L = lorcainide; NL = nor-lorcainide; PCR = plasma concentration range of lorcainide and nor-lorcainide during the time of electrophysiologic testing; Retro = retrograde; SCL = sinus cycle length; VA = ventriculoatrial conduction time; Ventr = ventricular.

sinus. This allowed registration of the earliest atrial depolarization in the vicinity of the bypass tract during right ventricular stimulation. The intracardiac electrograms were simultaneously recorded with standard electrocardiographic leads I, aVF, and V_1 at a paper speed of 100 mm/s using filter setting of 70 Hz (Mingograph 6 channel, Siemens Elema). Pacing and programmed stimuli at twice diastolic threshold strength and a duration of 1.8 ms were delivered by a Medtronic 5325 stimulator. Refractory periods of the right atrium, the right ventricle, the anterograde and retrograde conduction properties of the accessory pathway were determined using the extrastimulus technique with extrastimuli after every eighth driven beat. Pacing was performed from the right ventricular apex, the coronary sinus, and the right atrium. Rapid pacing was started with a cycle length of 500 to 600 ms and progressively shortened until second-degree atrioventricular or ventriculoatrial block had been observed or a cycle length of 200 ms was reached. Thereafter, the effective refractory period of the atrium and the right ventricle were evaluated by the extrastimulus technique. Identical cycle lengths were used before and after drug administration to avoid changes in excitability and refractoriness by variations in heart rate. During electrophysiologic testing, the sinus cycle length, the A-H and H-V intervals, and the QRS duration were measured before and after the drug had been given. In those patients in whom preexcitation was present during sinus rhythm, the H-V interval was measured when anterograde conduction over the atrioventricular node occurred during echo-beats or circus movement tachycardia. The ventriculoatrial conduction time over the accessory pathway was measured from the beginning of the earliest ventricular depolarization on either the His bundle electrogram or the right ventricular electrogram to the earliest atrial electrogram. For demonstrating relative changes in ventriculoatrial conduction, this procedure appears appropriate.

In 15 patients atrial fibrillation was induced by atrial stimulation up to a rate of 800 beats/min before and after lorcainide administration. The shortest R-R interval of ventricular activation over the accessory pathway was measured to examine the effect of the drug on the conduction properties of the accessory pathway during atrial fibrillation.

Drug protocol: After control measurements were completed, lorcainide was administered intravenously over a 5-minute infusion period in a dose of 2 mg/kg body weight in 19

patients. In 1 patient (Case 14) electrophysiologic testing was repeated during chronic oral therapy with lorcainide (100 mg 4 times daily). Repeated electrophysiologic measurements were made starting 7 to 10 minutes after intravenous administration, up to 30 minutes. Plasma levels of the drug were obtained in 11 patients, in 10 of them immediately after the end of the infusion period as well as 3, 7, 15, and 30 minutes later and in 1 patient during long-term oral therapy. Lorcainide was determined in the blood plasma of these patients using a specific gas chromatographic technique.[9]

Statistical methods: Data obtained before and after drug administration were compared by using Student's t test for paired data.

Results

Effect on impulse generation and conduction: Table I lists the pertinent electrophysiologic data of the patients studied. The sinus cycle length decreased in all patients from a mean of 705 ± 117 to 636 ± 94 ms ($p < 0.001$). The atrioventricular conduction time increased from 84 ± 22 to 94 ± 22 ms ($p < 0.01$). The intraventricular conduction time lengthened from 41 ± 6 to 55 ± 10 ms ($p < 0.001$). Lorcainide caused a widening of the QRS complex from 92 ± 19 to 120 ± 29 ms ($p < 0.001$). In 2 patients bundle branch block developed (left in Case 4; right in Case 13). One patient (Case 19) demonstrated left bundle branch block before and after the drug. In 2 patients (Cases 10 and 15), QRS duration was difficult to assess because of varying degrees of preexcitation.

The effective refractory period of the atrium increased from 230 ± 27 to 243 ± 35 ms ($p < 0.05$). Lorcainide had no consistent effect on ventricular refractoriness (208 ± 16 to 214 ± 19 ms, difference not significant).

Effect on conduction properties of the accessory pathway: The ventriculoatrial conduction time over the accessory pathway was examined in 18 patients before and after drug administration. Two patients (Cases 13 and 18) showed conduction over the accessory pathway exclusively in an anterograde direction. After lorcainide, retrograde conduction was blocked in 5 patients, whereas in the remaining 13 patients ventriculoatrial conduction was prolonged from a mean of 107 ± 32 to 163 ± 57 ms ($p < 0.001$). An example is presented in Figure 1. A reciprocating tachycardia could be induced in 14 patients before and in 10 patients after lorcainide administration. In 2 patients (Cases 18 and 19) a circus movement tachycardia could be induced only after the drug had been given. The shortest R-R interval during tachycardia lengthened from a mean control value of 326 ± 40 to 364 ± 67 ms ($p < 0.05$) thereafter. No consistent effect of lorcainide on the tachycardia zone during atrial or ventricular stimulation was observed. During atrial stimulation, the tachycardia zone decreased in 4 patients and increased in 3 patients. Patient 14, who was receiving long-term oral therapy with lorcainide, had a considerable increase of the tachycardia zone up to 295 ms, while it was absent under control conditions. Despite this fact, the R-R interval of the tachycardia induced increased from 345 to 450 ms in this particular patient. During right ventricular stimulation the tachycardia zone decreased in 2 patients and increased in 2 other patients. Refractoriness of the accessory pathway in an anterograde and retrograde direction often could not be measured because the refractory periods of the atrium and of the right ventricle encroached on that of the accessory pathway. In 9 patients anterograde refractory periods of the bypass tracts were shorter than the effective refractory period of the atrium during the control period. After lorcainide administration, the anterograde refractory period of the accessory pathway remained shorter than the effective refractory period of the atrium in 3 of them. After drug administration the anterograde conduction of the accessory pathway was totally blocked in 6 patients. In the other patients, the effective refractory period of the accessory pathway increased considerably.

The retrograde refractoriness of the accessory pathway could not be measured in 6 patients during the control period and in 2 patients after drug administration because the effective refractory period of the right ventricle exceeded that of the bypass tract. After lorcainide the retrograde effective refractory period of the accessory pathway could not be measured in 5 patients in whom the conduction was blocked during the time of study. In the remaining patients a prolongation of the effective refractory period of the accessory pathway in a retrograde direction was found.

The ventricular rate after induced atrial fibrillation

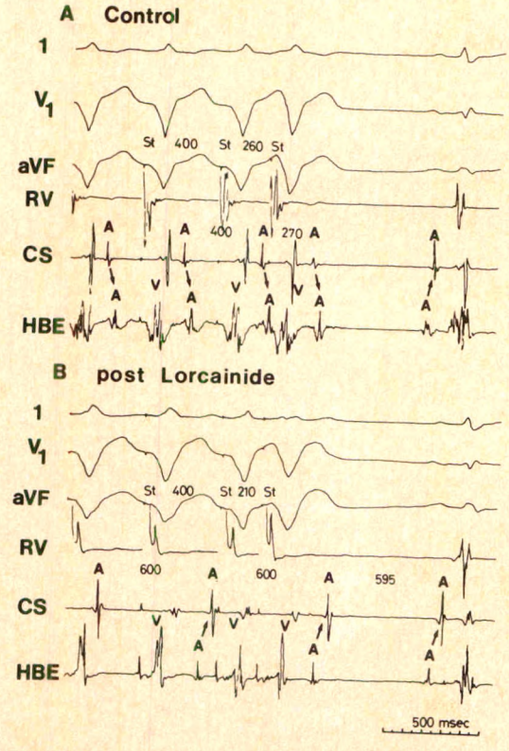

FIGURE 1. Effect of lorcainide on ventriculoatrial conduction over the accessory pathway (Case 10). Under control conditions the earliest atrial depolarization is detected in the coronary sinus during right ventricular (RV) stimulation, demonstrating a left atrial bypass tract. After lorcainide administration, ventriculoatrial conduction over the accessory pathway is blocked. CS = coronary sinus; HBE = His bundle electrogram; St = stimulus.

was assessed in 15 patients. In 1 patient (Case 4), anterograde conduction during atrial fibrillation occurred exclusively over the atrioventricular node. Another patient (Case 18) in whom anterograde conduction over the accessory pathway could not be observed during sinus rhythm and during atrial stimulation demonstrated QRS complexes with preexcitation intermittently during atrial fibrillation. The remaining patients showed anterograde conduction predominantly or exclusively over the accessory pathway. In these patients the anterograde conduction was either blocked (5 patients) or shifted to anterograde conduction predominantly over the atrioventricular node (Fig. 2). The shortest R-R interval over the accessory pathway increased from 228 ± 35 to 304 ± 103 ms ($p < 0.05$) (Fig. 3).

Plasma drug concentrations during the time of study: The plasma levels of lorcainide were measured in 10 patients during short-term administration and in Case 14 under long-term oral therapy with 100 mg lorcainide 4 times daily. The plasma concentration of lorcainide ranged from 0.46 to 0.16 μg/ml to 0.26 ± 0.06 μg/ml during the period of drug testing. Case 14 had a plasma level of 0.28 μg/ml, and the level of the N-dealcylated metabolite nor-lorcainide was 0.56 μg/ml. Nor-lorcainide levels were not detected after intravenous administration of the drug.

Side effects: No patient developed serious side effects from the drug. Fainting was reported by 2 patients. Two others complained of feeling hot and dizzy during the infusion. Two patients reported transient visual disturbances. One patient under chronic therapy with lorcainide complained of sweating, especially at night, and sleeplessness, which tended to diminish with ongoing therapy.

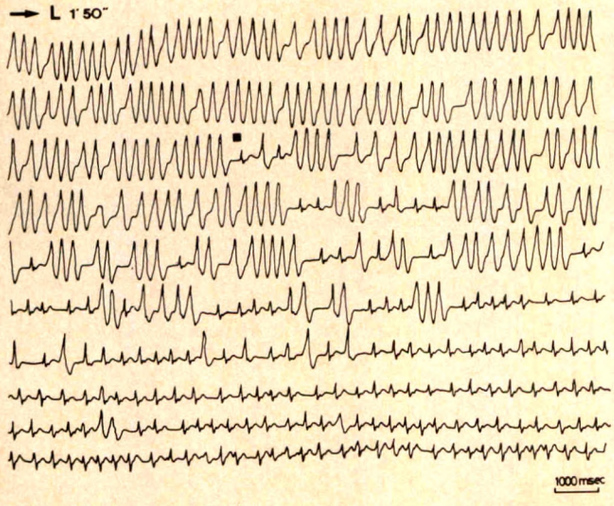

FIGURE 2. Effect of lorcainide on anterograde conduction over the accessory pathway after induced atrial fibrillation (Case 19). A continuous electrocardiogram registration during an ongoing lorcainide infusion depicted 1 minute and 50 seconds after the injection had begun (L 1'50") shows that anterograde conduction is shifted to antrioventricular conduction at the end of the infusion period exclusively.

Discussion

Effect on impulse generation and conduction: Until recently only a few electrophysiologic studies had been carried out to test the effects of lorcainide on electrical impulse generation and conduction in man. Our observation of increased sinus heart rate after intravenous administration of lorcainide in contrast to the prolongation of the atrioventricular, intraventricular, and intramyocardial conduction is consistent with findings in previous investigations. In these studies lorcainide decreased the R-R interval during sinus rhythm[10,13] or increased it only slightly.[12] This effect may be due in part to an anticholinergic effect of the drug.[10] The sinus node automaticity was depressed by the drug.[10,12] The atrioventricular and intraventricular conduction time was lengthened, as well as intramyocardial conduction.[10–13] The magnitude of these effects depends on the plasma concentration of the drug during oral therapy.[5]

Effect on the effective refractory period of the atrium and ventricle: A slight enhancement of the atrial refractoriness was noted. The effective refractory period of the right ventricle appeared to increase slightly. This change, however, was not statistically significant. Variable effects of the drug on the effective refractory period of the atrium and the ventricle have also been observed by other investigators.[12,13]

Effect on the conduction properties of the accessory pathway: Lorcainide caused a block in 6 of 17 patients in an anterograde direction and in 5 patients in a retrograde direction. Ventriculoatrial conduction was prolonged in all other patients in whom it could be measured. The negative dromotropic effect of the drug on the conduction properties of the accessory pathway was further substantiated by a prolongation of the cycle length of the circus movement tachycardia after drug administration.

Initial trials in a limited number of patients with the WPW syndrome have also shown that lorcainide can depress impulse conduction over the accessory pathway

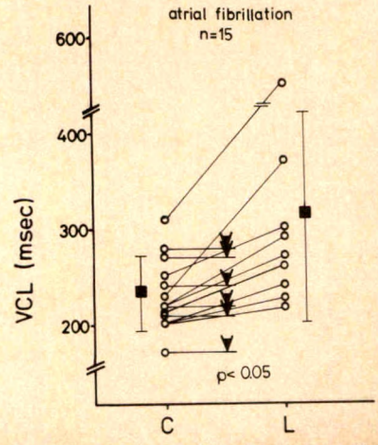

FIGURE 3. The ventricular cycle length (VCL) after induced atrial fibrillation increased in 9 patients and was blocked (**arrowheads**) in 6 patients. C = control; L = lorcainide.

in an anterograde and retrograde direction.[10,11,12] Similar to our findings in these studies, the refractory period of the accessory pathway was found prolonged in both directions.[11,12] Bär et al[11] reported that anterograde conduction over the accessory pathway was blocked after lorcainide administration in 8 of 11 patients. In a further study, anterograde conduction over the accessory pathway was blocked in 6 of 12 patients.[12] Retrograde conduction was blocked after the drug had been given in 2 of 11 patients.[11] In contrast, Manz et al[12] did not find a ventriculoatrial block in their patients.

A reciprocating tachycardia could be initiated in 14 of our patients before and in 10 after lorcainide. In 2 patients a circus movement tachycardia was only inducible after drug treatment. This finding is in accordance with observations of other investigators.[11,12] Pronounced prolongation of ventriculoatrial conduction over the accessory pathway by lorcainide with no or only little effect on the functional refractory period of the atrioventricular node[10] may have facilitated the initiation of tachycardia in these patients. The tachycardia zone was not systematically affected by the drug, which is consistent with findings by other workers.[11,12]

Patients with short refractory periods of the accessory pathway are prone to rapid ventricular rates if atrial fibrillation occurs. The marked negative dromotropic effect of lorcainide in a subgroup of patients characterized by a refractory period <270 ms deserves special consideration. Thirteen of our patients belonged to this subgroup.[14] Conduction was blocked in 3 of these patients (Cases 8, 11, and 15). In the remaining patients it was lengthened. The shortest R-R interval after induced atrial fibrillation was also prolonged after lorcainide.

The study was designed to investigate short-term effects of lorcainide on the accessory pathway. Therefore, conclusions cannot be drawn directly regarding the effects of the drug under long-term oral therapy. However, 1 patient who received long-term oral therapy with 400 mg/day of lorcainide demonstrated a favorable drug response. The accessory pathway was blocked in an anterograde direction, and the retrograde conduction properties of the pathway were considerably depressed. Despite these findings, a tachycardia zone of 245 ms was observed in a retrograde direction. Thus, in this patient the marked ventriculoatrial prolongation over the accessory pathway may have allowed the atrioventricular node to recover from refractoriness, resulting in a circus movement tachycardia. The tachycardia interval of the induced tachycardia was 450 ms. However, this was well tolerated by the patient.

Plasma drug concentrations determined in 11 of the 20 patients were comparable to the plasma concentrations found with long-term oral therapy.[5] It is possible that the electrophysiologic effects of lorcainide observed after intravenous drug administration were different from those which might be observed under chronic treatment. This may be due in part to the high plasma concentrations in the early distribution phase of lorcainide. On the other hand, it is well known that an active metabolite, nor-lorcainide, accumulates in the plasma in patients under long-term oral therapy,[5,8] which can enhance the electrophysiologic effects of the native compound.[5]

Clinical implications: The pronounced negative dromotropic effects of the drug on the accessory pathway, especially in patients with short refractory periods, might be of considerable value in the short-term treatment of circus movement tachycardia in patients with the WPW syndrome. The beneficial effect of lorcainide also seen in 1 patient under long-term oral therapy may indicate that this also holds true for long-term treatment. Further studies of long-term oral therapy are warranted to define the real therapeutic value of the drug in patients with the WPW syndrome.

One costs 13% less.

Nitro-Dur: a significant savings for the angina patient.

When a patient takes a medication every day and possibly for the rest of his life, cost becomes a significant factor.

Nitro-Dur is the most economical transdermal nitroglycerin: the 10 cm^2 size costs 11% less and the 20 cm^2 size costs 13% less than the comparable products from Ciba. In one year, patients using Nitro-Dur can save up to $75 compared to patients using the Ciba product.[1]

Nitro-Dur patients save in another way. The larger adhesive surface of Nitro-Dur means that there is less chance of adhesive failure, thus saving the patient the cost of replacement.

Reduced patient cost. One more reason why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

The most widely prescribed transdermal nitroglycerin system.

Please see next page for a summary of prescribing information.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release in vivo of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[2] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

INDICATIONS AND USAGE: Prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without a prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

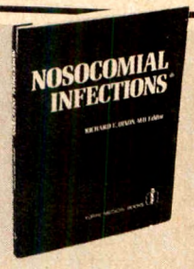
NOSOCOMIAL INFECTIONS

edited by
Richard E. Dixon, M.D.

appx. 344p June 1981,
$29.50 hardbound
ISBN 0-914316-24-9
$19.50 softbound
ISBN 0-914316-29-X



Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

The book includes:

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups

and many other topics.

DIFFERENT DOCTORS, DIFFERENT PATIENTS, ONE SYSTEM.

Don't compromise. With System Q from Quinton, you can test the way you want to test. And so can every doctor who works with you.

It adapts. So you don't have to.

State-of-the-art microprocessor technology gives System Q the power to adapt to your individual testing requirements. The Q2000 monitor can store up to five programmed test procedures, each customized to meet the specific needs of a different physician.

It adapts to your patients, too. You can modify your procedure for a single test, with flexible control over 17 elements of the test, from ST sample point to treadmill protocol.

A superior diagnostic tool.

The Q2000 gives you more data, more accurately than ever before possible. Its averaged beat final report, with computed ST parameters, gives you more usable ECG information. Its QRS detection algorithms are the most sophisticated ever developed. It offers you a more precise calculation of ST parameters. And a more stable heart rate indication.

Stress testing simplified.

The most advanced stress test system ever built is also the simplest to use. You can learn to operate System Q in a few minutes. And learn to program it in less than an hour.

A new standard for treadmills.

No treadmill has ever been quieter. Or more functional. Quinton's Q55 is the state-of-the-art.

Its sleek, low-profile design with wider walking surface improves patient safety and gives the subject more room to maneuver. The transmission was Quinton-engineered to offer quieter overall performance. Larger drums provide improved tracking. And a self-leveling feature makes it solid as a rock.

SYSTEM Q.

Engineered to be a workhorse.

System Q offers one specification you won't find on other stress test systems: Quinton reliability. It was engineered to work, day in and day out. To meet the changing demands of different doctors. To test more people with greater reliability.

It could be working for you (for less than you'd expect). Find out more. Call or write Quinton Instrument Company, 2121 Terry Ave., Seattle, WA, 98121, 1-800-426-0347, Telex 328840.

TO A "DOER"
Your angina patients* can become more active now...with PROCARDIA protection. They'll be pain-free more of the time[1] and find their need for nitroglycerin greatly reduced.[2] They'll be able to work harder, exercise more.[3] And be more active participants in their own lives once again.
feeling better...doing more
PROCARDIA®
(NIFEDIPINE) Capsules 10 mg
*Procardia is indicated for the management of:
• Confirmed vasospastic angina.
• Angina where the clinical presentation suggests a possible vasospastic component.
• Chronic stable angina without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or nitrates or who cannot tolerate these agents. In chronic stable angina (effort-associated angina) Procardia has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.
Please see PROCARDIA® brief summary on next page.

feeling better...doing more

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

–Usual effective dosage is 30-60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because Procardia decreases peripheral vascular resistance, careful monitoring of blood pressure during initial administration and titration is suggested. Close observation is especially recommended for patients taking medication known to lower blood pressure.

–Offers a favorable safety profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

BRIEF SUMMARY
PROCARDIA® CAPSULES
(nifedipine)
For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in those patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Carcinogenesis, mutagenesis, impairment of fertility: When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose.

Pregnancy: Category C. Please see full prescribing information with reference to teratogenicity in rats, embryotoxicity in rats, mice and rabbits, and abnormalities in monkeys.

ADVERSE REACTIONS: The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation, inflammation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, and sexual difficulties. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

Laboratory Tests: Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms. Cholestasis, possibly due to PROCARDIA therapy, has been reported twice in the extensive world literature.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

Cardiology 1983

What is CARDIOLOGY 1983?

- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1983 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

- **William C. Roberts, MD**
  Chief, Pathology Branch National Heart, Lung & Blood Institute National Institutes of Health Bethesda, Maryland, and Clinical Professor of Pathology and Medicine (Cardiology) Georgetown University, Washington, D.C.

Instead, do just one thing: Compare our image for yourself...

E FOR M / Honeywell

A76

Imager

The Electronics for Medicine/ Honeywell Ultra Imager gives you so many features for such a reasonable price, you could choose it for this reason alone.

But we don't want you to.

Instead, what we want you to do is call us, along with the manufacturer of any other comparable cardiac ultrasound system, for a demonstration. You can even let them bring along their best sonographer.

Then, compare the quality of the two images side-by-side.

What will you find?

We're convinced that once you've seen the difference for yourself, you'll find that in this comparison, there is just no comparison.

The E for M/Honeywell Ultra Imager.

We don't just *claim* to have better image quality.

We're willing to prove it.

For more details or a demonstration, call, toll-free, (800) 328-5111 extension 174. In Minnesota, call collect (612) 870-2682, extension 174. Or write our Customer Communications Center, P.O. Box 16525, Denver, Colorado 80216.

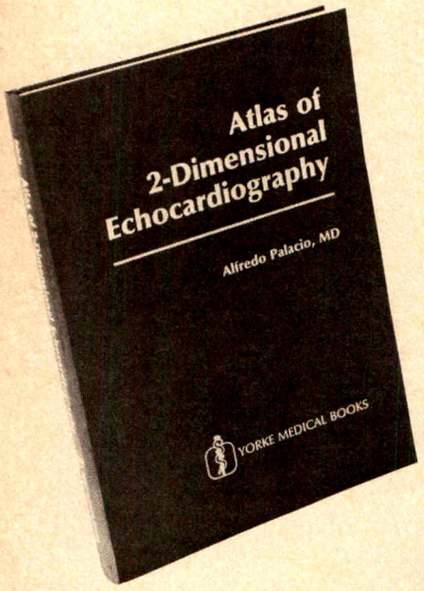
The First Practical Atlas of 2-D Echocardiography Ever Published



A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms

Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School; Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts
ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $65.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

To order your copy of this important new book use the order form to the right.

Table of Contents

Foreword
Preface
Prologue
Introduction
EQUIPMENT
THE ECHOCARDIOGRAPHIC EXAMINATION
Parasternal position
  Longitudinal plane
  Transverse plane
Apical position
  Hemiaxial plane
  Axial plane
Subxiphoid position
  Transvascular plane
  Transcardiac plane
Suprasternal position
  Longitudinal plane
  Transverse plane
Final recommendations for the beginning technician
Special controls
Compendium of tomographic sections
DISEASES
Mitral stenosis
  Characteristics of the mitral stenosis in 2-dimensional echocardiography
  Longitudinal plane, long axis of the left ventricle
  Transverse plane, short axis
  Direction of future investigations
Mitral regurgitation
Tricuspid valve
Aortic valve and aortic root
Pulmonary valve
Intracardiac masses and tumors
Pericardial effusion
Ischemic heart disease
Congenital heart disease
Cardiomyopathies
Systemic arterial hypertension
MISCELLANEOUS
Valvular prostheses
Performance and volume of the left ventricle
Intracavitary cables and catheters

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Prescribing Information Tablets of 50 mg
Tablets of 100 mg

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure. (see **Warnings**)

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions Impaired Hepatic or Renal Function: The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

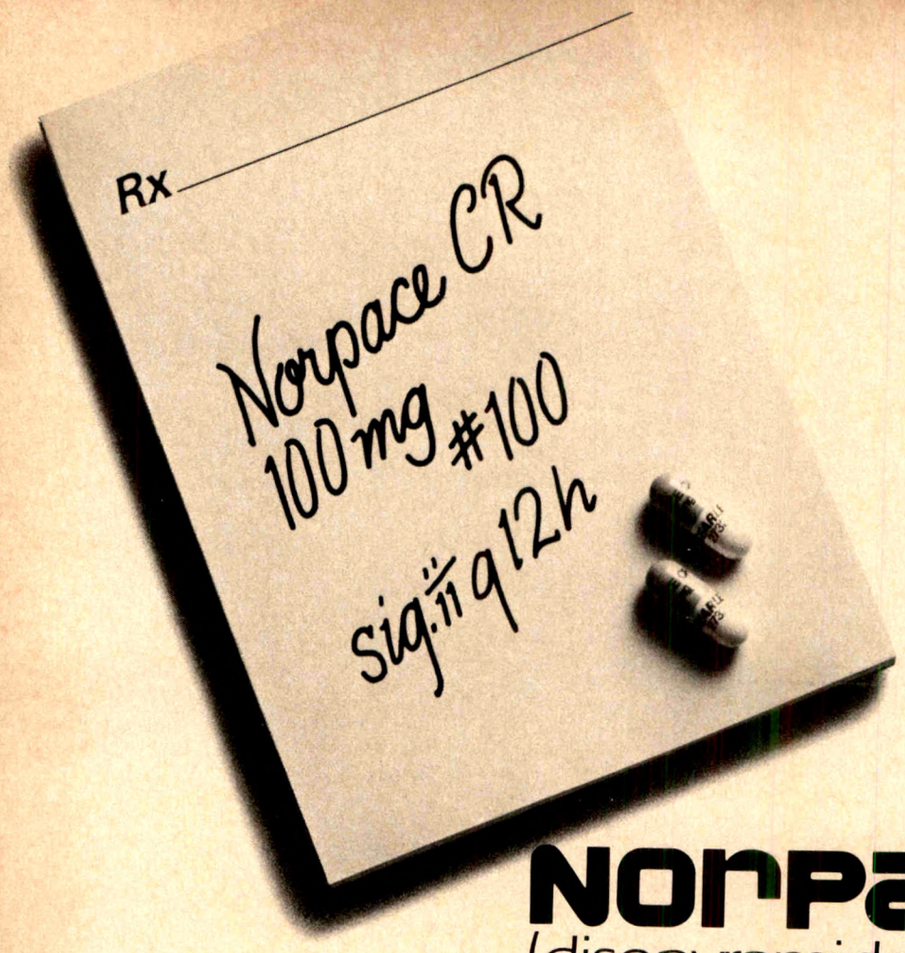
Norpace® CR
(disopyramide phosphate)
100-mg and 150-mg controlled release capsules
The only antiarrhythmic that offers a specific q12h dosage schedule
☐ Convenient dosage schedule
☐ Enhanced patient compliance
☐ The continuous efficacy you expect
The most commonly seen side effects from disopyramide phosphate are anticholinergic, and the most severe are due to its negative inotropic properties.
Please see the brief summary of prescribing information on the following page.
SEARLE



Norpace® CR

(disopyramide phosphate)

100-mg and 150-mg controlled release capsules

Before prescribing, please consult current complete prescribing information, a summary of which follows: **Indications:** For suppression and prevention of recurrence of the following cardiac arrhythmias: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Norpace CR should not be used initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide phosphate has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace or Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace or Norpace CR, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace or Norpace CR should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace or Norpace CR should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patients should be monitored closely, and discontinuation of Norpace or Norpace CR considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic agents and/or propranolol should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace or Norpace CR should be reduced. If the block persists, continuation of Norpace or Norpace CR must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or trifascicular block requires discontinuation of drug unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. In patients with a family history of glaucoma, intraocular pressure should be measured before initiating Norpace or Norpace CR therapy. Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to Norpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of disopyramide phosphate. Therefore, a loading dose of Norpace should not be given to such patients, and initial dosage and subsequent dosage adjustments should be made under close supervision. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs for overdosage. Norpace CR is not recommended for patients with severe renal insufficiency. Concomitant administration of disopyramide phosphate with phenytoin or other hepatic enzyme inducers may cause lower disopyramide plasma levels. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace or Norpace CR therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of labor and delivery are unknown. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory difficulty, thrombocytopenia, and gynecomastia. **Dosage and Administration:** Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg/day given in divided doses: q6h for Norpace and q12h for Norpace CR. **See current complete prescribing information for dosage recommendations.**

Electrophysiologic Testing in the Management of Patients With the Wolff-Parkinson-White Syndrome And Atrial Fibrillation

FRED MORADY, MD, CARLOS SLEDGE, MD, EDWARD SHEN, MD, RUEY J. SUNG, MD, ROLANDO GONZALES, MD, and MELVIN M. SCHEINMAN, MD

Twenty patients with the Wolff-Parkinson-White (WPW) syndrome and 1 or more episodes of symptomatic atrial fibrillation (AF) due to rapid anterograde bypass tract conduction underwent electrophysiologic testing. The mean ventricular rate during spontaneous AF was 242 ± 56 beats/min (± standard deviation) and the shortest preexcited R-R interval was 194 ± 40 ms. Six patients underwent surgical bypass tract ablation and 14 were treated medically, based on the results of electropharmacologic testing. Over a mean follow-up period of 35 ± 19 months (± standard deviation), only 1 patient treated medically had a recurrence of minimally symptomatic AF. The successful chemoprophylaxis of symptomatic AF was associated with the inability to induce AF and atrioventricular reciprocating tachycardia during drug testing (7 patients) or with the induction of AF with a ventricular rate <200 beats/min and a shortest preexcited R-R interval of >250 ms (7 patients). Electrophysiologic testing can identify a subgroup of patients with WPW and AF in whom medical therapy is a suitable alternative to bypass tract ablation.

Patients with the Wolff-Parkinson-White syndrome (WPW) who have an episode of atrial fibrillation (AF) may have an extremely rapid ventricular rate due to rapid conduction through an atrioventricular bypass tract. In addition to causing symptoms due to hemodynamic compromise, such as syncope or weakness, the rapid ventricular rate that occurs during AF may also result in ventricular fibrillation.[1,2] One option available for the treatment of patients with WPW who have had an episode of AF associated with an extremely rapid ventricular rate is surgical ablation of the bypass tract.[3] This therapeutic option exposes the patient to the potential risks of open-heart surgery. Few data are available regarding the long-term results of medical therapy in patients with WPW and AF. We therefore examined the role of electrophysiologic testing in selecting patients with WPW and AF who may be appropriate candidates for medical therapy and in designing a drug regimen effective in preventing life-threatening episodes of AF.

From the Department of Medicine and the Cardiovascular Research Institute, University of California, San Francisco, California. Manuscript received December 22, 1982; revised manuscript received February 22, 1983, accepted February 25, 1983.

Address for reprints: Fred Morady, MD, Room 573, Moffitt Hospital, University of California, San Francisco, California 94143.

Methods

Twenty patients with WPW and at least 1 episode of symptomatic AF were referred to our institution between September 1976 and February 1982. A clinical profile of these patients is presented in Table I. Mean age was 35 ± 17 years (± standard deviation). Three patients had mitral valve prolapse, 1 had mitral regurgitation, and 1 had coronary heart disease; 15 patients had no structural heart disease. The patients had a mean of 2.1 ± 1.4 episodes of symptomatic AF over a period of 11 ± 12 months before referral to our institution. All patients had symptoms of syncope, presyncope, chest pain, or palpitations in association with AF. The mean ventricular rate during spontaneous episodes of AF in 18 patients was 242 ± 56 beats/min. The mean shortest preexcited R-R interval in 18 patients was 194 ± 40 ms. In 2 patients, AF with a rapid ventricular response degenerated into ventricular fibrillation after arrival at the hospital; in 1 patient, AF was observed on an electrocardiographic monitor before ventricular fibrillation but was not recorded. A third patient who had a previous history of AF had a cardiac arrest and was found by paramedics to be in ventricular fibrillation. Thus, in 2 patients a recording of AF was not available for analysis. Direct-current countershock was used to terminate AF or ventricular fibrillation on 1 to 4 occasions in 12 of 20 patients. The remaining 8 patients were treated emergently with intravenous procainamide or lidocaine. At the time that AF or ventricular fibrillation occurred, 10 patients were not being treated with any antiarrhythmic drug; 6 patients were being

* Shortest preexcited R-R interval during atrial fibrillation.
† Cardiac arrest due to ventricular fibrillation.
AF = atrial fibrillation; AVRT = atrioventricular reciprocating tachycardia; CA = cardiac arrest; DCC = direct-current countershock; ND = not documented; SD = standard deviation.

treated with quinidine (0.8 to 1.2 g/day), 2 with procainamide (1.4 to 2.0 g/day), 2 with propranolol (80 to 160 mg/day), and 1 with digoxin (0.25 mg/day). In addition to having at least 1 documented episode of AF, 10 of 20 patients also had a 1 to 40-year history of recurrent palpitations of presyncope due to orthodromic atrioventricular reciprocating tachycardia. The bypass tract location was left-sided in 11 patients, right-sided in 2, and posteroseptal in 7.

After informed consent was obtained, an electrophysiologic study was performed with the patient in the fasting, nonsedated state. In 12 patients all antiarrhythmic drugs were discontinued at least 4 half-lives before the electrophysiologic study. At the time of referral to our institution, 8 patients had been treated empirically for at least 1 week with 1 or more antiarrhythmic drugs that were well tolerated. These patients were referred for evaluation of the efficacy of empiric therapy, and a baseline study was not performed.

Three quadripolar electrode catheters were inserted into a femoral vein by the Seldinger technique and positioned against the high lateral right atrium, across the tricuspid valve, and against the right ventricular apex. An additional quadripolar electrode catheter was inserted into a subclavian or antecubital vein and positioned in the coronary sinus. Surface leads V_1, I, and III and the high right atrial, His bundle, coronary sinus, and right ventricular electrograms were displayed on a VR-12 oscilloscope and recorded on an Electronics for Medicine recorder at a paper speed of 100 mm/s. Cardiac stimulation was performed with a programmable stimulator (Bloom, Narberth, Pennsylvania) at 2 to 3 times the diastolic threshold and with a pulse duration of 2 ms. Incremental right atrial, left atrial (coronary sinus), and right ventricular overdrive pacing was performed to a minimum paced cycle length of 250 ms. During overdrive pacing at a cycle length of 500 ms, single atrial or ventricular stimuli were introduced at 10 ms decrements throughout the respective diastolic cycles. Attempts were made to induce AF by repeated 15 second bursts of atrial overdrive pacing at cycle lengths of 200 to 40 ms (by 20 ms decrements), with a current strength of up to 10 mA. If the induced AF did not terminate spontaneously within 20 minutes, the patient was treated with either direct-current countershock (2 patients) or 100 to 1,000 mg of procainamide intravenously (10 patients) to terminate the AF. Nonsustained AF or reciprocating tachycardia was defined as AF or reciprocating tachycardia that terminated spontaneously within 30 seconds.

During drug testing, the following parameters were measured: anterograde effective refractory period (ERP) of the bypass tract, the shortest atrial overdrive cycle length at which there was a 1:1 conduction through the bypass tract, the inducibility and average rate of atrioventricular reciprocating tachycardia and AF, and the shortest cycle length between 2 consecutive preexcited complexes during AF. Whenever possible, at least a 2-minute duration of AF was analyzed to determine the average ventricular rate and the shortest prexcited R-R interval. In several patients, determination of the bypass tract ERP was limited by atrial refractoriness; in such cases the bypass tract ERP was expressed as being equal to or less than the atrial functional refractory period.

Drugs were chosen for testing depending upon each patient's history of drug intolerance and previous clinical drug trials. Electropharmacologic testing was performed immediately after the intravenous infusion of 1 or more of the following drugs: procainamide, 750 to 1,500 mg, propranolol, 0.2 mg/kg, or amiodarone, 10 mg/kg. One or more of the following drugs were tested after oral adminstration for at least 4 half-lives: procainamide, 1.5 to 6.0 g/day, quinidine, 1.2 to 2.0 g/day, disopyramide, 0.8 g/day, digoxin, 0.25 mg/day, propranolol, 160 mg/day, or metoprolol, 100 mg/day. Testing was performed with amiodarone after oral administration of 200 to 1,000 mg/day for 6 weeks because of the extended period of time required for this drug to attain its full therapeutic effect.[4]

Patients were selected to undergo surgical bypass tract ablation if sustained AF remained inducible during drug testing, with a mean ventricular rate ≥200 beats/min and a shortest preexcited R-R interval of ≤250 ms. The latter cri-

* Shortest preexcited R-R interval.
† Drug regimen most effective in suppressing or controlling the ventricular rate of induced atrial fibrillation and atrioventricular reciprocating tachycardia.
‡ Nonsustained (spontaneous termination within 30 seconds).
§ Noncompliant patient.
AF = atrial fibrillation; Am = amiodarone; D = disopyramide; Dig = digoxin; M = metoprolol; N = nadolol; NI = noninducible; P = procainamide; Pr = propranolol; Q = quinidine; RT = reciprocating tachycardia; V = ventricular.

terion was used because of an earlier study showing that patients with WPW who have had ventricular fibrillation have a shortest preexcited R-R interval of ≤250 ms during AF.[2] Bypass tract ablation was also recommended in 1 patient (Patient 15) who required open-heart surgery for correction of mitral regurgitation.

Patients not selected for surgical therapy were treated with drugs as guided by the results of electropharmacologic testing. Drug therapy was adjusted to yield serum drug levels that matched drug levels found to be successful in controlling or suppressing AF in the laboratory. All patients were followed by 1 of the authors or referring physicians and were seen at intervals of 3 to 4 months.

Values are expressed as mean ± 1 standard deviation. Statistical analyses were performed with Student's *t* test (paired or unpaired, as appropriate).

Results

Electropharmacologic testing and selection of long-term therapy (Table II): During drug testing in 5 patients, AF remained inducible and had a ventricular rate of ≥200 beats/min (mean 227 ± 42) and a shortest preexcited R-R interval of ≤250 ms (mean 216 ± 29). These patients were selected to undergo surgical bypass tract division. While being treated with procainamide and propranolol, Patient 15 had inducible AF with a ventricular rate of only 140 beats/min. She underwent bypass tract division at the time of mitral valve surgery for mitral regurgitation.

The remaining 14 patients were treated medically. Atrial fibrillation could not be induced in 7 of these patients during drug testing. Nonsustained AF was inducible in 3 patients and sustained AF was inducible in 4. In all 7 patients who had inducible AF, the mean ventricular rate during AF was <200 beats/min (mean 135 ± 24) and the shortest preexcited R-R was >250 ms (mean 356 ± 103).

Effects on bypass tract characteristics (Table III): In 8 of 15 patients in whom inducible AF was suppressed or controlled during drug testing and in 4 of 5 patients in whom it was not, a baseline electrophysiologic study was performed before drug testing. In the baseline state there was no significant difference between patients in whom inducible AF was suppressed or controlled and patients in whom the ventricular rate during induced AF was not controlled in the mean bypass tract ERP (≤287 ± 38 ms versus ≤250 ± 22 ms) or in the shortest atrial paced cycle length at which there was a 1:1 bypass tract conduction (316 ± 42 ms versus 275 ± 25 ms).

In the patients in whom inducible AF was suppressed or controlled, there was a significant increase in the bypass tract ERP during drug testing (≤287 ± 40 ms versus ≤321 ± 43 ms, $p < 0.05$); however, because determination of ERP was often limited by atrial refractoriness, a firm conclusion cannot be drawn regarding the ERP. There was no change in the shortest atrial paced cycle length at which there was a 1:1 bypass tract conduction before and after drug testing (316 ± 42 ms versus 325 ± 40 ms).

In the patients in whom the ventricular rate during induced AF was not controlled during drug testing,

† Shortest atrial paced cycle length at which there was 1:1 bypass tract conduction.
‡ Nonsustained (<30 seconds in duration).
AVRT = atrioventricular reciprocating tachycardia; BT = bypass tract; CL = cycle length; ERP = effective refractory period; NI = not inducible; NM = not measured, due to induction of atrial fibrillation by atrial pacing.

there was no significant change in the bypass tract ERP (≤250 ± 22 ms versus ≤280 ± 29 ms) or in the shortest atrial paced cycle length at which there was 1:1 bypass tract conduction (275 ± 25 ms versus 283 ± 14 ms) before and after drug testing, respectively.

During drug testing in the 5 patients in whom the ventricular rate during induced AF was not adequately controlled, the mean bypass tract ERP (≤282 ± 26 ms) was significantly shorter than in the 15 patients in whom suppression or control of AF was achieved (≤330 ± 38 ms, $p < 0.02$). The shortest atrial paced cycle length at which there was 1:1 bypass tract conduction was significantly shorter in the patients in whom induced AF was not controlled than in the patients in whom induced AF was controlled or suppressed (283 ± 14 ms versus 337 ± 41 ms, $p < 0.002$).

Effects on reciprocating tachycardia (Table III): Orthodromic reciprocating tachycardia remained inducible during drug testing in 4 of 5 patients in whom the ventricular rate during induced AF could not be controlled (tachycardia cycle length = 378 ± 86 ms). In contrast, among the 15 patients in whom control or suppression of inducible AF was achieved, sustained reciprocating tachycardia could not be induced by either atrial or ventricular pacing in 13 patients and was inducible in 2 (cycle length = 400 and 450 ms). Among the 6 patients who had inducible reciprocating tachycardia in the baseline state but not during drug testing, the site of block in the tachycardia circuit was the bypass tract in 5 patients and the atrioventricular node in 1.

Follow-up (Table III): Five of the 6 patients who underwent surgical bypass tract division have had no recurrence of symptomatic AF or reciprocating tachycardia over a mean follow-up period of 43 ± 31 months. In 1 patient, an attempt at surgical division of posteroseptal bypass tract was unsuccessful and reciprocating tachycardia recurred postoperatively. This patient was subsequently treated with amiodarone when it became available and has had no recurrence of symptomatic AF or reciprocating tachycardia over a 42-month follow-up period.

The mean follow-up period in the 14 patients treated medically was 32 ± 19 months. One patient had a spontaneous episode of palpitations due to AF with a mean ventricular rate of 150 beats/min; this was treated with intravenous procainamide. A second patient who admitted to erratic drug compliance had 2 episodes of palpitations due to a recurrence of orthodromic reciprocating tachycardia (140 beats/min). The other 12 patients have had no episodes of symptomatic AF or reciprocating tachycardia.

Spontaneous versus induced atrial fibrillation (Table II): Of the 12 patients who underwent a baseline study, in 2 patients orthodromic reciprocating tachycardia spontaneously degenerated into AF. Atrial fibrillation was induced by atrial overdrive pacing in the other 10 patients. The mean ventricular rate during induced AF in these 12 patients was 203 ± 32 beats/min, and the shortest preexcited R-R interval was 224 ± 38 ms.

In 11 patients in whom records of both spontaneous and induced AF were available, the ventricular rate during spontaneous AF, 244 ± 47 beats/min, was greater than during induced AF, 203 ± 34 beats/min ($p < 0.01$). The shortest preexcited R-R interval during spontaneous AF, 183 ± 33 ms, was shorter than during induced AF, 223 ± 40 ms ($p < 0.01$).

Atrial effective refractory period: The atrial ERP was measured in 12 patients before and during drug testing. All 12 patients had inducible AF during the baseline study. In 5 patients who no longer had inducible AF during drug testing, the atrial ERP increased after administration of drugs (232 ± 39 ms versus 298 ± 46 ms, $p < 0.01$). In 6 patients in whom AF remained inducible during drug testing, the atrial ERP also increased after administration of drugs, although to a lesser degree (229 ± 42 ms versus 256 ± 35 ms, $p < 0.05$).

Discussion

Our results suggest that a subset of patients who have WPW and potentially life-threatening AF can be treated safely and effectively with a drug regimen based on the results of electropharmacologic testing. Effective prophylaxis against the recurrence of symptomatic AF was associated with the inability to induce AF during the electropharmacologic testing or with the induction of AF with a ventricular rate <200 beats/min and a shortest preexcited R-R interval >250 ms.

In 2 patients in this series, orthodromic reciprocating tachycardia was observed to spontaneously degenerate into AF. This mechanism of AF in patients with WPW has been reported previously.[5–8] In such patients it may be necessary to suppress episodes of reciprocating tachycardia to prevent recurrences of AF. If induction of reciprocating tachycardia cannot be suppressed, a reduction in the rate of the tachycardia may be helpful in preventing a recurrence of AF, because the vulnerability to AF decreases as the atrial rate decreases.[9]

A previous study by Bauernfeind et al[10] also achieved successful medical therapy of patients with WPW and symptomatic AF. Among 8 patients with WPW who underwent electropharmacologic testing and were treated chronically with drugs that suppressed the induction of AF, over a mean follow-up period of 24 months, AF recurred only in 2 patients whose drug regimens were altered due to adverse effects. Our findings extend the observations of Bauernfeind et al by demonstrating that the complete suppression of AF induction during drug testing may not be necessary for successful long-term management of patients with WPW and AF. A good clinical response may also be obtained with drug therapy that does not suppress the induction of AF but that does decrease the ventricular rate during induced AF to <200 beats/min, lengthen the shortest preexcited R-R interval to >250 ms, and suppresses induction of reciprocating tachycardia.

There usually was no measurable prolongation in bypass tract refractoriness during drug testing when the baseline bypass tract ERP was <270 ms, as reported by Wellens et al.[11] However, because the determination of bypass tract ERP was often limited by atrial refractoriness, no firm conclusions can be drawn regarding the effects of drug testing on bypass tract ERP.

It is interesting to note that the mean ventricular rate during induced AF in the baseline state was significantly slower than during spontaneous AF in the same patients. Sympathetic tone would be expected to increase to a greater degree during a prolonged bout of spontaneous AF than during an episode of AF that is induced in a supine patient in the electrophysiology laboratory. Previous reports have shown that beta-adrenergic stimulation with isoproterenol may shorten the bypass tract anterograde ERP and result in an increased ventricular rate during AF.[12,13]

As reported by Bauernfeind et al,[10] suppression of inducible AF during drug testing was associated with significant prolongation of the atrial ERP. Although the atrial ERP was also lengthened during drug testing in patients who continued to have inducible AF, the magnitude of the change was less than in patients in whom the induction of AF was suppressed. An inadequate prolongation in the atrial ERP may be one factor accounting for the inability to suppress the induction of AF during drug testing.

Our study has the following limitations. (1) Ten of 20 patients had only 1 episode of symptomatic AF before undergoing electrophysiologic study. We must assume that without therapy, these patients would have had recurrent AF. (2) A baseline electrophysiologic study was not performed in 8 patients, 2 of whom did not have inducible AF during drug testing. In these 2 patients, we must assume that AF would have been inducible in the baseline state and that the inability to induce AF was due to a drug effect. (3) Bypass tract ablation was performed in all 5 patients in whom the ventricular rate during induced AF was not controlled. The long-term course of these patients had they been treated medically is not known. Therefore, it cannot be concluded that bypass tract ablation is necessary in such patients, since it is possible that drug therapy that suppresses ectopic beats may be effective in preventing life-threatening episodes of AF by eliminating the trigger for AF.

In conclusion, in patients who have WPW and episodes of AF with a rapid ventricular response, the decision to treat the patient medically or surgically should be individualized, based on the potential risks and benefits of each approach. The high success and low mortality rates associated with surgical division of bypass tracts (especially when the bypass tract is located in the free wall of the left or right ventricle[14]), together with elimination of the cost, inconvenience, and potential adverse effects of long-term drug therapy, argue in favor of this approach. However, the surgical approach exposes the patient to all the risks of open-heart surgery. We have demonstrated that electrophysiologic testing can identify a subgroup of patients with WPW and AF in whom medical therapy is a suitable alternative to surgical bypass tract ablation.

Long-Term Recording of Monophasic Action Potentials From Human Endocardium

MICHAEL R. FRANZ, MD

In 36 patients undergoing routine cardiac catheterization, a new "contact electrode" catheter technique was used to record monophasic action potentials (MAPs) from right atrial and right and left ventricular endocardial sites without the application of suction. Although of smaller amplitude, typically ranging from 15 to 40 mV, and of different reversal ratio (33 ± 3%), MAP recordings closely resembled transmembrane action potentials in configuration and duration. Continuous MAP recordings of stable amplitude and, during regular pacing, of constant duration (±1% at 90% repolarization) could be made from the same endocardial site for test periods of 1 hour (n = 4), permitting direct evaluation of the effect of cycle length alterations on local myocardial repolarization. A linear relation was found between MAP duration and basic cycle length varying from 350 to 700 ms. These rate-dependent changes in MAP duration were caused by a change in the slow phase of repolarization (phase 2), whereas the slope of rapid repolarization (phase 3) was unaltered. Single premature MAPs or MAPs after a pause showed changes in both phases. No MAPs could be recorded in areas of infarcted, aneurysmal myocardium, indicating that local viable myocardium is a prerequisite for the generation of the monophasic signal. Thus, in human subjects this catheter permits safe, long-term recording of MAPs which, although of smaller amplitude than transmembrane action potentials, bear appropriate and predictable phase relations. Such recordings may be useful in evaluating changes in local myocardial electrical activity induced by pacing or resulting from myocardial disease, or both.

To examine the time course of local electrical activity under experimental conditions in which microelectrode recordings are difficult or impossible to make, such as in the vigorously beating in-situ heart, investigators have often used suction electrodes.[1–3] The signal obtained with suction electrodes is monophasic and, although of smaller amplitude, accurately reflects the onset of depolarization and the entire repolarization phase of transmembrane action potentials recorded from cells in the same vicinity.[3] Suction electrodes have also been used in human subjects,[4–6] but the potential for subendocardial damage and S-T segment elevation[5,7] has limited its clinical use to short recording periods of 2 minutes or less.[5–7] Because the shape and duration of the action potential vary from site to site in the heart,[8] longer recording time from a single endocardial site is needed to evaluate long-term MAP changes, such as heart rate effects over several basic cycle lengths or in response to pharmacologic interventions.

On the basis of earlier observations that MAPs can be obtained by simply bringing the exploring electrode into firm approximation with the myocardial surface,[9–11] we have developed a new "contact electrode" catheter that permits easy and safe long-term MAP recording from the human endocardium during routine cardiac catheterization.[12] This study (1) describes the characteristics of such MAP recordings from atrial and ventricular endocardium, (2) demonstrates the effects of abrupt and sustained cycle-length changes on MAP recordings from a single endocardial site, and (3) suggests that MAP mapping with this contact electrode technique may be useful in identifying abnormal myocardium.

Methods

Catheter design: The design is illustrated in Figure 1. Teflon® tubing and nonpolarizable electrodes made from cylindrical pellets of sintered silver-silver chloride are used. The tip electrode protrudes to form a smooth spherical surface 1 mm in diameter. The second, the reference electrode, is 0.5 mm in diameter 5 mm proximal to the tip and somewhat recessed so that contact is made only with the outer medium

(blood) and not the endocardium. Unipolar catheters were also used, and contain only the tip electrode with a reference electrode placed in subcutaneous tissue remote from the heart, that is, at the site of catheter insertion. Total length of the catheters was 100 to 150 cm, and intravascular positioning was aided by a movable spring-steel guide wire.

Recording procedure: Before catheterization, electrodes were immersed in sterile 0.9% saline solution for 1 hour with leads short-circuited to balance half-cell potentials. This procedure ensured that no appreciable direct-current drift occurred during the course of the investigation. Diastolic baseline of intracavitary electrograms usually remained stable within ±1 mV during the entire recording time (1 to 3 hours), whereas stainless steel or platinum electrodes conventionally used in clinical electrophysiology may produce considerable baseline drift of up to 160 mV during the first 30 minutes (unpublished observation). After percutaneous catheter insertion by Seldinger technique and fluoroscopic positioning of the catheter within the heart, electrode leads were connected with sterile cables to a battery-powered differential preamplifier with an input impedance of 10^{11} Ω and a frequency range from direct current to 100 kHz (Grass Instruments, P16). The preamplified intracardiac signal and a standard precordial lead were displayed on a Tektronix storage oscilloscope and written out on a multichannel photographic recorder (Electronics for Medicine, VR-12). Data analyzed for MAP duration were recorded at 100 mm/s paper speed.

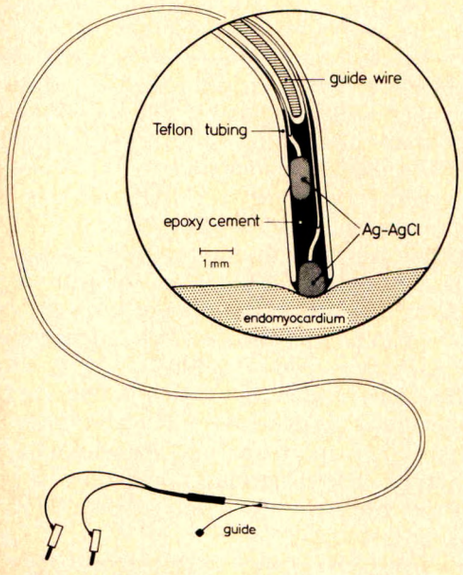

FIGURE 1. Design of contact electrode catheter (bipolar type). Ag-AgCl = silver-silver chloride.

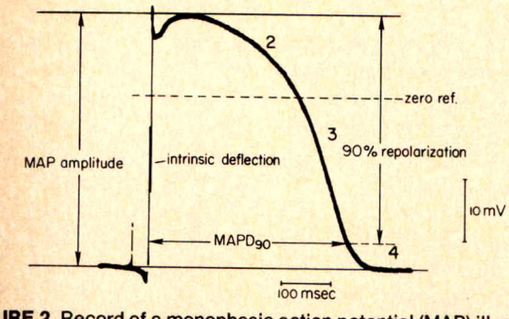

FIGURE 2. Record of a monophasic action potential (MAP) illustrating the methods of analysis. The plateau phase (phase 2), the phase of final repolarization (phase 3), and the diastolic baseline (phase 4) are labeled as conventional in intracellular recordings. The (retouched) upstroke of the MAP is much slower than that in intracellular recordings and is distorted by a notch that occurs at the time at which the intrinsic deflection[13] of the endocardial surface electrogram was recorded before the genesis of the monophasic signal. The superimposed intrinsic deflection was used as a reference marker for the beginning of the MAP, because its inscription accurately indicates the instant at which the excitation wave front passes the exploring electrode.[14,15] The MAP was negative during diastole and late systole and reversed its polarity during the early phase of activation with respect to zero reference which was derived from the isoelectric baseline of the intracavitary electrogram **(dashed horizontal line)**.

Characterization of the MAP: Figure 2 shows a typical MAP recording from a right ventricular endocardial site. The MAP amplitude was defined as the potential difference between the diastolic baseline and the crest of the plateau (phase 2). The duration of the MAP was measured as the time in milliseconds from the onset of local activation to the time of 90% repolarization ($MAPD_{90}$).

Electrical stimulation: To examine the effects of rate and rhythm on the MAP, recordings from a single endocardial site

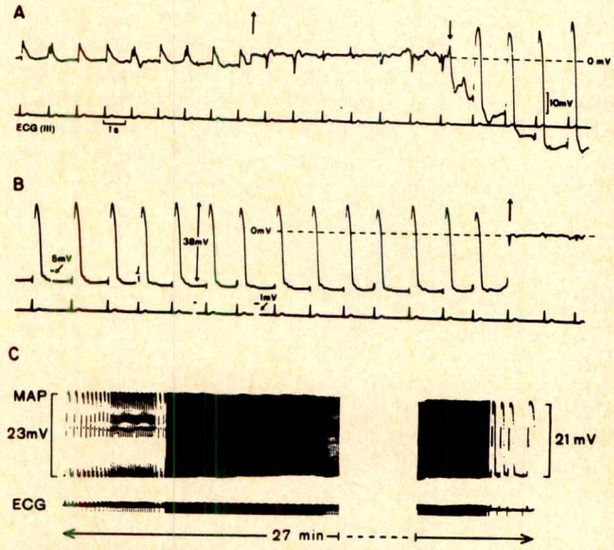

FIGURE 3. Monophasic action potential (MAP) recordings, intracardiac electrograms, and surface electrocardiogram (ECG) during catheter positioning in different locations within the right heart. At the beginning of the upper tracing (**A**), the electrode contacted the atrial endocardium close to the tricuspid valve, giving rise to MAPs of triangular shape typical of atrial muscle (notches appearing in some potentials are artifacts due to unstable endocardial contact). Withdrawal of the catheter from the endocardium (**arrow indicating upward**) resulted in a sudden return to the intracavitary signal. During the subsequent 7 heart beats the catheter was advanced through the tricuspid valve orifice into the apical region of the right ventricle, resulting in varying intracavitary electrograms. Firm approximation of the tip electrode to the endocardium (**downward arrow**) produced successively increasing negative potentials during diastole and positive displacements (reversal) during systole. Tracing **B** shows MAPs from a different right ventricular site. Withdrawal of the catheter from the endocardial surface is indicated by **upward arrow.** Note the absence of premature beats in these recordings. **C,** off-line recordings at varying tape and paper speeds, demonstrating MAP stability.

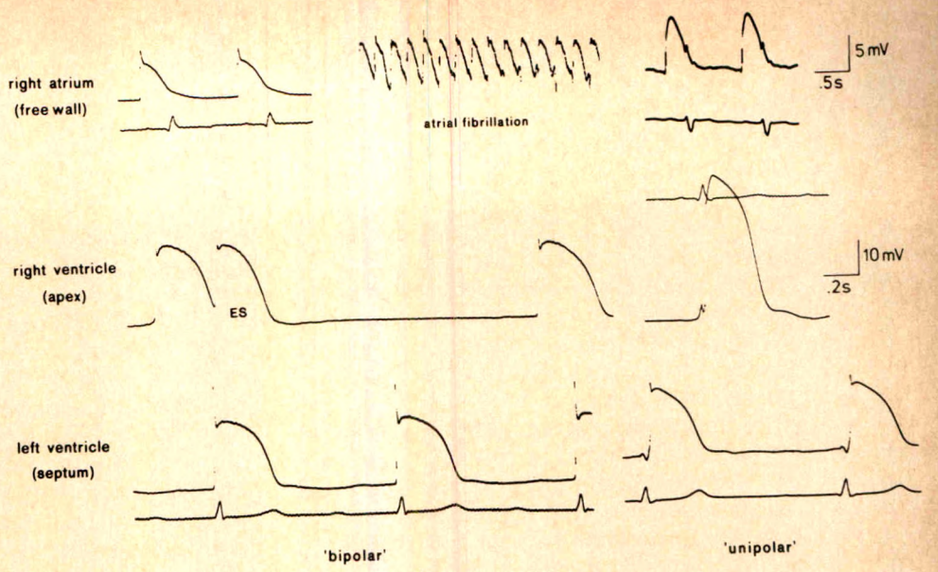

FIGURE 4. Monophasic action potentials recorded from various endocardial sites. Superimposed electrical activity (QRS) is minimized using a *bipolar* type of contact electrode catheter. ES indicates a premature beat followed by a compensatory pause.

were made during right atrial or ventricular pacing with rectangular stimuli of 1-ms duration and twice diastolic threshold strength.

Study population: Studies were carried out in 36 patients undergoing routine diagnostic cardiac angiography or electrophysiologic study. Informed consent was obtained from each patient, with the study design having been approved by the Committee on Human Investigations. Six patients had recordings from the right atrium, 32 from the right ventricle, and 5 from the left ventricle. Effects of heart rate alterations were evaluated in 8 patients, effects of atrial or ventricular extrasystoles, or both, in 12, and recordings from infarcted and noninfarcted areas of the same ventricle in 2. S-T segment changes did not occur and patient discomfort was not reported during the recordings.

Results

Recordings of MAPs: Adequate recordings were obtained in 34 of 36 patients. Contact of the electrode with the endocardium was indicated by the appearance of a fast biphasic deflection constituting the initial phase of the endocardial surface electrogram (Fig. 3). Pressing the electrode tip gently against the endocardium resulted in MAPs successively increasing in amplitude which reached a stable value within 2 to 6 beats. Although of smaller amplitude, the MAP shows close similarities in configuration to transmembrane action potentials. Withdrawal of the catheter from the endomyocardial wall resulted in a sudden return of the recorded potential to the isoelectric baseline. Premature beats sometimes occurred when the catheter was made to contact the endocardium but rarely resulted from the endocardial contact during the recording.

Stability of MAP recordings: Introduction of the catheter and establishment of stable endocardial contact were generally accomplished within a few minutes. Once stabilized, MAPs could be recorded continuously from the same endocardial site for periods of up to 3 hours without further manipulation of the catheter or readjustment of the electrode position. An example of the stability of the recorded MAP is demonstrated in Figure 3C in which a continuous record of 27 minutes is shown. As seen fluoroscopically, there was no movement of the catheter tip along the myocardial wall during the recording.

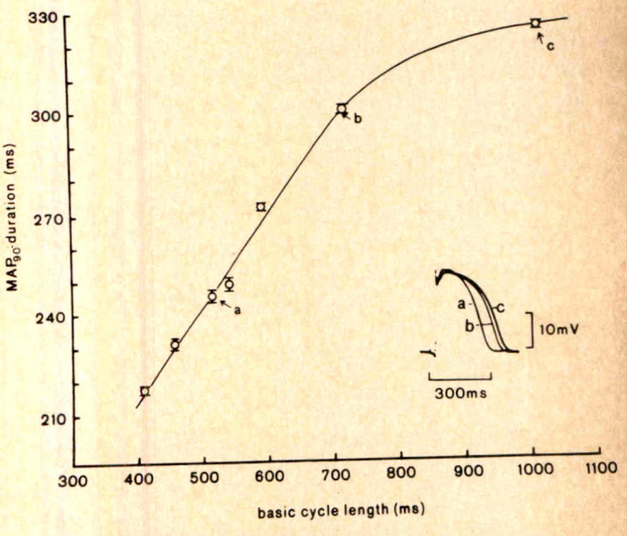

FIGURE 5. Effect of pacing at different basic cycle lengths on monophasic action potential configuration and duration at 90% repolarization (MAP_{90}) in a continuous record from a single right ventricular site in a patient who permitted atrial pacing at basic cycle lengths of up to 1,000 ms without escape beats. Data points and horizontal bars represent mean steady-state values (after 3 minutes of pacing) ±1 standard deviation. The curve was fitted by eye. Data points labeled a, b, and c refer to actual recordings as shown in the **inset.**

MAP recordings from different heart chambers: Typical examples of MAP recordings from the right atrium and both ventricles are shown in Figure 4. Similar to intracellular measurements, atrial MAPs are more triangular in shape because of a shorter phase 2 and a decreased slope of phase 3, as compared with MAPs recorded from ventricular endocardium.

Steady state recordings: At a single paced basic cycle length, the duration of the MAP at 90% repolarization ($MAPD_{90}$) was stable within ±1% for a test period of 60 minutes (n = 4). In Figure 5 a representative example of the effect of changes in basic cycle length on $MAPD_{90}$ is shown. With basic cycle lengths varying from 350 to 700 ms, $MAPD_{90}$ increased in linear fashion; at basic cycle lengths >600 to 700 ms, $MAPD_{90}$ approached a plateau. These steady-state cycle-length dependent changes in $MAPD_{90}$ were caused by changes in the duration of phase 2 whereas the slope of phase 3 was largely unchanged (Fig. 5, inset). Only at very long basic cycle lengths (≥1,000 ms) was a slight decrease in the slope of phase 3 observed.

Abrupt cycle length alterations: Changes in duration and repolarization contour of the MAP similar to those seen in transmembrane action potentials were observed in spontaneously arrhythmic beats or when the cycle length was abruptly altered by right atrial or ventricular pacing. Typical examples of premature and delayed right ventricular MAPs are shown in Figure 6. Premature depolarizations elicited within 100 ms after the effective refractory period were followed by MAPs of shorter duration because of an abbreviated phase 2 and a slightly steepened phase 3. However, those premature MAPs that were clearly separated from the preceding steady state response by a diastolic interval longer than 80 ms exhibited a prolonged phase 2 and a greater total duration. Relatively prolonged cycle lengths resulted in a greater total duration of the MAP because of a decreased slope of phase 3.

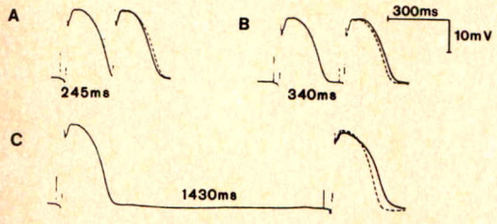

FIGURE 6. Changes in monophasic action potential duration and configuration after *abrupt* alteration in basic cycle length. Each set of recordings shows the last steady-state action potential at a cycle length of 428 ms, followed by an action potential at the indicated cycle length. The dotted recordings are superimposed reproductions of the steady-state action potential.

Amplitude and polarity of MAP recordings: Amplitudes of MAPs recorded from the right or left ventricular endocardium were comparable and usually ranged between 15 and 40 mV. MAPs recorded from the right atrium were considerably smaller and usually below 10 mV. The use of nonpolarizable electrodes in conjunction with direct-current recording made it possible to observe the magnitude of negative and positive potentials with respect to the isoelectric baseline of the intracavitary electrogram. With the exploring (tip) electrode connected to the positive input of the amplifier, a negative potential is recorded during diastole and a positive potential (reversal) during the initial part of systole (Fig. 3). As also seen in Figure 3, the reversal (positive displacement) increases with the total amplitude of the MAP. The ratio between MAP reversal and total amplitude was stable (33 ± 3%, n = 19) regardless of the total amplitude or the site from which the recording was made within the heart.

Effect of myocardial scarring on MAP recordings: In 2 patients with large left ventricular aneurysms demonstrated by cardiac angiography, recordings were carried out at several left ventricular sites (Fig. 7). At sites in which wall motion appeared relatively preserved, MAPs of >25 mV amplitude were recorded, whereas at the center of the aneurysm no MAP could be recorded, but rather only a signal similar to the intracavitary electrogram. At an intermediate location close to the area of preserved wall motion, small monophasic deflections were recorded (site 2, Fig. 7).

Discussion

This study shows that by using a specially designed contact electrode catheter, stable MAPs can be recorded from a single endocardial site continuously over prolonged periods of time. These MAP recordings resemble intracellular recordings in showing similar configuration

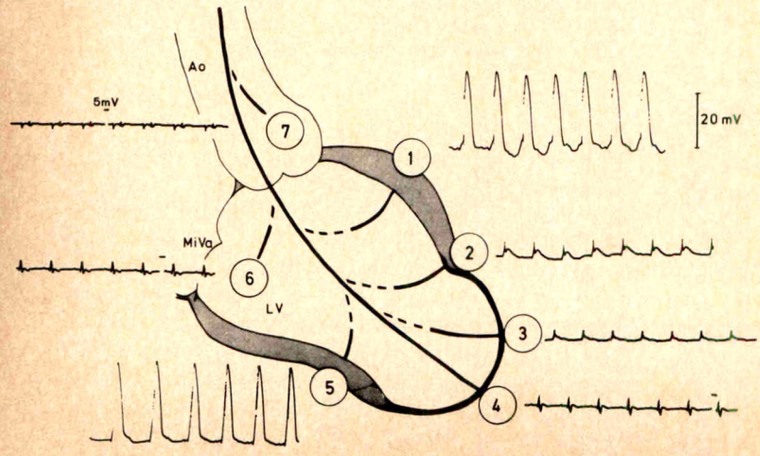

FIGURE 7. Monophasic action potential (MAP) recordings (unipolar type of catheter) from various left ventricular (LV) sites in a patient with 1-year-old anteroapical aneurysm (schematically depicted). Positions 6 and 7 show electrograms recorded from within the LV cavity and ascending aorta, respectively. Positions 1 and 5 indicate normally contracting wall segments. Positions 3 and 4 indicate recordings from the akinetic segment and show no true MAPs, rather only intracavitary signals. Position 2 is in the border zone of the aneurysm and shows small monophasic deflections.

and duration which change appropriately in response to abrupt or sustained cycle-length alterations. Prolongation of phase 2 and steepening of phase 3 in premature action potentials and opposite changes after single, relatively prolonged intervals (Fig. 6) have previously been observed in intracellular recordings from isolated dog,[16] rabbit,[17] pig,[18] and human[19] ventricular myocardium. Changes in MAP duration and configuration with different *basic* cycle lengths were due mainly to a change in plateau duration while the slope of phase 3 remained unaltered. This and the finding that the steady-state interval-duration relation of the MAP was closely linear over the physiologic range and flattened at long cycle lengths (Fig. 5) are also similar to previous, intracellular measurements from excised canine[20] and human ventricular muscle.[21]

Because the endocardium is rich in Purkinje fibers, it is possible that some recordings may be a composite of Purkinje and ventricular muscle fibers which mutually affect each other electronically. However, the cycle-length–dependent changes in MAP configuration shown in Figure 6 contrast with those reported for Purkinje fibers,[18] suggesting that these recordings represent mainly ventricular muscle activity.

Although the (relative) repolarization time course of the MAP appears to reflect that of intracellular measurements, the MAP does not contain information about the absolute magnitude of the transmembrane resting and action potential.[3] MAPs recorded with this technique from ventricular sites had amplitudes typically between 15 and 40 mV and, in contrast to intracellular measurements, were considerably smaller at atrial sites, rarely exceeding 10 mV. It is also important to note that the upstroke of the MAP signal has a lower rise velocity than do intracellular recordings and often shows shape irregularities (Fig. 2). These may result from the fact that the contact electrode is large and must record from a number of cells whose activity is somewhat dispersed in time and space. Irregularities in the upstroke of the MAP may also arise from nearby electrical activity associated with the excitation wave front.[3,15] Further distortion of the recordings may result from remote potentials (QRS complex and T wave) superimposed on the MAP. Such superimpositions are minimized by the close proximity of the recording electrodes and differential amplification (Fig. 4).

The extent to which the MAP reverses its polarity during activation has attracted much attention.[1–3,22–25] In suction electrode recordings the positive (systolic) potential is usually greater than the negative (diastolic) potential.[3,23,24] A lesser but still significant difference from intracellular measurements was found in our recordings in which the positive reversal was one third the total amplitude, regardless of the value of the latter or the site from which the recording was made. A similar and likewise uniform reversal ratio was described in an early analysis of MAPs which were also obtained by pressing an electrode onto the myocardial surface.[22]

Although this study in human subjects cannot define the exact mechanism underlying the genesis of the contact electrode MAP, the following theoretical concept conforms with the presented data. Pressure against the endocardium depolarizes a number of subendomyocardial cells to a degree that they no longer participate in regenerative depolarization and repolarization. During diastole, the local current flow resulting from the potential gradient between the depolarized area and the normal resting potential causes a negative potential at the recording site. During systole, the overshooting depolarization in normal cells reverses the potential gradient and thus the direction of current flow, and a positive potential is recorded. Under the existing volume conductor conditions,[15,26] the magnitude of local current flow, and therefore of the MAP, may be influenced by the number of cells depolarized by the tip electrode. In summary, the contact electrode likely creates an area of continuously diminished membrane potential which serves as a reference for the potential changes in adjacent cells. This reference need not be at zero potential, as cells affected by the electrode contact may maintain some resting potential, which may explain the observation that the reversal ratio of the MAP is greater than that in intracellular recordings.

The concept of the genesis of MAP just suggested herein explains why, in an area of scar, no MAPs could be recorded, but rather only remote electrical field changes generated by the entire heart, similar to an intracavitary electrogram (Fig. 7). Nonviable myocardium not only is devoid of a membrane potential but also is electrically uncoupled[27,28] and therefore cannot generate the current flow responsible for the MAP. However, electrical uncoupling and therefore the ability to record the extracellular potential may result from conditions other than cell death such as extremely high myoplasmic calcium concentration.[28]

Suction electrode recording requires sterile filling of the catheter with saline solution, manipulation with a suction pump, and other technical features[6] that make their clinical application cumbersome. More important, suction electrode catheters result in focal hemorrhage at the site of suction within a few minutes.[7] In contrast, no macroscopic damage to the subendocardium was seen in animal studies in which continuous contact electrode recording was performed for 30 minutes.[12,29] Furthermore, the stability of the contact electrode MAP over long recording periods may be considered indirect evidence that cellular alterations that lead to electrical uncoupling were minimal.

Thus, MAP recording by means of this specific method appears to be safe and can easily be performed during routine cardiac catheterization along with other electrophysiologic measurements and pharmacologic interventions.[30] A recent study in the animal model shows that MAPs recorded with this technique also provide a sensitive index of acute myocardial ischemia,[29] suggesting that endocardial MAP mapping may serve as a method not only for estimating normal cellular electrical activity but also for detecting electrophysiologically abnormal or nonviable myocardial areas.

Acknowledgment: I wish to express my deep gratitude to Dr. Jochen Schaefer, whose encouragement and support made this work possible, and to Dr. Michael Schöttler, whose skill in cardiac catheterization helped in many aspects of the study.

I am grateful to Dr. Myron L. Weisfeldt for his editorial advice. Barbara Bennemann is thanked for her dedicated technical assistance.

A PATIENT INFORMATION BOOK TO HELP REDUCE THE COMPLICATIONS OF HYPERTENSIO

The most comprehensive patient information book on hypertension today.

Learning to Live with Hypertension—the fourth in a unique series of patient information books—contains a detailed yet highly understandable discussion on the nature and treatment of hypertension.

Consulting physicians from major medical centers have pooled their expertise on hypertension and on communicating patient information to produce a work that encourages patient compliance with your prescription for controlling this disease. As part of your prescription, *Learning to Live with Hypertension* can contribute significantly to the adjustment of the hypertensive patient to his illness.

Pfizer *Learning to Live with Hypertension*
Valuable information for patient compliance.

Distributed as a public service by Pfizer.

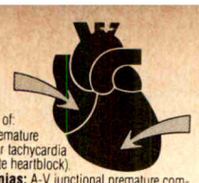
QUINAGLUTE®
(quinidine gluconate)
DURA-TABS®



INDICATIONS AND USAGE: Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of: **1. Ventricular arrhythmias:** Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock). **2. Junctional (nodal) arrhythmias:** A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).

CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.

WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine. 2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered. 3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring. 4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals. 5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity. 7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal. 8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.

Drug Interactions:

Drug	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.

Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.

Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.

ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea. Less frequently encountered adverse reactions:

Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.

Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.

Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.

Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.

Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

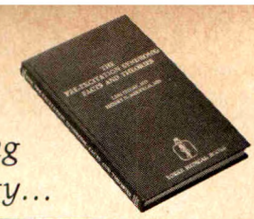
Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...



THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

Association of Hyponatremia With Increased Renin Activity in Chronic Congestive Heart Failure: Impact of Diuretic Therapy

GARY L. SCHAER, MD, ANDREW B. COVIT, MD, JOHN H. LARAGH, MD, and ROBERT J. CODY, MD

A correlation between hyponatremia and increased plasma renin activity (PRA) has been reported in patients with severe congestive heart failure (CHF), implying both clinical and pathophysiologic significance. To determine the impact of diuretic therapy on this relation, we evaluated the correlation of serum sodium, prerenal azotemia (blood urea nitrogen/creatinine ratio [BUN/Cr]), and PRA in 44 patients with severe CHF who were maintained on diuretic therapy. Serum sodium level was inversely related to PRA ($r = -0.389$, $p < 0.02$). However, a significant correlation also existed between the BUN/Cr ratio and PRA ($r = 0.365$, $p < 0.025$) and an inverse correlation between serum sodium level and the BUN/Cr ratio ($r = 0.332$, $p < 0.025$). Multiple regression analysis of the 3 variables yielded significant interdependence ($p < 0.01$). To evaluate the effect of diuretic therapy, 12 patients with severe CHF discontinued diuretic therapy and received, for 1 week each, 10 and 100 mEq sodium diets in balance studies. PRA ranged from 0.14 to 16 ng/ml/h. Despite this range, there was no significant correlation between either serum sodium or BUN/Cr ratio and PRA. It is concluded that the presence of marked hyponatremia and prerenal azotemia in patients with diuretic-treated CHF may suggest increased PRA. However, substantial patient-to-patient variability limits the predictive value of these correlations. Although some clinical value may be derived from such correlations, they should not be used to draw major inferences regarding the severity of CHF or the pathophysiology of water balance in CHF.

It is a well-established observation that hyponatremia commonly occurs in patients with chronic congestive heart failure (CHF) during periods of decompensation.[1] Proposed mechanisms for this observation include increased vasopressin secretion[2,3] and decreased delivery of sodium and water to the distal diluting segment of the nephron.[4] However, another possible explanation is the use of large-dose diuretic therapy in chronic CHF when sodium intake is restricted but free water intake is not. The clinical precedent for this has been described.[5,6] Recently, a significant inverse correlation has been reported between serum sodium levels and plasma renin activity (PRA) in patients with chronic CHF.[7,8] That is, as the serum sodium level decreases, PRA increases. It has been suggested that severe hyponatremia may be a marker of increased PRA in chronic CHF.[8] However, this observation has been made in the presence of diuretic therapy or shortly after its discontinuance. The correlation of hyponatremia and increased PRA is of potential clinical and pathophysiologic importance in patients with chronic CHF. Therefore, we assessed the influence of diuretic therapy on this correlation in a cohort of patients treated with diuretics and in a cohort of patients studied in formal metabolic sodium balance after discontinuation of diuretic therapy.

From the Cardiovascular Center, Departments of Medicine and Pharmacology, New York Hospital-Cornell University Medical College, New York, New York. This study was supported in part by general CRC Grant RR-47, from the National Institutes of Health, Bethesda, Maryland. Manuscript received January 5, 1983; revised manuscript received March 1, 1983, accepted March 4, 1983.

Address for reprints: Robert J. Cody, MD, Cardiovascular Center, Section J-3, New York Hospital-Cornell University Medical College, 525 East 68th Street, New York, New York 10021.

Methods

The study consisted of 44 patients, 37 men and 7 women aged from 20 to 79 years, with severe stable chronic CHF. Twenty-six had coronary and 18 had idiopathic etiologies of the CHF, and none had valvular disease or hypertension. The severity of the disease was manifested by functional class 3 or 4 (of 4) of the New York Heart Association classification in all patients and invasive hemodynamic studies indicating mean values for the group as follows: cardiac index, 1.70 ± 0.08 liters/min/m^2; pulmonary capillary wedge pressure, 23 ± 2 mm

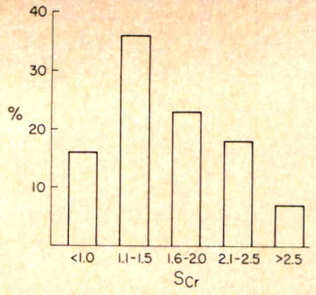

FIGURE 1. Distribution of serum creatinine levels (SCr) in the 44 patients with congestive heart failure receiving diuretics. The upper limit of normal is 1.4 mg/100 ml, and the number of patients is expressed as a percentage of total population studied.

Hg; and systemic vascular resistance, 1,958 ± 142 dynes s cm^{-5}. Exercise tolerance tests indicated marked reduction in exercise capacity in all patients. For this study, digoxin and diuretic therapy was maintained, but neither was administered in the 12 hours preceding the collection of blood samples. All patients were receiving furosemide in an average daily dosage of 97 ± 16 mg. In addition to furosemide, 13 patients were receiving a thiazide-like diuretic, 3 were receiving spironolactone, and 3 were receiving both a thiazide and spironolactone in addition to furosemide. All vasodilator drugs had been discontinued for at least 3 days before study. No overt primary glomerular disease was evident in any patient, suggesting that any renal insufficiency present was secondary to abnormalities produced by CHF. The range of serum creatinine values is shown in Figure 1.

In addition to the 44 patients receiving diuretics, 12 patients with similarly severe stable CHF (cardiac index, 2.08 ± 0.12 liters/min/m^2; pulmonary capillary wedge pressure, 23 ± 2 mm Hg; and systemic vascular resistance, 1,646 ± 71 dynes s cm^5) discontinued diuretic therapy at least 1 week. They then received 1 week each of a 10 and a 100 mEq sodium diet in balance studies. Total daily fluid intake was maintained at 2 liters and daily potassium was 60 to 80 mEq, held constant for each patient throughout the study. The only drugs maintained during this interval were digoxin in all patients and sodium warfarin when clinically indicated.

All blood samples were drawn in the morning, after overnight fast, in the supine position. Simultaneous blood samples were obtained for PRA, serum sodium, blood urea nitrogen (BUN), and serum creatinine (Cr). Plasma renin activity was estimated by radioimmunoassay of angiotensin I generated in vitro as previously reported from our laboratory,[9] and values were expressed as nanograms per milliliter per hour. In normal individuals, the normal range of PRA is based on a nomogram relating PRA to urinary sodium excretion. A normal range for this relation has not been established for patients with CHF. Serum sodium (mEq/liter), BUN (mg/dl), and serum Cr (mg/dl) were determined on a multichannel analyzer. As an index of prerenal azotemia, the BUN/Cr ratio was calculated for all patients.

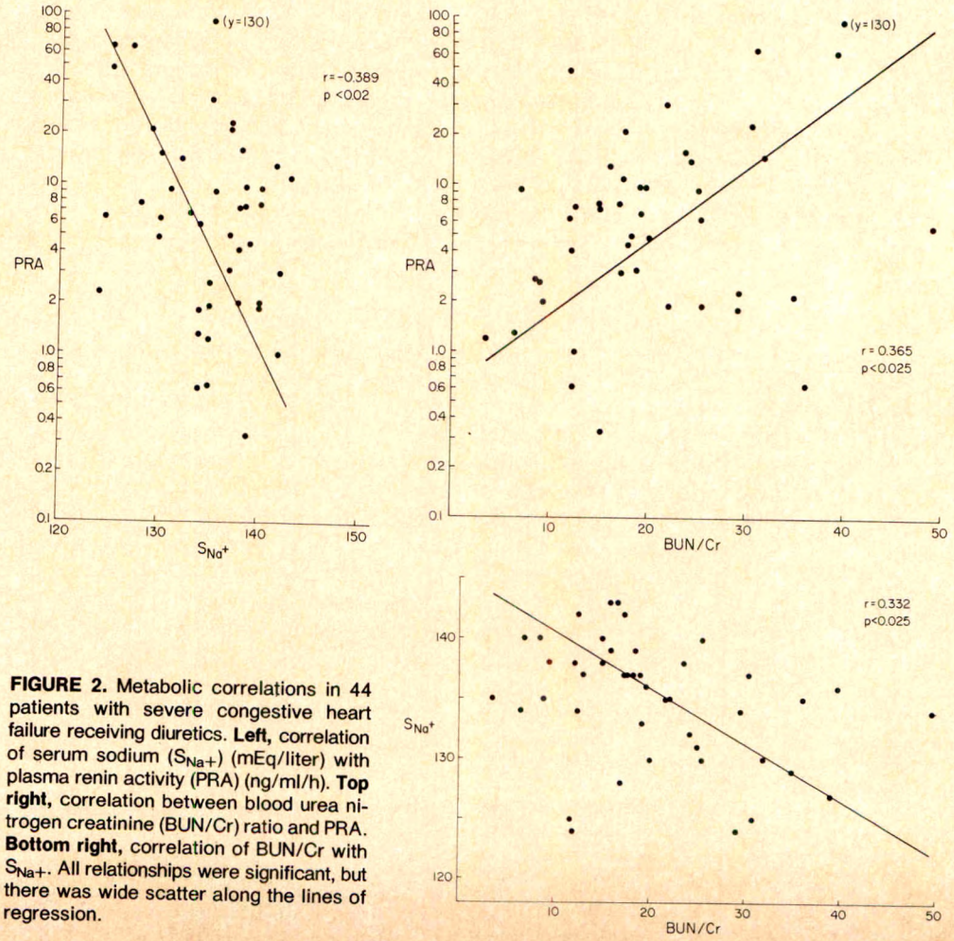

FIGURE 2. Metabolic correlations in 44 patients with severe congestive heart failure receiving diuretics. **Left,** correlation of serum sodium (S_{Na+}) (mEq/liter) with plasma renin activity (PRA) (ng/ml/h). **Top right,** correlation between blood urea nitrogen creatinine (BUN/Cr) ratio and PRA. **Bottom right,** correlation of BUN/Cr with S_{Na+}. All relationships were significant, but there was wide scatter along the lines of regression.

Linear regression analysis was used to determine the statistical significance of all correlations. As PRA is an exponential value, log transformation of this value was performed for the correlations. To assess the interrelation of PRA, serum sodium, and the BUN/Cr ratio in the 44 patients receiving diuretics, multiple linear regression analysis was used.

Results

The interrelation of serum sodium and PRA is shown in Figure 2, left. PRA ranged from 0.33 to 130 ng/ml/h. Serum sodium ranged from 124 to 146 mEq/liter. The correlation of these values was −0.389 ($p < 0.02$). However, there was wide scatter of values along the regression line, so that the index of determination was only 0.151. As prerenal azotemia is a reflection of decreased renal blood flow, a known stimulus for renin release, we then correlated the BUN/Cr ratio with baseline PRA (Fig. 2, top right). Despite similar wide scatter, the r value was 0.365, yielding statistical significance ($p < 0.025$). However, it was also clear that an inverse correlation of comparable significance was present when prerenal azotemia was correlated with serum sodium (Fig. 2, bottom right). Because of the implicit interrelation between hyponatremia, PRA, and prerenal azotemia, we then performed multiple linear regression analysis of these 3 variables, which resulted in a significance of $p < 0.01$, confirming this interrelation.

Because diuretic therapy could account for this interrelationship to a significant degree, we repeated the analysis in 12 patients with CHF who were not receiving diuretic therapy. To assess a wide range of values and the influence of sodium intake, each patient was studied on both 10 and 100 mEq sodium diets, thereby yielding 24 points of analysis (Fig. 3). For the group, PRA ranged from 0.14 to 16 ng/ml/h. Despite this 2-log range of PRA, 22 of 24 determinations of serum sodium were within a normal range of 135 to 145 mEq/liter, and 20 of 24 determinations of the BUN/Cr ratio were within a normal range of 8 to 20. As a result of this data clustering, there were no significant correlations of these 3 variables in the absence of diuretic therapy.

Discussion

Both Dzau et al[7] and Levine et al[8] reported an inverse correlation between serum sodium levels and PRA. However, Skorecki and Brenner[10] recently reemphasized that the attainment of sodium balance is of major importance in evaluating the renin-angiotensin system in CHF. In contrast to previous observations, we found that the hyponatremia-renin relation may be significantly influenced by diuretic therapy. Obviously, most patients with severe CHF are being treated with diuretics at the time of evaluation. Thus, such observations are useful clinically, if hyponatremia can identify a subgroup of patients with CHF with high PRA, as such patients are more likely to respond to converting enzyme inhibition.[11] In terms of pathophysiologic

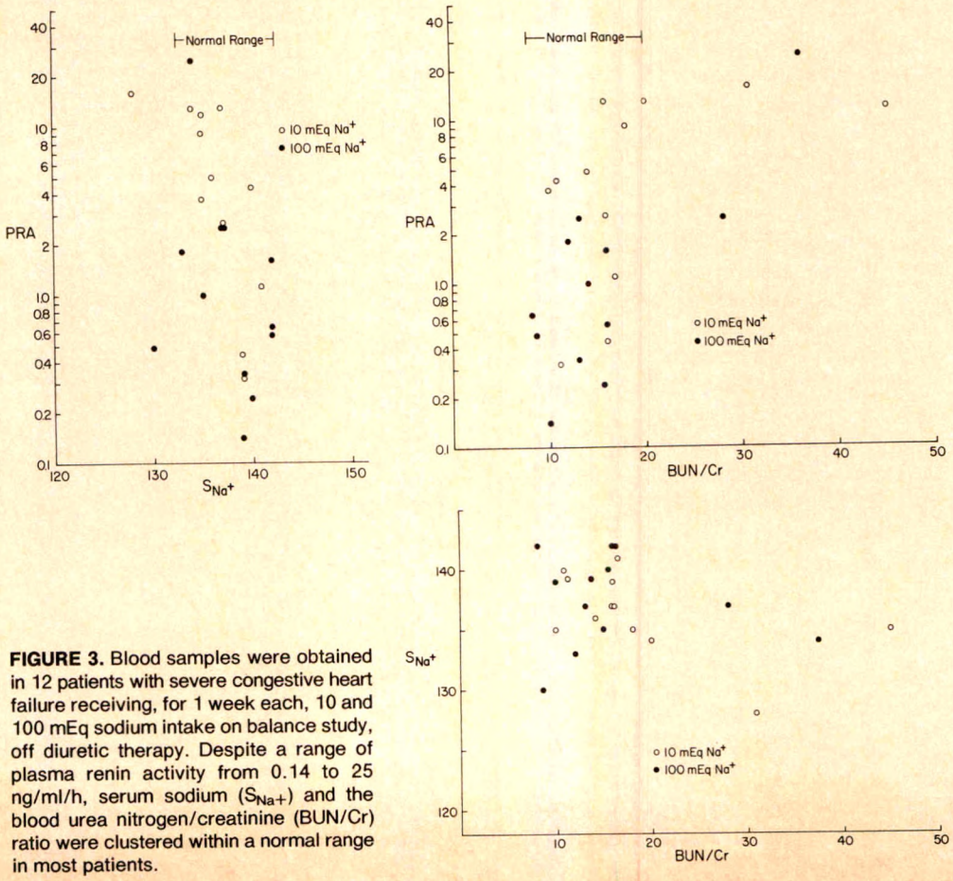

FIGURE 3. Blood samples were obtained in 12 patients with severe congestive heart failure receiving, for 1 week each, 10 and 100 mEq sodium intake on balance study, off diuretic therapy. Despite a range of plasma renin activity from 0.14 to 25 ng/ml/h, serum sodium (S_{Na+}) and the blood urea nitrogen/creatinine (BUN/Cr) ratio were clustered within a normal range in most patients.

mechanisms, the correlation of hyponatremia and increased PRA could be a manifestation of a previously reported direct angiotensin II-hypothalamic-vasopressin relation.[12]

However, classification of patients based on serum sodium[7,13] or inferences regarding vasopressin mediation of this hyponatremia,[2,8] in the setting of diuretic therapy may be an oversimplification. It is well documented that diuretic therapy, especially with the potent loop agents, can cause marked hyponatremia and prerenal azotemia,[14,15] and their hyponatremic stimulus will be even more accentuated when free water intake is not limited.[5] In CHF, diuretic therapy[16] and, for that matter, rigid sodium restriction[17] are capable of stimulating the renin-angiotensin-aldosterone axis. Additionally, through volume-depleting effects, diuretics will stimulate vasopressin secretion directly.[18] Thus, diuretic therapy by itself appears to be in a perfect position to govern the interrelation of serum sodium, prerenal azotemia, and PRA. In fact, when diuretics were discontinued and sodium and water intake was controlled, our results showed no correlation between either serum sodium or prerenal azotemia and PRA. Preliminary studies[19,20] show a lack of correlation between hyponatremia and vasopressin in patients with CHF not taking diuretics. However, a good correlation occurs between vasopressin levels and PRA.

On the basis of the present data, we would draw several conclusions. In patients with severe stable chronic CHF receiving diuretic therapy, the presence of hyponatremia and prerenal azotemia suggests that increased PRA may be evident; however, wide patient-to-patient variation of the hyperreninemia may occur. This relation may be useful in choosing a specific vasodilator, such as a converting-enzyme inhibitor to block the renin-angiotensin system, as this class of drugs yields its greatest hemodynamic improvement in the presence of increased renin-angiotensin system activity. Other vasodilators may actually increase PRA and angiotensin-induced vasoconstriction.[21] Also, this interrelation may identify those patients with high PRA in whom diuretic therapy should be decreased before administration of converting-enzyme inhibitor to avoid excessive hypotension.[22] However, in terms of pathophysiologic mechanisms hyponatremia during diuretic therapy should not be used as a marker of hormonal activity or disease severity in CHF.

Respiratory Gas Analysis During Exercise as a Noninvasive Measure of Lactate Concentration in Chronic Congestive Heart Failure

JOHN R. WILSON, MD, NANCY FERRARO, RN, and KARL T. WEBER, MD

Measurement of blood lactate during exercise in patients with chronic congestive heart failure provides a useful index of oxygen (O_2) availability in working muscle. Bicarbonate buffering of lactate produces carbon dioxide (CO_2) in excess of that resulting from oxidative metabolism. Therefore, calculation of excess CO_2 production from measured CO_2 production and O_2 uptake may offer a noninvasive quantitative index of changes in blood lactate during exercise in these patients. To investigate this possibility, 22 patients with congestive heart failure and depressed left ventricular function were studied during progressive maximal upright bicycle exercise. Oxygen uptake, expired carbon dioxide, arterial lactate, O_2 extraction, and cardiac output were measured at each 20 W incremental work load and peak exercise. Exercise increased $\dot{V}O_2$ from 3.5 ± 0.9 ml/min/kg at rest to 13.1 ± 2.9 ml/min/kg, O_2 extraction from 49 ± 9% at rest to 78 ± 6%, lactate from 12 ± 5 mg/dl at rest to 41 ± 15 mg/dl, and cardiac index from 1.7 ± 0.4 at rest to 3.8 ± 1.2 liters/min/m^2. The increase in lactate at each work load was linearly related to excess CO_2 production ($r = 0.92$, $p < 0.01$). Exercise was repeated the following day in 10 patients; measurements of excess CO_2 production was highly reproducible ($r = 0.98$, $p < 0.01$). Excess CO_2 production also correlated with the decrease in bicarbonate produced by exercise ($r = 0.81$), supporting the hypothesis that excess CO_2 is produced by bicarbonate buffering of lactate. Thus, calculation of excess carbon dioxide production from noninvasive measurement of respiratory gas exchange provides a reliable and reproducible method of continuously assessing alterations in lactate throughout bicycle exercise in patients with chronic congestive heart failure.

Patients with chronic congestive heart failure have a reduced aerobic exercise capacity[1–3] due to inadequate oxygen (O_2) transport to working skeletal muscle.[3–7] This impairment in O_2 transport causes working muscle to become anaerobic and to produce lactate,[3–7] with the onset and degree of lactate production being proportional to the degree of muscle underperfusion.[3,8,9] Therefore, measurement of lactate during exercise in patients with congestive heart failure provides a simple method of assessing skeletal muscle O_2 availability[5,10–13] and of grading the severity of chronic congestive heart failure.[3] Measurements of lactate for these purposes has not become widely used, however, due to the inconvenience of obtaining and assaying blood lactate levels.

Lactate released during exercise is buffered by bicarbonate, producing carbon dioxide (CO_2) in excess of that resulting from oxidative metabolism.[14–16] Theoretically, this excess CO_2 is equivalent to the difference between total expired CO_2 ($\dot{V}CO_2$) and the amount of CO_2 produced by aerobic metabolic processes.[14] Aerobic CO_2 production can be estimated by multiplying the O_2 uptake ($\dot{V}O_2$) by an estimated metabolic respiratory quotient such as 0.75.[14] Combining these 2 equations, excess CO_2 production can be estimated as $\dot{V}CO_2 - (0.75 \times \dot{V}O_2)$. This value can be calculated on a minute-by-minute basis. Therefore, this approach potentially offers a noninvasive method of describing lactate concentrations throughout exercise in patients with heart failure.

Accordingly, the present study was undertaken to determine whether the calculation of excess CO_2 production during progressive upright bicycle exercise is a reliable and reproducible measure of lactate concentration during exercise in patients with congestive heart failure. An additional objective of this study was to determine whether respiratory gas analysis, previously utilized by us to evaluate the onset of anaerobic metabolism during treadmill exercise in patients with congestive heart failure,[3] can also be utilized to assess anaerobic activity during bicycle exercise.

Methods

Patients: Twenty-two patients with chronic left ventricular dysfunction (mean ejection fraction 26 ± 10%, range 11 to 40) were studied. The mean age was 55 ± 7 years; there were 20 men and 2 women. All patients were limited by dyspnea, fa-

tigue, or both during exercise despite administration of digoxin and diuretics and had no peripheral edema or ascites at the time of study. All patients had a decrease in peak $\dot{V}O_2$ (mean 13.1 ± 2.9 ml/min/kg) below the expected normal response (≥25 ml/min/kg).[17,18] Left ventricular dysfunction was attributed to coronary heart disease in 9 patients and to idiopathic dilated cardiomyopathy in 13.

Protocol: On the day before study, a trial maximal exercise test was performed. Exercise was performed on an upright bicycle ergometer (Monarch) and begun at a work load of 20 W. Every 3 minutes, the work load was increased by 20 W to symptomatic maximum. All exercise tests were performed at least 4 hours after meals.

The following morning, a Swan-Ganz catheter and radial arterial catheter were inserted. Thirty minutes later, maximal exercise testing was performed. Respiratory gases were measured for 5 to 10 minutes with patients at upright rest and throughout exercise. Pulmonary artery and wedge pressure recordings and pulmonary artery and arterial blood samples for O_2 saturation and lactate concentration were obtained at rest, 2 to 3 minutes into each stage of exercise, and at maximal exercise. Arterial blood samples for pH, partial pressure of carbon dioxide (pCO_2), and partial pressure of oxygen (pO_2) were also obtained at rest and at maximal exercise in 11 patients. Maximal exercise testing with respiratory gas analysis was repeated the following day in 10 patients to evaluate their reproducibility.

Measured variables: Minute oxygen consumption ($\dot{V}O_2$; milliliters per minute), minute carbon dioxide production ($\dot{V}CO_2$; milliliters per minute), and minute ventilation ($\dot{V}_E$; liters per minute) were measured with a Beckman Metabolic Cart equipped with O_2 and CO_2 analyzers (OM-11 and LB-2, respectively) and a turbine volume transducer. The respiratory gas exchange ratio was calculated as $\dot{V}CO_2/\dot{V}O_2$. Excess CO_2 was calculated every 30 seconds as ($\dot{V}CO_2 - 0.75 \cdot \dot{V}O_2$), using the $\dot{V}CO_2$ and $\dot{V}O_2$ measured during the previous 30 seconds. The metabolic respiratory quotient was arbitrarily chosen to be 0.75 as suggested by Issekutz and Rohdahl.[14] In addition, excess CO_2 was calculated using the measured resting respiratory gas exchange ratio, an estimate of the actual metabolic respiratory quotient, instead of 0.75. Excess CO_2 was expressed as milliliters produced per minute.

Arterial blood samples for lactate determination were deproteinized with cold perchloric acid and assayed with a spectrophotometric technique (normal 3 to 12 mg/dl).[19] Hemoglobin concentration was measured by Coulter Counter. Hemoglobin O_2 saturation was measured with a co-oximeter (Instrumentation Laboratories) precalibrated with human blood. Blood O_2 content was calculated as the product of hemoglobin, 1.34 ml O_2/g hemoglobin, and percent O_2 saturation. O_2 extraction was calculated as the ratio of the arteriovenous O_2 difference and arterial O_2 content. Cardiac output was calculated from the Fick principle as $\dot{V}O_2$/arteriovenous O_2 difference. Arterial blood gas samples were analyzed by a blood gas analyzer (Corning 168); bicarbonate concentration was calculated from pH and pCO_2 using a nomogram.

Statistical methods: All values are expressed as mean ± standard deviation. Linear regression analysis was performed using the method of least squares. A probability of <0.05 was considered significant.

Results

Results are summarized in Tables I and II and Figures 1 to 3. The resting cardiac index of the patients was 1.7 ± 0.4 liters/min/m^2 and the resting pulmonary wedge pressure was 20 ± 10 mm Hg.

Exercise hemodynamic findings: On the average, patients exercised for 6.8 ± 2.4 minutes (range 3 to 13) to a peak work load of 51 ± 18 W (range 20 to 100). At peak exercise, $\dot{V}O_2$ had increased from 3.5 ± 0.9 ml/min/kg at rest to 13.1 ± 2.9 ml/min/kg, while heart rate increased from resting levels of 88 ± 12 to 130 ± 17 beats/min. Cardiac index increased modestly from 1.7 ± 0.4 liters/min/m^2 at rest to 3.8 ± 1.2 liters/min/m^2; the pulmonary wedge pressure increased from resting values of 20 ± 10 to 35 ± 12 mm Hg.

Metabolic responses and respiratory gas analysis: Percent O_2 extraction was 49 ± 9% at rest and increased to 78 ± 6% at peak exercise with all but 1 patient exceeding 70% extraction. Arterial lactate concentration increased from 12 ± 5 to 41 ± 15 mg/100 ml ($p < 0.001$), the mean increase being 30 ± 15 mg/100 ml with all patients exhibiting increases >10 mg/100 ml.

Exercise resulted in a peak excess CO_2 production rate of 336 ± 176 ml/min when calculated using an assumed metabolic respiratory quotient of 0.75 and of 303 ± 155 ml/min when calculated using the measured resting respiratory gas exchange ratio of 0.79 ± 0.80.

Exercise increased the respiratory gas exchange ratio from 0.79 ± 0.80 at rest to 1.10 ± 0.13.

Dynamic changes in arterial lactate concentration and respiratory gas exchange are illustrated for 2 different patients in Figure 1. Up to 20 to 40% of peak $\dot{V}O_2$, $\dot{V}CO_2$, and $\dot{V}_E$ increased in proportion to $\dot{V}O_2$ while the respiratory gas exchange ratio remained stable; there was no excess CO_2 produced, and lactate did not increase. Subsequently, at ≥50% of the peak $\dot{V}O_2$, there was a progressive increase in the respiratory gas exchange ratio, excess CO_2, and lactate.

The increase in arterial lactate concentration measured at the end of each stage of exercise was linearly related to the production rate of excess CO_2 calculated from the respiratory gases obtained during the same time period. This was the case both when the excess CO_2

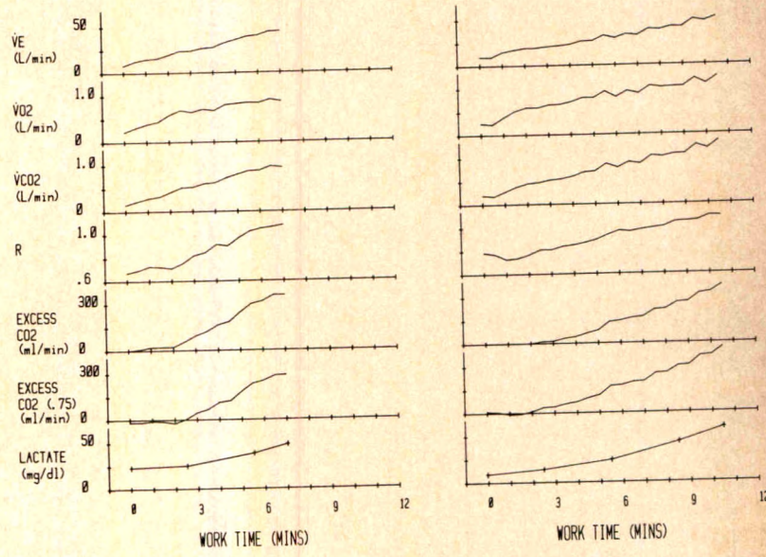

FIGURE 1. Respiratory gas exchange variables during an incremental bicycle exercise test in 2 patients with heart failure. Changes in arterial lactate paralleled changes in excess CO_2 and the respiratory gas exchange ratio (R). Excess CO_2 was calculated using the measured R and an assumed metabolic respiratory quotient of 0.75 (excess CO_2 [0.75]). Respiratory gas measurements were calculated every 30 seconds and the points connected.

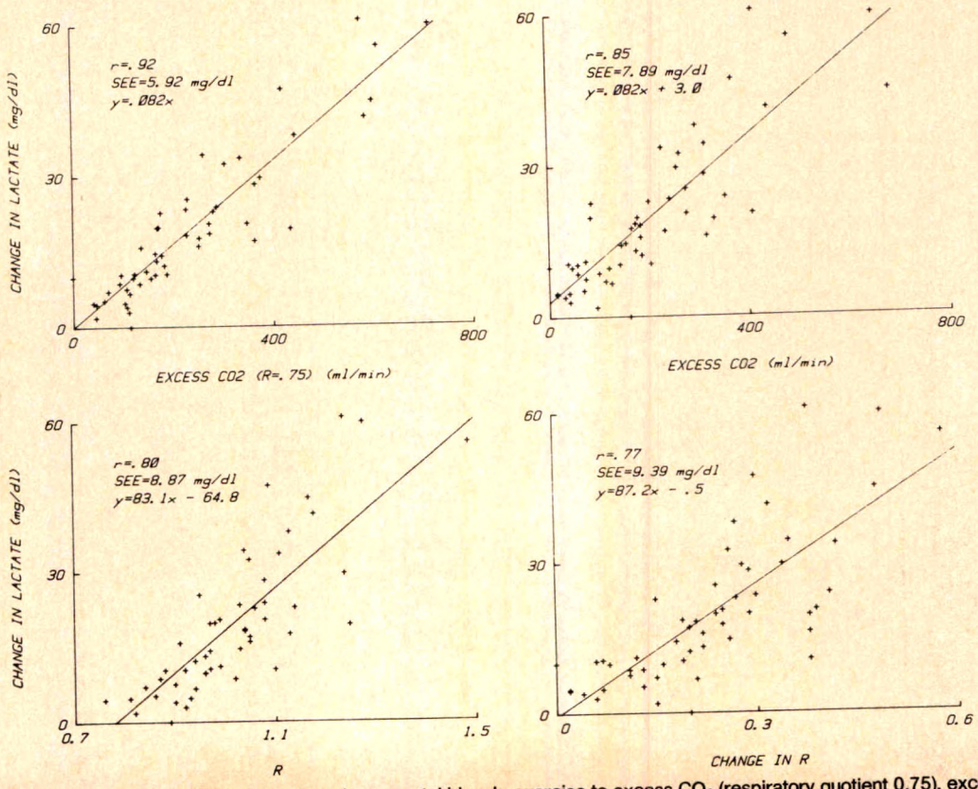

FIGURE 2. Relation of changes in arterial lactate during incremental bicycle exercise to excess CO_2 (respiratory quotient 0.75), excess CO_2 calculated using the measured resting R, R, and changes in R. Measurements were made at the end of each work load and at peak exercise in 22 patients with heart failure.

production rate was calculated using a metabolic respiratory quotient of 0.75 ($r = 0.92$, $p < 0.01$, $n = 54$) (Fig. 2) and when it was calculated using the resting respiratory gas exchange ratio as an estimate of the metabolic quotient ($r = 0.85$, $p < 0.01$, $n = 54$) (Fig. 2).

These relationships were not affected by the resting lactate concentration. In 5 of the patients, lactate levels ≥12 mg/dl were observed at rest. Excess CO_2 correlated closely with changes in lactate in all 5 of these patients. The elevated resting lactate levels were not associated with markedly impaired exercise capacity and therefore may have been due to hyperventilation during or after instrumentations; respiratory alkalosis is known to increase arterial lactate concentrations.[20,21]

The increase in lactate concentration during exercise correlated less well with the respiratory gas exchange ratio ($r = 0.80$, $p < 0.01$, $n = 54$) and with the change in this ratio ($r = 0.77$, $p < 0.01$, $n = 54$) (Fig. 2). This is to be expected since the effect which a given level of anaerobic CO_2 production has on the respiratory gas exchange ratio depends on the corresponding $\dot{V}O_2$.

Relation between bicarbonate and respiratory variables: The effect of maximal exercise on arterial blood gases and calculated bicarbonate is shown in Table II. Maximal exercise had no effect on pH (rest 7.48 ± 0.03 versus exercise 7.47 ± 0.06), but reduced the arterial pCO_2 (rest 32 ± 5 mm Hg versus exercise 27 ± 4 mm Hg; $p < 0.01$) and bicarbonate (rest 23.5 ± 3.0 mEq/liter versus exercise 19.8 ± 1.8 mEq/liter; $p < 0.01$).

At maximal exercise, the decrease in bicarbonate correlated with the minute production rate of excess CO_2 calculated using a metabolic respiratory quotient of 0.75 ($n = 11$, $r = 0.81$, $p < 0.01$) (Fig. 3) and with the minute production rate of excess CO_2 calculated using the measured resting respiratory gas exchange ratio ($r = 0.72$, $p < 0.01$).

Reproducibility: Respiratory gas measurements during maximal exercise were repeated in 10 patients. Temporal changes in ventilatory parameters were comparable to those noted during the first exercise test. The peak exercise $\dot{V}O_2$ varied by only 5 ± 6%, whereas the maximal exercise duration varied by 13 ± 8%. There was a close correlation between the excess CO_2 calculated using a metabolic respiratory quotient of 0.75 measured during test 1 and test 2 when these 2 measurements were compared at the end of identical work loads ($r = 0.98$, $p < 0.01$, $n = 21$). There was also a close relationship between respiratory gas exchange ratios measured at identical work loads ($r = 0.86$, $p < 0.01$, $n = 21$). Duplicate measurements of excess CO_2 calculated using the measured resting gas exchange ratio correlated less well ($r = 0.76$, $p < 0.01$, $n = 21$), primarily due to variations in the resting exchange ratio.

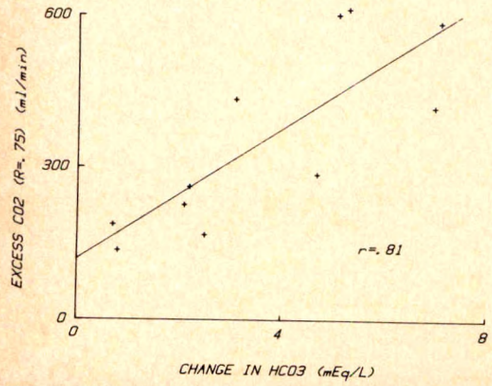

FIGURE 3. Relation of total changes in arterial bicarbonate concentration during incremental bicycle exercise to peak excess CO_2 (respiratory quotient = 0.75) in 11 patients with heart failure.

Discussion

Recently, it has been demonstrated that respiratory gas analysis can be used to identify noninvasively the onset of lactate production or the anaerobic threshold during treadmill exercise in patients with chronic heart failure.[3] This approach involves detection of the point at which a disproportionate rise in $\dot{V}CO_2$ occurs relative to $\dot{V}O_2$ and therefore is based on detecting the onset of bicarbonate-buffering of lactate and release of excess CO_2.[3,14,15] This technique does not, however, describe the rate of increase in lactate during exercise, a parameter which may correlate with the extent and severity of anaerobic activity. Moreover, the anaerobic threshold is identified by noting relatively subtle changes in respiratory gas exchange that may be difficult to identify precisely. A more complete and reliable description of anaerobic metabolic activity throughout exercise would therefore be desirable.

Respiratory gas analysis of arterial lactate: The results of the present study suggest that calculation of the rate of excess CO_2 production at any given point during exercise correlates closely and reproducibly with the total increase in arterial lactate which has occurred. This approach therefore provides a noninvasive method of continuously assessing alterations in lactate throughout exercise. The best correlation was noted when excess CO_2 was calculated based on an assumed metabolic respiratory quotient of 0.75. Calculation of excess CO_2 using this approach was also found to be most reproducible. The excess CO_2 calculated using the measured basal respiratory gas exchange ratio correlated somewhat less closely with changes in lactate and was less reproducible. This lower correlation and reproducibility was primarily due to hyperventilation-induced elevations in the basal respiratory gas exchange ratio in several patients, either at the initial study or when restudied. Thus, a major advantage of using an assumed metabolic respiratory quotient is that the presence of resting hyperventilation does not influence the calculation of excess CO_2 during exercise.

These findings are consistent with prior studies in normal subjects and patients with mitral stenosis. In 26 untrained normal subjects, Issekutz and Rohdahl[14] observed a close correlation ($r = 0.92$, $n = 102$) between changes in lactate during exercise and the minute production of excess CO_2 calculated using a respiratory quotient of 0.75. Naimark et al[15] reported similar results in 19 normal subjects and in 10 patients with mitral stenosis or primary pulmonary hypertension. Using a

breath-by-breath technique to measure the respiratory gas exchange ratio, they reported that changes in this ratio and in excess CO_2 parallel changes in lactate and bicarbonate.

Mechanism of excess CO_2 production: The close relationship noted between excess CO_2 and changes in both lactate and bicarbonate suggest that the excess CO_2 was primarily produced by bicarbonate buffering of lactic acid. However, several other factors may also have influenced CO_2 production to a lesser extent. Hyperventilation can produce a decrease in arterial pCO_2 and consequent transient release of stored CO_2. The arterial pCO_2 dropped slightly during exercise in our patients, suggesting that hyperventilation was present. However, the decrease in pCO_2 was relatively small and similar to the response noted in normal subjects during exercise.[22] Exercise-induced changes in substrate utilization by aerobic metabolic pathways could also alter excess CO_2 production. However, major changes in substrate utilization do not appear to occur during exercise.[14,15] Increases in blood temperature during exercise[23] could release small amounts of CO_2 due to the effect of temperature on blood pH. Finally, it has been suggested that marked increases in mixed venous pCO_2 during exercise may cause some release on CO_2 from storage sites.[24]

Potential limitation: This study examined the relationship between the rate of excess CO_2 production and changes in arterial lactate concentration during progressive bicycle exercise. Whether the same relationship is present using a different bicycle exercise protocol, another form of exercise, or after a major therapeutic intervention remains to be determined. In addition, the initial 20 W work load used in our protocol may cause immediate lactate production in patients with severe functional impairment. In such patients, identification of the anaerobic threshold is therefore not possible using our protocol, although characterization of the rate of lactate release still is possible using calculation of excess CO_2. In such patients, use of an exercise protocol which involves a more gradual increase in work load may be desirable.

Clinical implications: This study suggests that measurement of excess CO_2 using a metabolic respiratory quotient of 0.75 provides a reliable and reproducible index of changes in arterial lactate concentration during bicycle exercise in patients with chronic congestive heart failure. This method therefore can be used to examine the rate of lactate accumulation during exercise as well as the onset of anaerobic metabolic activity. A more complete description of anaerobic metabolism during exercise than simply identifying the onset of the anaerobic threshold is thereby provided.

This characterization of anaerobic metabolic activity during exercise can be used to grade the severity of chronic heart failure. With increasingly impaired cardiovascular function during exercise, $\dot{V}O_2$ maximal is reduced and anaerobic metabolism therefore commences earlier in exercise and at a lower level of $\dot{V}O_2$.[3,16] Documentation of the pattern of anaerobic metabolic activity during exercise therefore helps to confirm that $\dot{V}O_2$ maximal is reduced. Moreover, demonstration of an accelerated pattern of lactate accumulation during exercise can be used to identify impaired O_2 transport to working muscle in patients who are unwilling or unable to achieve their maximal $\dot{V}O_2$.

In addition, this method may be useful in evaluating the effects of therapeutic regimens on O_2 delivery to exercising muscle. Inadequate O_2 availability to working muscle increases blood lactate concentration.[3,5–7] Consequently, improved skeletal muscle O_2 availability should be associated with a delayed anaerobic threshold, a lower rate of lactate accumulation, or both after attainment of the anaerobic threshold. These changes should in turn be detectable as a reduction in excess CO_2 for any given work load.

Conduction Disturbances Related to the Site and Severity of Mitral Anular Calcification: A 2-Dimensional Echocardiographic and Electrocardiographic Correlative Study

TOSHIHIKO TAKAMOTO, MD and RICHARD L. POPP, MD

To investigate an apparent association of mitral anular calcium (MAC) and electrocardiographic abnormalities, the relation between location of 2-dimensional (2-D) echo-quantified MAC and conduction disturbances was studied in 140 patients with MAC (MAC group) and in 135 age- and sex-matched patients without MAC (control group). The MAC group was subclassified regarding site and severity of calcium in the mitral anulus. The site of MAC was defined as Type I, near the primary conduction system—MAC located in the medial segment and/or extending to the anterior mitral leaflet; and Type II—MAC located at the central and/or lateral segments away from the primary conduction system. The severity of MAC was graded on 2-D echocardiography as mild (localized within 1 segment) and moderate to severe (>1 segment).

Seven patients with MAC, and only 1 control subject, had pacemakers in place. Conduction disturbances were present in 44 (31%) of 140 patients with MAC, and in 37 (27%) of 135 control patients (difference not significant). But there were more conduction disturbances in patients with Type I MAC (53%) than in those with Type II MAC (26%) ($p < 0.01$). Specifically, complete left bundle branch block and intraventricular conduction delay were more prevalent when MAC was near the conduction system. Conduction disturbances also were more prevalent in patients with Type I MAC than in the control group: intraventricular conduction delay (Type I, 12% versus control, 4%; $p < 0.05$) and total conduction disturbances (53 versus 28%; $p < 0.01$). These data suggest that moderate to severe degrees of MAC located near the conduction system are associated with conduction disturbances, especially intraventricular conduction delay.

Mitral anular calcium (MAC) or fibrosis is considered a consequence of aging and has long been associated with conduction disturbances in elderly people. Since the early 20th century, the relation between MAC and conduction disturbances has been reported in autopsy studies.[1,2] Several articles[3–7] have demonstrated the use of echocardiography in the diagnosis of MAC, underlying tissue degeneration, fibrosis, and calcium in the area of the conduction system. Most of these studies were performed with only M-mode echocardiographic analysis or with small numbers of patients, or both. The goal of this investigation was (1) comparison of the occurrence of conduction disturbances in patients with and without MAC, and (2) observation of the echocardiographic site and severity of MAC relative to associated conduction disturbances.

Although the sensitivity and specificity of echo-quantified MAC have not been well established, there is evidence that echocardiography is a sensitive tool for the detection of MAC in comparison with chest roentgenography and fluoroscopy.[3–8]

Methods

Patient selection: One hundred-forty patients with MAC and 135 age- and sex-matched subjects without MAC (control group) were studied. The patients with MAC were identified from the echocardiographic records in the Computerized Patient Data Bank of our Cardiology Division indexed between January 1980 and May 1982. Age- and sex-matched control patients with suspected cardiac disease but no evidence of echocardiographic MAC were similarly selected. We excluded patients with recent myocardial infarction, a prosthetic mitral valve, and those with a technically limited study. Conduction disturbance in the setting of infarction is a special

consideration and patients with a prosthetic mitral valve were excluded because of the difficulties in distinguishing the dense echoes of MAC from reverberation echoes of the valve ring or stents. Recognition of associated heart disease in patients of the 2 groups was obtained from the patient data bank containing complete echocardiographic diagnostic categories based on the criteria reported previously.[9] Additionally, coronary artery disease was diagnosed if regional left ventricular wall motion abnormalities were seen by echocardiography or if there was evidence of old myocardial infarction (abnormal Q wave, coronary T wave with reciprocal ST-T change) by electrocardiography.

Echocardiographic measurements: M-mode and 2-D echocardiographic studies in the MAC group were reviewed systematically by 2 observers. Echocardiographic images were obtained with a Hewlett-Packard model 77020A, Toshiba SSH-10A, or Irex System III ultrasound imaging system utilizing a 2.25 MHz or 3.5 MHz medium focused transducer. M-mode echocardiograms were derived from the 2-D instrument and were recorded on a strip chart.

Our M-mode echocardiographic criteria for MAC are the standard criteria which have been published by others.[5–7] These criteria consist of dense echoes, more than 3 mm thick, behind the posterior mitral leaflet and anterior to the left ventricular wall endocardium, moving parallel to the left ventricular posterior wall. Two-dimensional echocardiographic criteria for MAC include (1) an intense echo-producing structure located at the junction of the atrioventricular groove and posterior mitral leaflet, on long-axis view, and (2) an echo-dense structure posterior to the posterior mitral leaflet on short-axis view.

We routinely recorded 2-D echocardiographic parasternal long- and short-axis views, midprecordial long- and short-axis views, apical long-axis and 4-chamber views, and subcostal long- and short-axis views.[10] For the assessment of MAC, we particularly focused our attention on the parasternal short-axis view just above the mitral leaflet level, obtained by scanning from the aortic root toward the mitral leaflet. To record the location and extension of MAC, we prepared a diagram of the mitral anulus viewed in the short-axis view (Fig. 1). The 4 labelled segments were referenced to the posteromedial, central, and anterolateral portions of the posterior mitral anulus and the basal portion of the anterior mitral leaflet. The patients with MAC were subclassified into 2 types: Type I, near the primary conduction system (Fig. 2)—MAC located in the medial segment and/or extending to the anterior mitral leaflet; and Type II—MAC located at the central and/or lateral segments away from the primary conduction system. The degree of severity of MAC was determined both by M-mode and 2-D echocardiography. M-mode echocardiographic thickness criteria were mild (3 to 5 mm), moderate (6 to 7 mm), and severe (≥8 mm). Two-dimensional echocardiographic extent criteria were: mild (localized within 1 segment), moderate (present in 2 segments), and severe (3 or all 4 segments).

All of the 2-D echocardiographic studies had diagnostic image quality for analysis. Real-time, slow motion, and frame-by-frame analysis were carried out on an off-line video analysis system. Extended bright echoes from the calcific aortic valve and sclerotic aortic root wall may mask the presence of calcification at the basal portion of the anterior mitral leaflet. To avoid these possible errors, we carefully observed the 2-D parasternal short-axis view throughout scanning from the mitral leaflet toward the aortic valve. In the case of discordant readings regarding the location of MAC, 2-D images were reviewed and a decision was made by consensus. M-mode echocardiographic evaluation of severity of MAC was available in 130 of 140 patients, but M-mode echocardiograms were not recorded in 10 patients with limited parasternal ultrasonic window.

Electrocardiographic studies: A standard 12-lead electrocardiogram recorded within 2 weeks of the echocardiographic examination was analyzed. The clinical history and electrocardiographic indications for pacemaker placement were reviewed from the medical records of 8 patients with pacemaker implantation before echocardiography. Electrophysiologic data were not available uniformly and therefore were not included. Electrocardiographic abnormalities were categorized as arrhythmias, conduction disturbances, and other findings (sinus bradycardia, prolonged Q-T interval).

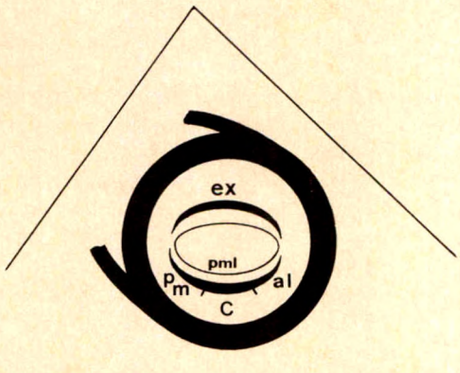

FIGURE 1. Diagram of the mitral anulus, viewed in the short-axis view, used for localization of anular calcification. The segments are referenced to the posteromedial (pm), central (C), and anterolateral (al) portions of the posterior mitral anulus and the basal portion of the anterior mitral leaflet. pml = posterior mitral leaflet; ex = extended calcification.

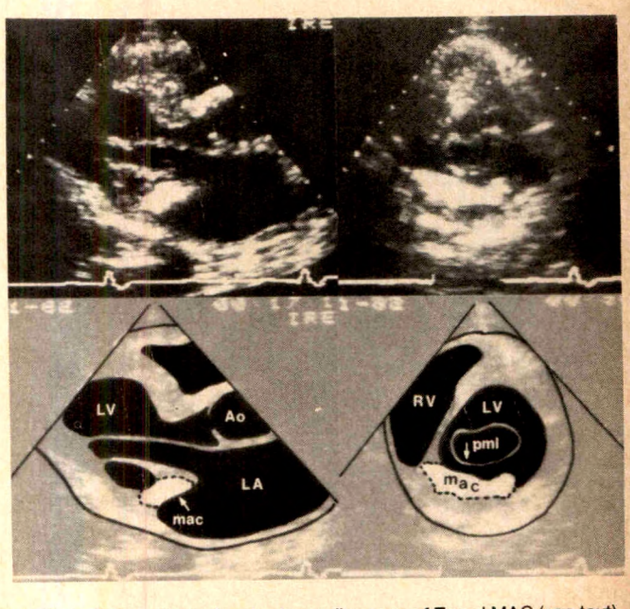

FIGURE 2. Two-dimensional echocardiograms of Type I MAC (see text). In the parasternal long-axis view (**left panels**), dense echoes representing MAC are noted (**arrow**) between the base of the posterior mitral leaflet (pml) and the posterior junction of the left atrium (LA) and left ventricle (LV). Note the medial extension of these bright echoes (MAC) toward the base of the interventricular septum on the short-axis view (**right panels**). Ao = aorta; RV = right ventricle.

TABLE I Patient Characteristics

Cardiac Condition	MAC Group (n = 140) n	%	Control Group (n = 135) n	%
Aortic stenosis or aortic stenosis with regurgitation	39	28	11	8
Coronary artery disease	17	12	30	22
Dilated cardiomyopathy	15	11	17	13
Rheumatic mitral valve disease	8	6	8	6
Aortic regurgitation	4	3	14	10
Hypertrophic cardiomyopathy	3	2	0	0
Mitral valve prolapse	2	1	8	6
Congenital heart disease	1	1	0	0
Total	89	64	88	65

Arrhythmias included atrial fibrillation, atrial flutter, and atrial or ventricular tachyarrhythmias. Conduction disturbances included atrioventricular block, right or left bundle branch block, and intraventricular conduction delay. Fascicular block was categorized by the criteria proposed by Rosenbaum et al.[11] Intraventricular conduction delay was diagnosed in the presence of a QRS duration of >120 ms when the pattern was not typical of either right or left bundle branch block. Bradycardia was defined as <50 beats/min.

Statistical analysis: Statistical analysis for the group comparison was done using the chi-square test.

Results

Patient characteristics: Ninety of the 140 patients (64%) with MAC were women and 50 patients (36%) were men. The control group consisted of 86 (64%) women and 49 men (36%). The ages of the patients with MAC ranged from 27 to 92 years (70 ± 13, mean ± standard deviation) and the ages of the patients without MAC ranged from 40 to 93 years (69 ± 11). In the MAC group, the patients had a much higher incidence of calcified aortic valve with restricted leaflet motion consistent with aortic stenosis, aortic regurgitation, or both, but had a lower incidence of coronary artery disease than the control group. Other associated heart disease was seen with similar incidence in the 2 groups (Table I).

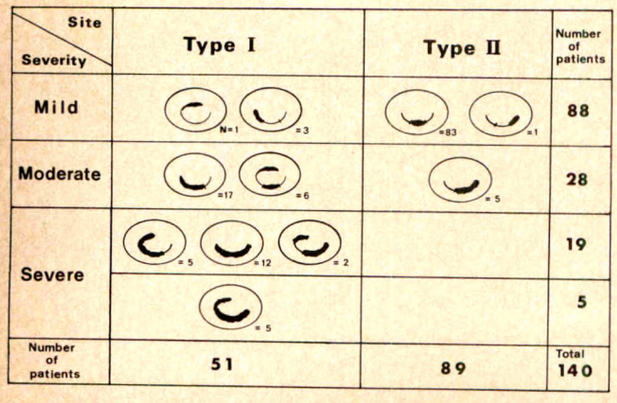

FIGURE 3. The total 140 patients with MAC were classified according to the site and severity of calcified lesions (see text for definitions).

Two-dimensional echocardiographic evaluation of MAC: There were 51 of 140 cases (36%) of Type I MAC with medial posterior location, extension to the anterior mitral leaflet, or both, and 89 of 140 (64%) of Type II MAC with central or lateral location, or both. In grading MAC for severity, we found 88 of 140 (63%) mild (located in 1 segment), 28 of 140 (20%) moderate (located in 2 segments), and 24 of 140 (17%) severe cases (3 or all 4 segments). All severe cases were medial (Type I) and most of the mild cases were in Type II (Fig. 3). Extension of calcification onto the anterior mitral leaflet was noted as a continuous set of bright echoes from the medial portion of the anulus or as a continuous dense set of echoes from the posterior aortic wall. J-shaped or U-shaped configuration of bright echoes surrounding the mitral orifice were observed in severe MAC cases.

M-mode echocardiographic evaluation of MAC: The severity of MAC by M-mode criteria was mild in 79 of 130 (61%), moderate in 41 of 130 (32%), and severe in 10 of 130 (8%). Eighty-six of 130 cases (66%) had the same grade of severity seen by M-mode and 2-D echocardiography. The remaining 44 of 130 patients (34%) fell into an unmatched group regarding grade and extent of severity (Fig. 4).

Incidence of conduction disturbances in patients with and without MAC: Conduction disturbances were found in 50 of 140 patients (36%) with MAC, and in 38 of 135 patients (28%) without MAC (Table II). Arrhythmias were found in 24% of patients with MAC and in 21% of patients without MAC. There were no statistically significant differences, either for type of conduction disturbance or arrhythmia, between the 2 groups if subgrouping was not performed. Seven patients in the MAC group had previously implanted pacemakers; however, this was true in only 1 control patient. In the MAC group, electrocardiographic findings before pacemaker implantation were sick sinus syndrome (2 cases), atrial fibrillation with intermittent heart block (1 case), second-degree atrioventricular block (1 case), and complete atrioventricular block (3 cases). Third-degree block was the reason for pacemaker placement in the 1 control patient without MAC (who had echocardiographic study for possible pericardial effusion during radiation for carcinoma of the breast). By surveying the medical records of the patients with pacemakers, we noted that 2 patients with MAC and a control patient without MAC had a documented episode of syncope related to conduction system disease. There were 6 patients in the MAC group and 2 in the control group with second- or third-degree atrioventricular block. There was no statistical difference in the incidence of heart block (second or third degree) between the 2 groups.

Incidence of conduction disturbances related to the site of MAC (Table II): Medial Type I MAC had much higher incidence (27 of 51, 53%) of conduction disturbances than Type II (23 of 89, 26%; $p < 0.01$). Specifically, complete left bundle branch block (Type I: 7 of 51, 14% versus Type II: 2 of 89, 2%; $p < 0.01$) and intraventricular conduction delay (Type I: 6 of 51, 12% versus Type II: 2 of 89, 2%, $p < 0.05$) were noted with significantly higher incidence in the Type I group. The

incidence of intraventricular conduction delay and all conduction disturbances also were higher in Type I MAC compared with the control group.

Relationship between the conduction disturbances and the severity of 2-dimensional quantified MAC: Conduction disturbances were found in 27 of 88 (31%) patients with mild MAC and in 23 of 52 patients (44%) with moderate to severe MAC. There were no statistically significant differences in the incidence of aggregate conduction disturbances comparing the mild and the moderate to severe MAC groups. However, both complete left bundle branch block and intraventricular conduction delay specifically were more frequently seen in moderate to severe cases compared with the mild cases (both $p < 0.05$). Only intraventricular conduction delay occurred with much higher incidence in the moderate to severe MAC group compared with the control group ($p < 0.05$).

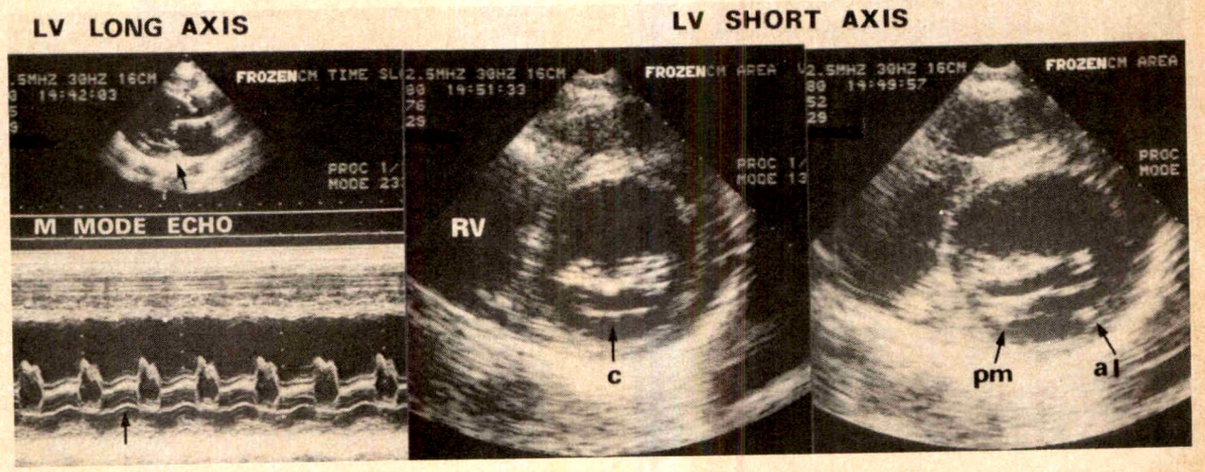

FIGURE 4. Echocardiograms labelled as mild MAC by M-mode echocardiographic criteria, but classified as severe MAC by 2-dimensional echocardiographic criteria (see text). Accurate recognition of the extent of MAC may not be available from a single short-axis view. The **center and right panels** show bright echoes from the central (c) portion of the anulus at 1 tomographic level and bright echoes from the posteromedial (pm) and anterolateral (al) portions at another level.

Discussion

MAC has been studied by pathologists for many years as a possible cause of conduction disturbances.[12–14] There is a wide spectrum of MAC, from microscopic lesions to massive calcification, but only the more severe cases of MAC can be detected by chest roentgenography or fluoroscopy.[15–16] These techniques have not been performed serially or quantitatively so the natural history of the condition is not clear. The echocardiographic features of MAC were first noted in 1973, as associated with mitral regurgitation.[17] Since then, several echocardiographic studies of MAC have been published.[3–7,18–23] There has been some discussion about the reliability of echocardiographically quantified MAC,[23,24] but we believe echocardiography has a reasonably high sensitivity of approximately 70%, judged by surgery or autopsy.[25] In addition, echocardiographic detection of MAC is increasing with the evolution of high resolution ultrasonic imaging equipment which also provides improved echo amplitude information now used to help note tissue characteristics.[26]

A relation between conduction disturbances and MAC has been reported but whether this is a causative relationship remains controversial. The previously reported incidence of conduction disturbances in patients with MAC has varied from 26 to 70%.[3–7] D'Cruz et al[3] found atrioventricular or intraventricular conduction defects in 52% of 38 patients with MAC. However, they commented that only complete right bundle branch block occurred significantly more often in their MAC group compared with control subjects without MAC (by echocardiography). Nair et al[5] reported a 70% incidence of conduction disturbances in their MAC group versus 34% in control subjects. Conversely, the same group later studied the incidence of MAC in 68 patients with symptomatic bradyarrhythmias who subsequently underwent pacemaker implantation, and reported an 87% incidence of MAC.[7] Some articles note prominence of Adams-Stokes syndrome in patients with MAC.[27,28] The occurrence of both conduction disturbances and MAC seem to increase with age and patient selection may be a factor in the figures reported in various series.

The present study showed no difference of overall incidence of conduction disturbances in the MAC group and our age-matched control group with heart disease. However, there were statistically increased incidences of intraventricular conduction delay alone and aggregate conduction disturbances in patients with medial Type I MAC and in those with moderate to severe MAC, compared with the control group. This suggests that MAC specifically involving the area adjacent to the bundle of His and its primary branches may be etiologically related to conduction disturbances. All severe cases of MAC involved this area (Type I) so advanced tissue degeneration may be the common factor in MAC and abnormal conduction. Only 4 of our 140 cases with MAC had a mild degree of calcification of the presumed critical medial area of the anulus near the septum. The site of MAC has not been assessed this way previously.

Limitations of M-mode and 2-dimensional echocardiography for the evaluation of MAC: M-mode echocardiography seems quite sensitive to the presence of MAC, but it does not discern medial extension within the mitral anulus that we suggest is associated with an increased prevalence of conduction disturbances. Thus, 2-D echocardiography is preferred to analyze MAC.[26] We evaluated the severity of MAC by the 2 methods (M-mode and 2-D echocardiographic criteria) with discrepancy of the methods in 34% of patients. This may be explained by the 2 criteria for severity of MAC being qualitatively different. In the presence of MAC, dense echo-producing structures behind the posterior mitral leaflet where echo reflections normally are not seen may be seen with either echocardiographic method. It is not difficult to note these extra echoes, that typically have an intensity equal to or exceeding that from the aortic wall or pericardium. There was no discrepancy between the 2 independent interpreters in this study. The echocardiographic criteria for MAC are based on the nonquantified increased amplitude of the echo signals, so some diagnostic difficulties may exist in differentiation of calcified lesions from fibrous or sclerotic lesions which present similar echocardiographic features. Fulkerson et al[24] commented that echocardiography was too sensitive for the detection of MAC. Our study demonstrates that echocardiographically diagnosed MAC often may include clinically insignificant findings regarding conduction disturbances.

Clinical background of the studied population: Most patients referred to our echocardiographic laboratory have heart disease of some type. Thus, we used such patients as a reasonable control group when trying to learn whether finding MAC had special significance with regard to coincidentally found conduction disturbances in a hospital laboratory. This surely accounts for the prevalence of conduction disturbances in our control group, but this is part of the answer we sought. Our study suggests the finding of MAC deserves clinical notation only if it is of moderate to severe degree and it is located near the conduction system. We currently have no data on the natural history of patients with calcium in this location.

Analysis of Surgical Versus Medical Therapy in Active Complicated Native Valve Infective Endocarditis

CHARLES H. CROFT, MB, ChB, FCP (SA), WAYNE WOODWARD, PhD, ALAN ELLIOTT, MAS, PATRICK J. COMMERFORD, MB, ChB, FCP (SA), CHRISTIAAN N. BARNARD, MD, PhD, and WALTER BECK, MSc, MMed, FRCP

From 1972 to 1980, 23 patients (Group A) with native valve infective endocarditis underwent surgical intervention, often for multiple indications, during the active stage of the infective process because of progressive class III and IV (New York Heart Association) heart failure (12 patients), persistent severe hypotension (3 patients), uncontrolled infection for over 21 days (11 patients), aortic root abscess (2 patients), and pericarditis (1 patient). Eighty-five patients (Group B) with active native valve endocarditis, matched for severity of illness, were treated medically. Two patients (9%) in Group A and 43 patients (51%) in Group B died during the hospital admission ($p < 0.001$). Any difference in long-term cumulative survival rate between the 2 groups was largely due to the beneficial impact of surgical management on the hospital mortality. Of 23 patients in Group A, 11 (48%) had an entirely uncomplicated postoperative course. Long-term mortality rates in those with aortic valve endocarditis treated medically (79%) were significantly higher than in those with mitral valve involvement (47%) ($p < 0.05$). Patients with aortic valve involvement treated surgically had a better hospital ($p < 0.005$) and long-term ($p < 0.0005$) survival rate than those treated medically. Two groups at risk for postoperative complications were identified; 3 of 11 patients (27%) with uncontrolled infection had an early postoperative recurrence, and 4 of 7 patients (57%) with an aortic root abscess had postoperative prosthetic paravalvular regurgitation.

Surgery therefore effects a substantial reduction in hospital mortality in patients with complicated active infective endocarditis (9% versus 51%), but patients with preoperative prolonged periods of uncontrolled infection or with aortic root abscess are liable to postoperative complications.

The last 50 years have seen not only significant changes in the epidemiology of infective endocarditis,[1–4] but also major advances in its therapy. The introduction of antibiotics resulted in survival rates of 50 to 85%[1,2,4,5] in a previously almost uniformly fatal disease,[3] and replaced persistent septicemia with congestive heart failure secondary to valvular destruction[6,7] as the leading cause of death in these patients. More recently, valve replacement in the presence of active infection has been demonstrated to be of value.[8–10] A number of reports of absolute survival rates in surgical series have been published,[9,11–14] as have comparisons of surgery in active and healed infection[9,14,15] and of surgical series with unselected and unmatched medical series.[10–16] The latter comparisons[10–16] were further biased since major complications generally resulted in surgical treatment. The magnitude of the impact of surgery during active endocarditis on mortality has, therefore, not been measured in any direct comparison of surgical and medical management in well-matched patients. This report describes the findings in such an analysis of patients with active infective endocarditis. In addition, it identifies subsets of patients at risk for postoperative complications and defines the role of preoperative cardiac catheterization.

From the Cardiac Clinic, Department of Medicine and the Department of Cardiothoracic Surgery, Groote Schuur Hospital, University of Cape Town, South Africa, and the Department of Computer Sciences at the University of Texas Health Science Center, Dallas, Texas, Manuscript received November 22, 1982; revised manuscript received March 14, 1983, accepted March 15, 1983.

Methods

Patients: Two hundred fifty-two patients treated for active infective endocarditis between January 1972 and March 1980 were reviewed. Of this group, 23 patients (Group A) (13 men, 10 women) underwent cardiac surgery during the active stage

TABLE I Indications for Surgery (Group A) and Criteria for Inclusion in Group B

	Group A (23 Patients)		Group B (85 Patients)		
	n	%	n	%	p Value
CHF (class III and IV, NYHA)	18	78	63	74	NS
Persistent infection	11	48	29	34	NS

NS = not significant; PDA = patent ductus arteriosus; VSD = ventricular septal defect.
* For group comparison, p = 0.079.

of infective endocarditis involving native heart valves. All patients were still receiving intravenous antibiotics at the time of surgery for clinically apparent ongoing bacterial endocarditis and fulfilled at least 1 of the following criteria defining persistent infection[6,8,9,15–17]: (1) positive blood cultures within 1 week before operation; (2) perianular or intramyocardial abscess at surgery; (3) clinical picture of decreasing hemoglobin level, fever, general malaise and hematuria cured by surgery; (4) a positive culture from the excised valve; (5) a positive Gram stain from the excised valve; or (6) histologic evidence of active inflammation in the excised valve.

Indications for surgery were often multiple and included at least 1 of the following: (1) moderate or severe congestive heart failure (New York Heart Association[18] class III or IV) irrespective of the type and amount of antifailure therapy; (2) active infection (positive blood cultures, typical clinical picture as defined above, or both) persisting for more than 21 days, despite adequate intravenous therapy with at least 2 well-selected bactericidal antibiotics; (3) persistent hypotension (defined as systolic blood pressure <90 mm Hg, oliguria, poor peripheral pulses, and mental confusion) due to the severity of valvular disease and requiring inotropic support; (4) new onset heart block (except first-degree heart block) suggesting a root abscess[9,19,20]; and (5) suppurative pericarditis.

An additional 85 patients (Group B) were identified during the same period. These patients were all treated conservatively with appropriate intravenous bactericidal antibiotics, therapy for congestive heart failure, and general supportive care for native valve endocarditis, but all fulfilled criteria as suggested by others,[6,8–10,16,17] and as defined above, for surgical intervention at a time when they had clinically active endocarditis. Patients in Group B did not undergo operation, primarily because of the individual physician's attitudes toward cardiac surgery during active infective endocarditis. Although surgery was, at other times, contemplated, this was postponed while further medical measures were instituted.

Other investigators have suggested that patients with left-sided Staphylococcus aureus endocarditis,[10] persistent Gram-negative endocarditis,[6,14,15] fungal endocarditis,[6,10,14,21] or recurrent emboli[10,14,15] should be operated on. Since no patient in Group A underwent surgery primarily for any of the above reasons, these criteria were not considered in selecting patients in Group B.

Surgery: Patients received mechanical prostheses during the initial part of the study. Later, because of the inconvenience of the required anticoagulant therapy, we preferentially employed the Carpentier-Edwards glutaraldehyde-preserved porcine heterograft. Postoperative antibiotic therapy, individually tailored according to organism, preoperative length of treatment, and intraoperative findings, was generally continued for 14 to 21 days.

Follow-up analysis: Patients were seen every 3 months after discharge. Mean time of follow-up was 24 months in Group A and 33 months in Group B. Full follow-up information up until the end of the study was available in 21 (91%) of 23 patients in Group A and in 74 (87%) of 85 patients in Group B.

Statistical analysis: Comparison of ages between the 2 groups was made using the Mann-Whitney U test[22] because of the skewness in the age distribution. Fisher's exact test[22] was employed in comparisons of 2 proportions. Comparisons of 2 groups on the basis of a categorical variable for which there were more than 2 categories were made using the chi-square test. Survival curves for the surgical and nonsurgical groups were constructed using the Kaplan-Meier technique,[23] and curves were compared by the modified Wilcoxon Text.[24] All p values quoted are 2-tailed.

Results

General characteristics: The age of Group A patients ranged from 10 to 54 years (29 ± 12, mean ± standard deviation) and was not significantly different from those in Group B who ranged from 13 to 85 years (35 ± 18, mean ± standard

TABLE III Infecting Organisms

	Group A (23 Patients)	Group B 85 (Patients)

Coxiella burnetti	0	2
Flavobacterium sp.	0	1
Listeria monocytogenes	0	1

deviation). Likewise, there was no significant difference between the groups with regard to sex distribution or year of entry into the study.

Indications for surgery: The indications for surgery in Group A and for inclusion in Group B are listed in Table I. There was no significant difference in the frequency of these various indications between Groups A and B. While more than 1 indication was often present, the 2 main indications in both groups were congestive heart failure and persistent infection. It is noteworthy that although 2 patients underwent surgery because of clinically suspected root abscess, this was a finding in a further 5 patients at operation.

Site of involvement by endocarditis: Table II illustrates the frequency with which various valves were involved by the infective process in the 2 groups. Four patients had double valve replacements. Apart from isolated aortic valve involvement, there was no significant difference between Groups A and B in the frequencies with which the various valves were involved (for overall group comparison $p = 0.079$).

Organisms: An organism was not identified in 12 patients in Group A and in 40 patients in Group B (difference not significant) (Table III). In each patient in Group A, however, infective endocarditis was confirmed at surgery. Furthermore, postmortem examinations obtained in 31 of the 43 patients who died during the initial hospitalization in Group B confirmed endocarditis in each case. A wide variety of organisms was encountered in both groups (Table III), but individual numbers were, on the whole, too small to make adequate comparisons.

Cardiac catheterization: Nine of the 23 patients in Group A underwent preoperative cardiac catheterization. This procedure identified additional valvular regurgitation, not recognized clinically, in 4 of these 9 patients. Preoperative cardiac catheterization, however, obtained in 4 of 7 patients shown to have a root abscess at surgery failed to identify this complication in any of the 4 cases. None of the 9 patients who were catheterized died in the hospital. Two of 14 who did not undergo catheterization died in the hospital. A review of these 14, however, revealed that catheterization would not have led to any change in management in the 2 patients who died in the hospital and would have altered management in 1 of the total group of 14 patients.

Cardiac catheterization was performed in 7 of 85 patients in Group B. In none were the derived data considered to have added materially to information already available from the bedside evaluation. Two of these 7 patients survived the hospital admission. No complications occurred as a result of cardiac catheterization in this total group of 16 patients in Groups A and B.

Intraoperative and in-hospital postoperative complications: No patient died intraoperatively. The postoperative course was entirely uncomplicated in 11 patients (48%). Postoperative complications included transient hypotension (3 patients), class IV (New York Heart Association[18]) heart failure (2 patients), mediastinal hemorrhage (3 patients), and nonseptic pericarditis (2 patients).

Early postoperative recurrence: There were 3 early postoperative recurrences (defined as the reappearance of typical clinical symptoms and signs with or without confirmatory blood cultures within 8 weeks after surgery) in Group A. All 3 belonged to the group of 11 patients with uncontrolled infection for more than 21 days before surgery (27%). Of these 3 patients, 2 died of recurrent culture-negative and rickettsial endocarditis, respectively. A third patient with recurrent Staphylococcus aureus endocarditis was successfully treated with antibiotics.

Comparison of in-hospital mortality: There were 2 in-hospital deaths (9%), both due to congestive heart failure, in Group A and 43 deaths (51%) in Group B ($p < 0.001$).

Postmortem examination was performed in 31 (72%) of the 43 patients who died during the acute illness. Bacterial endocarditis was confirmed in every case. On the basis of clinical and available pathologic information, the cause of death was directly attributed to intractable congestive heart failure in 22 patients, and to congestive heart failure in combination with another factor in a further 14 patients. Meningitis, cerebral emboli, rupture of a splenic artery mycotic aneurysm, ventricular fibrillation, and renal failure were considered to be the causes of death in other patients.

Congestive heart failure alone was the indication for surgery in 9 patients in Group A and the criterion for inclusion of 41 patients in Group B. The in-hospital mortality rate in this subset of patients was 11% (1 patient) and 56% (23 patients) in Groups A and B, respectively ($p < 0.05$).

Persistent infection alone was the indication for surgery (Group A) in 3 patients and for inclusion in Group B in 5 patients. All 3 in Group A lived. One patient (20%) in Group B died (not significant). Considering all patients with persistent infection, either alone or in association with other factors, 1 of 11 died in Group A (9%) and 10 of 29 died in Group B (34%) ($p = 0.233$).

Long-term complications: Twenty-one patients in Group A were followed for a mean time of 24 months (range 3 to 102) and 42 patients in Group B were similarly followed for a mean time of 33 months (range 3 to 103).

The long-term complications in Groups A and B are listed in Table IV. Ten of 21 patients in Group A discharged from the hospital had an uneventful long-term course. Of note is that late symptomatic valvular dehiscence was noted in 5 patients (24%) in Group A. All 5 involved an aortic prosthesis. Two additional patients (9%) had asymptomatic valvular dehiscence.

Apart from coronary emboli, there were no differences in the incidences of various long-term complications between the 2 groups.

Long-term mortality rates: Cumulative survival curves for all patients in Groups A and B are plotted in Figure 1. Plots are extended until the last death in each group. The overall survival rate for patients in Group A is significantly better than that for patients in Group B at the end of the follow-up

TABLE IV Major Long-Term Complications After Discharge

	Group A (21 Patients)		Group B (42 Patients)		
	n	%	n	%	p Value
Uncomplicated	10	48	14	33	NS
Symptomatic VD	5	24	...	...	...
Asymptomatic VD	2	9	...	...	...

Late recurrence	1	5	3	7	NS
Emboli					
Cerebral	2	10	0	...	NS
Mesenteric	0	...	1	2	NS
Peripheral (large vessel)	0	...	1	2	NS
Coronary	0	...	2	5	<0.05
Anticoagulant hemorrhage	0	...	1	2	NS

CHF = congestive heart failure; NS = not significant; NYHA = New York Heart Association; VD = valve dehiscence.

period (p = 0.0004). Figure 2 contrasts the survival rates of those patients in Groups A and B who survived the hospital admission. There is no significant difference in the survival rates after discharge (p = 0.624).

Poor prognostic factors in Group B and comparisons with outcome in Group A: Considering Group B only, the hospital mortality rate in medically treated patients with aortic valve involvement only (64%) was not significantly greater than in those with mitral involvement only (38%) (not significant). There was a significant difference, though, in long-term mortality rates between those with aortic (22 patients, 79%) and mitral involvement (15 patients, 47%) (p <0.05). Aortic valve involvement, therefore, carried an unfavorable long-term prognosis in moderately and severely ill patients with endocarditis treated medically. Surgically treated patients (Group A) with endocarditis of the aortic valve only had both a lower hospital (0 versus 64%, p <0.005) and long-term mortality (29 versus 79%; p <0.0005) than those treated medically (Group B).

Systemic hypotension was a particularly ominous sign in those treated medically. All 10 patients (100%) in Group B with persistent hypotension died despite hemodynamic monitoring and various combinations of vasopressor agents, digoxin, diuretics, and vasodilators. None of the 3 patients in Group A who underwent surgery for systemic hypotension died in the hospital (p <0.0005). These 3 patients have been followed for 30, 34, and 58 months, respectively.

An aortic root abscess was clinically suspected in 1 patient in Group B. He had Mobitz II second-degree atrioventricular block and died due to sudden exacerbation of heart failure. Of 7 patients with a root abscess in Group A, 4 (57%) had postoperative valve dehiscence (1 symptomatic, 3 asymptomatic).

Discussion

Since Wallace et al[25] reported the first case of aortic valve replacement in active infective endocarditis in 1965, the role of surgery in the management of this condition has become increasingly important. Valve replacement appears to have contributed to an improved survival rate[10,26] particularly in those patients

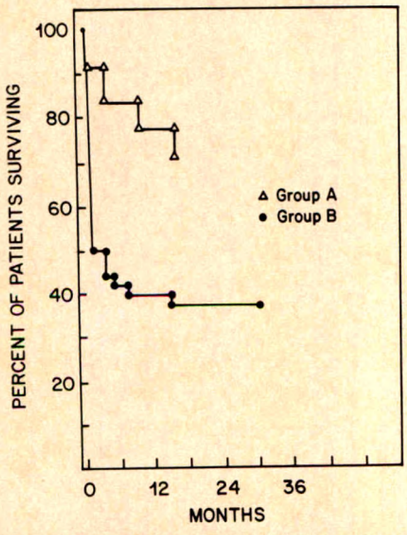

FIGURE 1. Plot of the cumulative hospital and long-term survival rate of all patients in Groups A and B. Plots are extended until the last death in each group. The overall survival rate for patients in Group A is significantly better than that for patients in Group B (p = 0.0004).

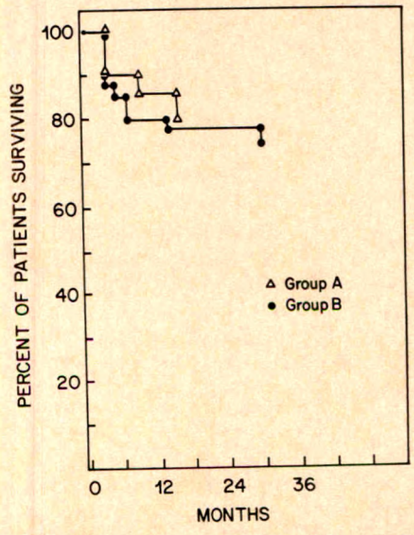

FIGURE 2. Plot of long-term survival rate of patients in Groups A and B who survived the hospital admission. Plots are extended until the last death in each group. There is no significant difference between the 2 groups in the survival rates after discharge (p = 0.624).

with congestive heart failure,[10] in whom the mortality rate when treated medically is 79 to 89%.[27] The magnitude of the improvement in survival rate, both short- and long-term, afforded by surgical intervention is, however, unclear. This study compares the results of surgical and medical therapy of active infective endocarditis at a single institution in patients matched for severity of disease. This was possible because of a generally conservative approach to surgical therapy on the part of internists together with delays in advising surgery due to institution of further medical measures. A sizable population of 85 patients (Group B) satisfying criteria for severe and progressive heart failure, persistent infection, pericarditis, or root abscess had baseline characteristics similar to a surgical group of 23 cases (Group A).

The data presented here demonstrate that surgery in these patients with active infective endocarditis results in a significantly improved hospital mortality rate (9 versus 51%, $p < 0.001$) and that any difference in cumulative long-term survival is largely due to the favorable effect of surgery during the initial hospitalization period. The hospital mortality in this series for patients undergoing valve replacement during active endocarditis (9%) is comparable to the mortality rate in patients undergoing elective aortic (4%)[28] or mitral (7%)[29] valve replacement. Surgery significantly reduced the hospital mortality rate in patients with congestive heart failure only, from 56 to 11%. Although there were no hospital deaths in patients with persistent infection in Group A as compared with a mortality rate of 20% in Group B, the absolute numbers of patients here were too small to make meaningful comparisons.

All patients in Group A and Group B satisfied the stated criteria for severity of illness. There are, however, inherent difficulties in defining more accurately the severity of, for example, congestive heart failure in individual cases. We cannot therefore exclude that individual differences in severity of the various indications within the groups accounted for some of the differences in hospital and long-term mortality rates.

The low yield of organisms from blood cultures in infective endocarditis in this series is in keeping with the overall experience at our institution and consistent with Cherubin and Neu's[4] statement that "in a considerable proportion of cases an organism cannot be cultured by conventional means." In a collective review of all cases of endocarditis at our institution from 1971 to 1980, cultures were persistently negative in 103 of 252 cases (41%) (unpublished data). This is comparable to the 13 to 50%[8,10,11,15,30] incidence of persistently negative cultures quoted in other series. Failure to culture organisms in this and other series may be related to antibiotic therapy before admission, possibly to poor technique in obtaining blood culture samples in individual cases,[31] and to failure to routinely aerate 1 culture bottle.[31] In those patients with culture-negative endocarditis in this series, the diagnosis was confirmed in each case at surgery. In addition, postmortem examination, performed in 31 of the 43 patients (72%) who died in Group B, confirmed infective endocarditis in every case. No patient was referred to surgery with an incorrect diagnosis of infective endocarditis. Our small experience with fungal endocarditis, in contrast to that of Boyd et al[14] is certainly due to the very low incidence of intravenous narcotic abuse locally.

As has been demonstrated before,[8,10,13,15] the risk of infection of prosthetic material sutured into the site of active infection, although contrary to fundamental surgical principles, is small in this situation. Twenty-seven prosthetic valves were implanted in 23 patients during the active stage of infective endocarditis. Only 3 of these patients (13%) had an early recurrence. We attribute this success to detailed attention to radical excision of infected tissue.[8,9] We concur with others[9] that the extent of valvular and perivalvular destruction rarely precludes successful valve replacement. The extent and severity of the infective process did not prohibit valve replacement in any instance when required, despite the presence of 7 root abscesses and extensive double valve disease in 4 patients in this series.

Two subsets of patients at high risk of having postoperative complications have been identified. The first is the group of patients with uncontrolled infection. All 3 patients with an early recurrence of infection had persistent sepsis despite antibiotic therapy for at least 21 days before surgery. This long time period may have allowed spread of infection from the valve itself, the initial site of infection,[32] to the perivalvular inflammatory tissue not excised at surgery. This nidus, generally resistant to antibiotic therapy,[6] might then infect the prosthetic valve. The other subset of high-risk patients are those with aortic root abscesses. Of 7 such patients, 4 (57%) had prosthetic valve dehiscence. This complication was clearly not related to reinfection, but to the edematous and friable nature of tissue into which holding sutures were placed.

The literature is divided as to whether unoperated aortic valve infection carries a worse prognosis than mitral valve infection.[1,33–35] In this series, patients with aortic valve involvement treated medically had a higher long-term mortality rate than those with mitral valve endocarditis. We concur with others,[15] therefore, that surgery should be considered earlier in those with aortic valve infection.

This study has demonstrated the feasibility of operating upon severely ill patients with systemic hypotension and confusion unresponsive to pressor agents. The removal of a septic focus and the dramatic correction of the cause of severe hemodynamic embarrassment in otherwise relatively healthy myocardium are major factors contributing to this improved survival rate with surgery.

Cardiac catheterization during active endocarditis carried no additional risk, thereby confirming the observations of others[17] in this regard. Fears of dislodgement and embolization of vegetations during catheterization[9,36,37] proved unfounded. However, while some reports[6,17,38] testify to the diagnostic usefulness of this procedure in infective endocarditis, others are less enthusiastic.[9,36] In this series, preoperative cardiac catheterization was only of limited value. We therefore recommend that while catheterization can and should be performed before nonemergency surgery with min-

imal additional risk, it should not delay surgery when required urgently and immediately. The course of infective endocarditis is extremely variable, but the subjective sensation of dyspnea at rest or on minimal effort is an excellent marker of even insidious hemodynamic deterioration. While cardiac catheterization is a valuable comfirmatory and diagnostic tool in this setting, we and others[9] believe that, irrespective of the stage of activity of the infective process, definite and progressive symptoms of heart failure should be the cornerstone on which the decision-making process regarding surgery should be built. Procrastination in replacing cardiac valves at this point, in an attempt to stabilize heart failure by medical therapy, to complete or alter antibiotic therapy preoperatively, or both, is usually disastrous.[8,10,36,37]

We conclude that surgery is superior to medical management in patients with active infective endocarditis experiencing progressive class III and IV (New York Heart Association[18]) heart failure. Although numbers were too small to draw conclusions about patients with persistent infection after 21 days of antibiotic therapy, patients should undergo surgery earlier rather than later to prevent postoperative recurrence of infection. Patients with aortic valve involvement treated medically have a poor long-term prognosis; this can be substantially improved by surgical therapy. Patients with aortic valve involvement who have a root abscess are, however, at considerable risk of having both early and late postoperative paravalvular regurgitation. Although cardiac catheterization should be performed in the nonemergency situation, we agree with others[9,36] that it is not essential when immediate surgery is required.

Acknowledgment: We thank Professor S. R. Benatar of the University of Cape Town for considerable encouragement and help in the preparation of the manuscript, Dr. James Willerson and Dr. J. V. Nixon of the University of Texas Health Science Center at Dallas, Texas for their support, and Paulette Newingham, Jan Wright, and Gloria Wheelan for secretarial assistance.

THE NEW QUANTUM™ PACEMAKER

8mm THIN

And in better shape than ever.

MORE PHYSIOLOGICALLY COMPATIBLE SHAPE.
The new thin oval shape of the model 253-19 unipolar Quantum is designed to fit more comfortably into a smaller pocket with less tissue irritation. No upward cut into the fascia is necessary, and the pacemaker stays more securely in place.

LESS HASSLE—A NEW INTER-LOCK™ LEAD CONNECTOR SYSTEM.
The model 253-19 incorporates the innovative Inter-Lock™ lead connector system. This new, easy-to-use system requires no set screw assembly and allows leads to connect quickly and easily into place without the handling of loose screws or caps.

SMALLER SIZE, SAME FULL QUANTUM CAPABILITIES.
The model 253-19 unipolar Quantum 8mm features the same advanced measured telemetry, full multiprogrammability and transtelephonic capabilities as our other Quantum pacemakers.

The new, more convenient unit houses the same proven circuitry that makes Quantum a complete patient management system. Over 10,000 prescription programming combinations plus measured telemetry allow the physician to adjust the pacemaker to the patient's changing needs. Both operating and programmed data are available in digital read-out or hard copy form to help in making better, faster clinical decisions.

The unique new connector system, plus the thinner, lighter, more physiologically compatible shape of the new Quantum pacemaker, is another example of Intermedics' commitment to aiding the physician in providing better patient care. As part of the complete Quantum Pacing System, the 8mm thin model 253-19 represents continuing progress in technological advancements for better patient management.

QUANTUM INDICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacing are increasing as pacemakers become more sophisticated and as advanced methods for patient management become more widespread. Generally accepted indications for long-term cardiac pacing include, but are not limited to: (1) sick sinus syndrome; (2) chronic, symptomatic drug-resistant sinus arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting such symptoms as intractable, recurrent congestive heart failure; cerebral or renal insufficiency; or recurrent drug-resistant tachyarrhythmias, and who have been shown to benefit from temporary cardiac pacing, are considered candidates for permanent cardiac pacing.

The indications for permanent pacing in cases of acute myocardial infarction have not yet been rigorously defined. Factors to be considered include the location of the myocardial infarct, the presence or absence of symptoms, ventricular rate, the mechanism of arrhythmias, and response to therapy. In general, symptomatic drug-resistant bradyarrhythmias that impair cardiac output are considered indications for pacing in patients with acute myocardial infarction, regardless of infarct location.

There are no known contraindications to the use of pacemakers as a medical method for control of heart rate.

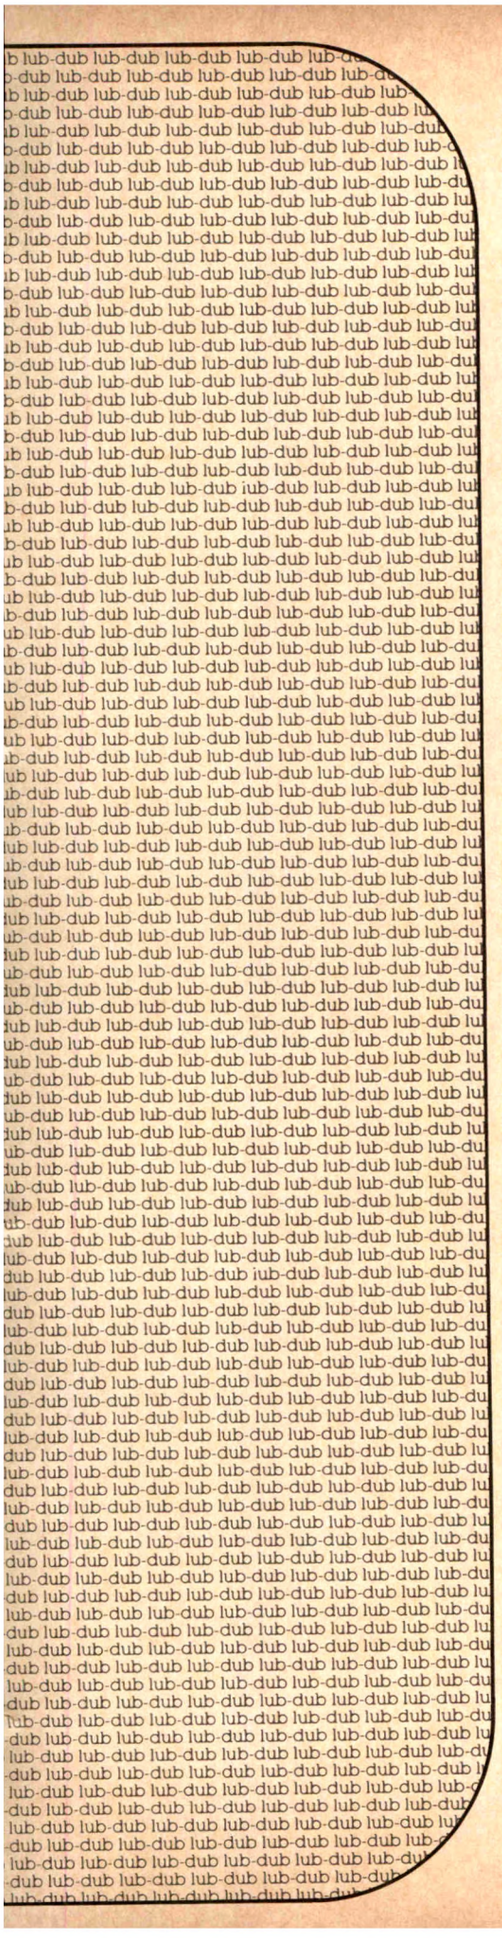
25,000,000,000
beats later
...and
counting



Norpace®
(disopyramide phosphate)
100-mg and 150-mg capsules

The brand that counts most often in control of dysrhythmia
Five years on the market...7 million patient-months of experience...more than 7 million prescriptions dispensed...and the beat goes on.

Norpace® CR
(disopyramide phosphate)
controlled release
100-mg and 150-mg capsules

True 12-hour dosing convenience
Now, with Norpace CR, you can add true 12-hour dosing convenience to the established efficacy of Norpace...with no increase in cost to the patient.

As a consequence of the negative inotropic properties of disopyramide phosphate, adequate cardiac function must be established and maintained. Norpace/Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac dysrhythmia.

The leading branded antiarrhythmic agent...Norpace

SEARLE

Please see page preceding ad for a brief summary of the complete prescribing information.

Norpace®
(disopyramide phosphate) 100-mg and 150-mg capsules

Norpace® CR controlled release
(disopyramide phosphate) 100-mg and 150-mg capsules

the leading branded antiarrhythmic agent

Before prescribing, please consult current complete prescribing information, a summary of which follows: **Indications:** For suppression and prevention of recurrence of the following cardiac arrhythmias: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Norpace CR should not be used initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide phosphate has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace or Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace or Norpace CR, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace or Norpace CR should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace or Norpace CR should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patients should be monitored closely, and discontinuation of Norpace or Norpace CR considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic agents and/or propranolol should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace or Norpace CR should be reduced. If the block persists, continuation of Norpace or Norpace CR must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or trifascicular block requires discontinuation of drug unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. In patients with a family history of glaucoma, intraocular pressure should be measured before initiating Norpace or Norpace CR therapy. Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to Norpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of disopyramide phosphate. Therefore, a loading dose of Norpace should not be given to such patients, and initial dosage and subsequent dosage adjustments should be made under close supervision. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs for overdosage. Norpace CR is not recommended for patients with severe renal insufficiency. Concomitant administration of disopyramide phosphate with phenytoin or other hepatic enzyme inducers may cause lower disopyramide plasma levels. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace or Norpace CR therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of labor and delivery are unknown. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory difficulty, thrombocytopenia, and gynecomastia. **Dosage and Administration:** Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg/day given in divided doses: q6h for Norpace and q12h for Norpace CR. **See current complete prescribing information for dosage recommendations.**

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

EDITED BY

DEAN T. MASON, M.D.
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-In-Chief, AMERICAN HEART JOURNAL

JOHN J. COLLINS, JR., M.D.
Professor of Surgery
Chief, Division of Thoracic and Cardiac Surgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Sample Table of Contents:

Section 1 - Stable Angina Pectoris and Asymptomatic Coronary Disease

Section 2 - Variant Angina Pectoris

Section 3 - Unstable Angina Pectoris

Section 4 - Acute Myocardial Infarction

Section 5 - Myocardial Preservation

Section 6 - Pharmacologic and Related Approaches to Coronary Dilatation

Section 7 - Percutaneous Transluminal Coronary Angioplasty

Section 8 - Intracoronary Thrombolysis in Evolving Myocardial Infarction

Section 9 - Long-Term Achievements of Myocardial Revascularization by Medical and Surgical Therapy

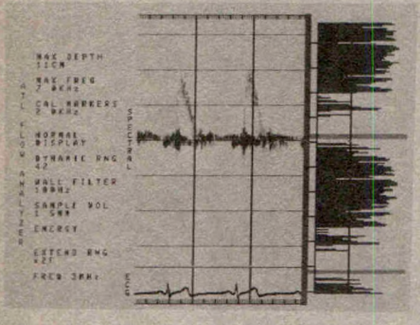
WE'VE TAKEN TECHNOLOGY TO HEART.

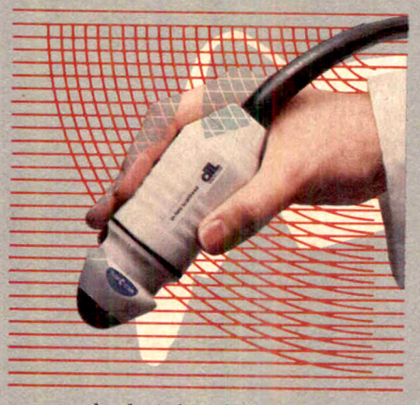
When it comes to high technology, ATL has its heart in the right place—a place where you can find even more diagnostic information about the entire cardiovascular system than you ever thought was possible. Today, it's not just possible—it's available. Improved 2D echocardiography and Adaptive Doppler™ bring ATL innovation to the noninvasive evaluation of cardiac function. We see it assuming a stronger role day by day in both adult and pediatric cardiac examination, in many cases obviating the need for angiography.



Our goal is to improve the information content of your diagnostic studies...to give you maximum benefit from this valuable resource.

Getting the best of technology.

We at ATL have one of the largest technology bases in the ultrasound industry—research scientists and engineers who have innovated their way from the ground floor of ultrasound technology a decade



ago to the height of today's imaging techniques. Adaptive Doppler technology, recently introduced in the MK 600 Ultrasound System, is the latest of their contributions—a major step in highly accurate, efficient, noninvasive blood-flow measurement.

To achieve complete diagnostic significance, your examination also requires a 2D real-time image of the highest quality—the quality image for which ATL has been widely recognized. Our CardioSeries™ Ultrasound Systems have all incorporated a new wide-range receiver, new "Blue Label" Scanheads with improved sensitivity, larger memory, and selective gray-scale M-mode. The immediate advantages are greater penetration and improved resolution, ultimately increasing the information content of your exam and helping you complete more exams in less time.

There are still innumerable informational bits to be uncovered within the human machine. We invite you to take ATL technology to heart and explore the cardiovascular system with new-found efficiency and accuracy.

The diagnostic possibilities are astronomical.

More details are available right now about our CardioSeries Ultrasound Systems. Call 800-426-2670, ask for "Customer Information." Or write: Advanced Technology Laboratories, Inc., 13208 Northup Way, P.O. Box 4639, Bellevue, WA 98009-0639.

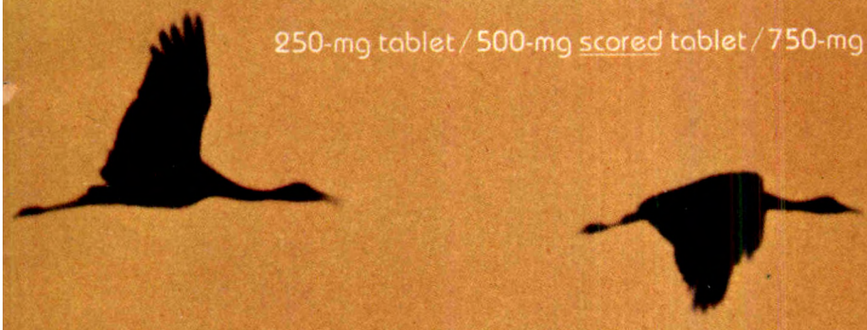
Return to a natural cardiac rhythm

SUSTAINED RELEASE Procan® SR (PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet / 500-mg scored tablet / 750-mg scored tablet



Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

- Administered half as often as conventional oral procainamide
- Wide versatility in cardiac conditions
- Can be used concomitantly with digoxin
- Ideal maintenance therapy

If in the past you have substituted another medication for maintenance therapy because of compliance problems with conventional oral procainamide, now you can logically turn to the modern oral procainamide.

Procan SR... the original sustained-release oral procainamide

PARKE-DAVIS
Division of Warner-Lambert Company
Morris Plains, New Jersey 07950

Please see next page for brief summary of prescribing information.

Procan® SR
(procainamide hydrochloride tablets)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information.
A Brief Summary follows.

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: General —During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia have been reported which may be related to this syndrome.

Laboratory Tests—Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy.

Routine blood counts are advisable during maintenance procainamide therapy.

ADVERSE REACTIONS: Agranulocytosis has occasionally followed the repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS).

Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

DOSAGE AND ADMINISTRATION: Procan SR (procainamide hydrochloride) tablets are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every-three-hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

Ventricular tachycardia—Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dose of 50 mg/kg of body weight given at three hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three-hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

Atrial fibrillation and paroxysmal atrial tachycardia—Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows. An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dose of 0.5 to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

HOW SUPPLIED: Procan SR 250 mg (green, film-coated tablet. P-D 202) is available in bottles of 100 (N 0071-0202-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0202-40). Each sustained-release tablet contains 250 mg procainamide hydrochloride.

Procan SR 500 mg (yellow, scored, film-coated tablet. P-D 204) is available in bottles of 100 (N 0071-0204-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0204-40). Each sustained-release tablet contains 500 mg procainamide hydrochloride.

Procan SR 750 mg (orange, scored, film-coated tablet. P-D 205) is available in bottles of 100 (N 0071-0205-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0205-40). Each sustained-release tablet contains 750 mg procainamide hydrochloride.

Storage—Protect from moisture. Store bottles below 86° F (30° C). Store unit-dose packages at controlled room temperature, 59°-86° F (15°-30° C).

Cardiac Disease After Radiation Therapy for Hodgkin's Disease: Analysis of 48 Patients

MARK M. APPLEFELD, MD, and PETER H. WIERNIK, MD

Occult or overt but delayed cardiac disease after thoracic radiotherapy for Hodgkin's disease may be common. Detailed cardiac evaluations were performed in 48 patients with Hodgkin's disease at risk a mean of 97 months after radiotherapy. The study protocol included echocardiography, gated radionuclide ventriculography, and cardiac catheterization. Cardiac disease was found in 46 patients (96%) and included constrictive or occult constrictive pericarditis (24 patients), an abnormal hemodynamic response to a fluid challenge (14 patients), coronary artery disease (6 patients), and left ventricular dysfunction (2 patients). Most patients (53%) had normal echocardiograms. Gated blood pool radionuclide angiocardiography was performed in 42 patients. Excluding patients with occlusive coronary artery disease, the left ventricular ejection fraction at rest (mean 59%) and during exercise (mean 69%) was within normal limits. Congestive heart failure occurred in 2 patients. Six patients had pericardiectomy for constrictive pericarditis and 3 patients had coronary artery bypass surgery for coronary artery disease. Thus (1) delayed cardiac disease after radiotherapy is common, (2) chronic pericardial disorders are the most frequent manifestations of this disease, and (3) the prognosis for patients who have radiation-induced cardiac disease is generally favorable.

> It is proposed that cardiac damage (from radiation therapy)—particularly acute and chronic pericarditis—is more frequent and significant than is generally recognized.
>
> Cohn et al[1]

After its discovery by Roentgen in 1896, the x-ray was first used to treat Hodgkin's disease (HD) and other lymphomas by Pusey[2] in 1902. Advances in technology with the introduction of x-ray equipment able to deliver progressively higher beam energies, a clearer understanding of the biologic behavior of HD, and the pioneering work of Gilbert[3] and Kaplan[4] in planning appropriate treatment fields and radiation doses have each led to control (and in many patients, cure) of HD. As patients with HD have achieved extended survival, physicians responsible for their care have noted late-appearing complications of its treatment. Thus, hypothyroidism, gonadal insufficiency and sterility, and second malignancies are recognized complications of either radiotherapy alone or of combined radiotherapy-chemotherapy in patients with HD. Although earlier reports called attention to cardiac disease complicating radiation therapy,[1,5] its frequency was uncertain and usually manifested by an effusive pericarditis which uncommonly caused pericardial constriction.[5] Based on previous experience,[6,7] we believed that radiation therapy caused delayed cardiac disease more frequently and initiated a study to test this hypothesis.

From the Department of Medicine (Division of Cardiology), and the University of Maryland Cancer Center, the University of Maryland Hospital, Baltimore, Maryland. Manuscript received December 17, 1982; revised manuscript received February 24, 1983, accepted February 25, 1983.

Method

Of 48 patients studied, 44 are from a cohort of 83 patients with HD who were given mantle radiotherapy before 1977 by either a 4 mV linear accelerator or cobalt-60 source. Details of radiotherapy at other centers were unavailable for 4 patients. In most patients, the technique of "anterior weighting" was used in the mantle. This results in an increased cardiac dose of radiation when compared with current methods.[7] Briefly, an anterior thoracic field of 200 to 250 rads/day for 5 days per week (total mid-plane dose 3,000 to 3,600 rads *or* total anterior dose 4,000 rads) was given over 4 weeks. Either during or after the anterior field, a posterior field was applied, giving a total mid-plane dose of 4,000 rads. Purposeful cardiac shielding was not used in these patients. Indeed, in most of them, 60 to 70% of the cardiac volume received the calculated radiation dose. These 48 patients are seen at the University of Maryland Cancer Center (formerly the Baltimore Cancer Research Center).

These patients were 11 to 60 years old (mean 25) when radiotherapy was given and 18 to 68 years of age (mean 33) when studied 37 to 172 months (mean 97) after the treatment. No patient had other diseases (such as hypertension, connective tissue disorders, prior myopericarditis) known to affect the heart. Thirty patients had chemotherapy (usually nitrogen mustard, vincristine, procarbazine, and prednisone given in 6 monthly cycles) after radiation therapy. Ten patients had an effusive pericarditis during the first 36 months after radiotherapy; 4 required a pericardial window to relieve cardiac tamponade. A viral origin was not confirmed in any of these 10 patients.

Fifteen patients were referred for evaluation of specific cardiac symptoms or signs. These included effort dyspnea (9 patients), angina pectoris and previous myocardial infarction (2 patients each), and an abnormal electrocardiogram and unexplained pleural effusions and hepatomegaly (1 patient each). Thirty-three patients were recruited during their annual evaluation at our center based solely upon their willingness to participate in this study. Of these 33 patients, 18 had mild and 4 had moderate effort dyspnea; 11 were asymptomatic.

The study protocol included M-mode echocardiography (47 patients), equilibrium gated radionuclide angiocardiography (42 patients), and graded treadmill exercise test (2 patients). Right heart catheterizations (usually with a fluid challenge of 1 liter of normal saline solution given intravenously over 8 to 10 minutes[6,8]) were performed in 41 patients; 5 patients had coronary cineangiography. Two patients did not have catheterization. There was no morbidity or mortality from this protocol.

Catheterizations were performed percutaneously after informed consent. Right heart pressures were measured during a rapid pullback (that is, within 10 to 15 seconds) from the pulmonary capillary wedge to right atrium. After catheterization, constrictive pericarditis was diagnosed if there was equalization (within 6 mm Hg) of right heart diastolic pressures and a ratio of pulmonary artery systolic-to-right atrial mean pressure of <3.5 to 1.[9] Most patients also had a dip-plateau configuration in the right ventricular diastolic pressure curve and an absence of respiratory variation in the right atrial mean pressure. Constrictive pericarditis was confirmed at surgery in 6 patients and at autopsy in 1 patient. If right heart diastolic pressures were normal at rest but criteria for constrictive pericarditis were fulfilled after the fluid challenge, occult constrictive pericarditis was diagnosed.[8] If criteria for occult constrictive pericarditis were not met but the diastolic pressures increased by >3 mm Hg after fluid challenge, the hemodynamic response was deemed abnormal.[8] Left ventricular dysfunction was diagnosed when the resting mean pulmonary capillary wedge pressure was elevated (that is, >15 mm Hg) and left ventricular contractility was either regionally or globally abnormal in the absence of angina pectoris or S-T segment depression during exercise. Coronary artery disease was diagnosed by finding coronary artery obstructions (>50%) in 3 patients with angina pectoris and in 1 patient with constrictive pericarditis. In another patient, minor irregularities were found in the right coronary artery 2 months after a proven acute inferior myocardial infarction. Coronary artery disease was suspected in 1 patient who had 2 mm S-T segment depression and left ventricular regional wall motion abnormalities in the absence of chest pain during exercise.

Results

After study, patients were classified as having constrictive or occult constrictive pericarditis, an abnormal hemodynamic response, coronary artery disease, left ventricular dysfunction, or a normal evaluation (Table I). Only 1 patient had more than 1 type of cardiac disease. Thus, among 48 patients with HD, 46 (96%) were found to have cardiac disease when evaluated an average of 97 months after completion of radiotherapy. Of the 2 "normal" patients, 1 had declined cardiac catheterization; the other died from HD and had no cardiac disease evident at necropsy.

Echocardiograms were performed in 47 patients using a 2.25 MHz focused transducer and standard scanning techniques. Paradoxic motion of the interventricular septum was found in 11 patients (23%), 6 with constrictive and 3 with occult constrictive pericarditis. Abnormal diastolic interventricular septal motion was not observed in any patient. A thickened pericardium was noted in 5 patients, 2 each with constrictive and occult constrictive pericarditis and 1 with an abnormal hemodynamic response. Four patients had pericardial effusions; 3 were small and 1 was moderate in size. The echocardiogram was normal in 25 patients (53%).

Forty-one patients had gated radionuclide cardiac studies (Table II). Symptom-limited upright bicycle exercise was performed in 5 patients; it was performed in the supine position (for technical reasons) in 35 patients. One patient had a resting study only. We consider the left ventricular ejection fraction by this technique to be normal if it is ≥45% at rest and if, during exercise, it increases by >8%. The left ventricular ejection fraction was abnormal at rest and during exercise in 7 (17%) patients each. Abnormal resting and exercise gated cardiac studies were present in 3 and 2 patients, respectively, with proven or suspected coronary artery disease. When these 5 patients (in whom abnormal gated cardiac studies might be expected because of their coronary artery disease) were excluded, the left ventricular ejection fractions at rest and during exercise in this patient population were normal (Table II).

Five patients had coronary artery disease; in a sixth, it was suspected when 2 mm S-T segment depression and left ventricular regional wall motion abnormalities developed during exercise. Among the former 5 patients, 4 had high-grade (that is, >75%) coronary artery stenoses. Three had coronary bypass surgery; 2 had a good clinical result and 1 died from sepsis after operation at another center. One patient died from a pulmonary embolus 2 months after an acute myocardial infarction. Marked adventitial fibrosis of the anterior descending and right coronary arteries were noted at necropsy. A fifth patient had minor right coronary artery irregularities and a left ventricular aneurysm 2 months after an acute inferior myocardial infarction..

Of 11 patients with constrictive pericarditis, 6 had a pericardiectomy for disabling effort dyspnea, or right heart failure, or both. The surgical result was good in 3 patients; 2 patients have postoperative hemodynamic findings of visceral pericardial constriction, restrictive cardiomyopathy, or both. One patient died from HD after pericardiectomy. Pericardiectomy was not performed in 5 patients. One patient has died from HD; the other 4 remain stable during a follow-up period extending to 3 years. None of the 13 patients with occult constrictive pericarditis have had pericardiectomy, as their symptoms were not incapacitating.

Discussion

Radiotherapy with or without combination chemotherapy is effective in curing many patients with HD. With the benefit of cure has come increasing recognition of the late-appearing complications arising from the treatment of HD. We believe that delayed-appearing radiation-induced cardiac disease is more common than previously recognized. Thus, we found cardiac disease in 46 of 48 (96%) at risk HD patients who were studied a mean of 97 months after treatment.

It is appropriate to consider whether the method of radiotherapy used in our patients is responsible for their unusually high incidence of cardiac disease. Certainly, a higher cardiac dose[7] of radiation was given when compared with patients treated at other centers where purposeful cardiac shielding[10] or parallel opposing port fields[7] are used. Several comments should be made. First, our radiotherapy method was not unique, that is, other centers used similar methods in the same era. Second, it is uncertain to what extent our treatment method influenced our results. To our knowledge, centers using other radiotherapy methods have neither confirmed nor refuted our findings by an equally detailed cardiac analysis of their patients. Such analyses seem appropriate. Further, at least 3 other reports[11–13] have described significant alterations in cardiac structure, function, or both after radiotherapy.

Some of our patients have abnormal left ventricular contractility by gated blood pool studies. This observation is in keeping with that of others.[12,13] Since constrictive pericarditis does not commonly affect left ventricular contractility, we believe these abnormalities may be indicative of myocardial fibrosis. However, we agree with Brosius et al[11] that clinical consequences of this presumed myocardial fibrosis seem to be unimportant. Whether this observation will remain valid as these patients age is uncertain. Indeed, cardiac changes induced by the aging process[14] may be synergistic with those caused by radiotherapy.[15] In turn, these changes may lead to significant disability among these patients in future years.

Evidence supporting the relation between radiation and cardiac disease in our patients comes from several sources. First, no patient had other diseases known to affect the pericardium or myocardium. Although 10 patients had acute pericarditis after radiation, a viral origin was not confirmed in any of them. Second, 2 patients with coronary artery disease had vascular changes consistent with effects of ionizing radiation. One had intimal proliferation; the other had coronary arterial narrowing by severe adventitial fibrosis. Third, the cardiac disease observed in our patients fits a pattern previously ascribed to radiotherapy.[1,2,10–13] Thus, although evidence *conclusively* linking cardiac disease to thoracic radiotherapy is unavailable in many of our patients, this relationship seems very compelling.

In conclusion, radiation-induced cardiac disease occurs frequently. This is certainly true among patients who have had "anterior weighted" mantle radiotherapy.[16] Whether this will also be the experience in patients treated by parallel opposing port mantle radiotherapy remains to be determined. Preliminary observations at our center are equivocal in this regard. It would seem that purposeful cardiac shielding during the mantle field should reduce the incidence of radiation-induced cardiac disease. This hypothesis has not yet been critically tested. The risk of developing cardiac disease extends for an indefinite period after radiotherapy and it is unknown to what extent the aging process modifies this risk. Pericardial abnormalities remain the most common manifestation of radiation-induced cardiac disease. Altered left ventricular contractility is not rare among such patients, although it seems to be unimportant clinically. Despite the occurrence of abnormalities in cardiac structure and function after mantle radiotherapy, the long-term prognosis for patients who have radiation-induced cardiac disease is generally favorable.

Contrasting Acute Effects of Vasodilators (Nitroglycerin, Nitroprusside, and Hydralazine) on Right Ventricular Performance in Patients With Chronic Obstructive Pulmonary Disease and Pulmonary Hypertension: A Combined Radionuclide-Hemodynamic Study

BRUCE N. BRENT, MD, HARVEY J. BERGER, MD, RICHARD A. MATTHAY, MD, DONALD MAHLER, MD, LINDA PYTLIK, RTNM, and BARRY L. ZARET, MD

Fourteen patients with chronic obstructive pulmonary disease, mild to moderate pulmonary hypertension, and diminished right ventricular (RV) ejection fraction were studied acutely with use of a combined radionuclide-hemodynamic approach to assess and contrast the effects of 3 vasodilators on RV performance and central hemodynamic function. *Nitroglycerin* significantly decreased mean right atrial pressure, RV end-diastolic volume index, mean pulmonary artery pressure, cardiac index, and arterial oxygen tension, but did not affect pulmonary vascular resistance index and increased RV ejection fraction. *Nitroprusside* had similar effects on mean right atrial pressure, RV end-diastolic volume index, mean pulmonary artery pressure, cardiac index, and arterial oxygen tension, but also mildly decreased pulmonary vascular resistance index and did not alter RV ejection fraction. In contrast, *hydralazine* decreased pulmonary vascular resistance index and increased cardiac index and RV ejection fraction. The increase in ejection fraction correlated well with the decrease in pulmonary vascular resistance. These data suggest that in patients with mild to moderate secondary pulmonary hypertension, acute administration of hydralazine results in a substantial improvement in RV performance by virtue of decreasing pulmonary vascular resistance. In contrast, nitroglycerin and nitroprusside demonstrate predominant effects that reduce preload, cardiac index, and arterial oxygen tension. Based on these data, afterload reduction with vasodilators such as hydralazine may be potentially useful in selected patients with pulmonary disease and secondary pulmonary hypertension and appear preferable to agents that primarily reduce preload. Further long-term studies are necessary to establish therapeutic efficacy.

By virtue of altering the loading conditions faced by the left ventricle, vasodilators have been shown to result in direct hemodynamic and clinical benefit in the treatment of patients with left ventricular failure.[1,2] These drugs may exert their primary effect on either the systemic resistance or capacitance vasculature, or both. The effects of vasodilators on right ventricular (RV) performance in patients with pulmonary hypertension and RV dysfunction have not been investigated extensively. To date, studies have focused for the most part on primary pulmonary hypertension and have emphasized measurement of intravascular pressures rather than direct assessment of volumetric changes and RV performance.[3–11] The objective of the present study was to evaluate the effects of 3 vasodilators, each with a different primary mode of action, on RV performance and central hemodynamic function with use of a combined radionuclide and hemodynamic approach. A selected homogeneous group of patients with chronic obstructive pulmonary disease, secondary pulmonary

* Patients with moderate obstructive airway disease; all others had severe airway obstruction.[15] DLCO = diffusing capacity for carbon monoxide; FEV_1 = forced expiratory volume in 1 second; FVC = forced vital capacity; PCO_2 = arterial carbon dioxide tension; % = percent of predicted; PO_2 = arterial oxygen tension; RV = residual volume; SD = standard deviation; TLC = total lung capacity.

hypertension, and decreased resting RV ejection fraction was studied. To assess the acute effects of preload and impedance reduction on the pressure-overloaded right ventricle, the following drugs were administered: *nitroglycerin*, which primarily decreases venous return thereby altering RV preload[11,12]; *hydralazine*, which decreases pulmonary vascular resistance thereby altering impedance to RV ejection[7–9,13]; and *nitroprusside*, a drug with combined effects.[14]

Methods

Patient group: A group of 14 patients with clinically stable chronic obstructive pulmonary disease was studied. Major criteria for inclusion in this study were the demonstration of abnormal right ventricular ejection fraction (<45%) and mild to moderate elevation of mean pulmonary artery pressure (≥20 mm Hg) at rest; both criteria were fulfilled by all 14 patients. Patients were selected from a larger population of well-categorized subjects in a respiratory disease clinic. All had symptoms of dyspnea, but the major factor for initial consideration for study was an abnormal RV ejection fraction at rest. Patients were relatively uniform with respect to hemodynamic and ventilatory characteristics (Tables I to III). Although 2 patients had had a previous episode of right heart failure, all were stable and without clinical evidence of heart failure at the time of study. None had right ventricular hypertrophy by conventional electrocardiographic criteria. No patient had clinical or electrocardiographic evidence of systemic hypertension, valvular heart disease, coronary artery disease, or primary myocardial disease. None manifested clinical or hemodynamic evidence of tricuspid regurgitation as defined by typical auscultatory findings or large V waves in the right atrial pressure tracing, respectively. Three patients had an unexplained mild decrease in left ventricular ejection fraction (45 to 48%, normal ≥55%); the remaining patients had normal left ventricular ejection fraction. Based on pulmonary function testing, 12 patients had severe and 2 moderately severe chronic obstructive pulmonary disease.[15] None had evidence of reversible bronchoconstriction (150 μg of isoproterenol [Isuprel®, Mistometer, Winthrop Laboratories]). Twelve patients were men and 2 women. Their ages ranged from 33 to 77 years (mean 58).

Radionuclide technique: First-pass radionuclide angiocardiograms were obtained with the patient in the anterior position using a computerized multicrystal scintillation camera (Baird-Atomic System-77, Bedford, Massachusetts).[16,17] Six to 10 mCi of high specific activity technetium-99m diethylenetriamine pentaacetic acid was injected into the superior vena cava through the proximal part of a balloon-tipped pulmonary artery catheter. This radioactive tracer is cleared relatively rapidly from the blood pool by renal excretion. Thirty minutes were allowed to pass between placement of the intravascular catheters and the onset of the study, thereby minimizing any potential hemodynamic effects related to anxiety or pain associated with catheter placement. A minimum of 30 to 45 minutes transpired between repeat radionuclide injections. RV and left ventricular ejection fractions were measured from time-activity curves according to standard techniques.[16,17] Reproducibility of these measurements in stable patients is within ± 5% (absolute ejection fraction units) for both right and left ventricular ejection fractions.

Hemodynamic technique: A catheter was placed percutaneously into the radial artery, and a balloon-tipped thermodilution pulmonary artery catheter was passed through an antecubital vein cutdown to the pulmonary artery. Intravascular pressures recorded from the fluid-filled catheters were measured using a Bentley transducer positioned 5 cm below the angle of Lewis and recorded on an Electronics for Medicine recorder (Echo IV). Systolic and diastolic pulmonary artery pressures (PAP) and pulmonary capillary wedge pressures (PCWP) and mean right atrial pressure were measured by averaging pressures over at least 2 respiratory cycles, and mean pressures were obtained by electronic integration. All pressure transducers were "zeroed" to air and calibrations checked with a mercury sphygnomanometer. Cardiac output was measured in triplicate by the thermodilution technique, with injection of iced saline solution and a commercially available microprocessor (Edwards Laboratories, model 9520A). The stated results represent the average of 3 clustered measurements with less than 10% variation. Derived values

P values are derived from paired *t* tests.
$DAaO_2$ = alveolar-arterial oxygen tension difference; H = hydralazine; NP = nitroprusside; PaO_2 = arterial oxygen tension; $PMVO_2$ = mixed venous oxygen tension; other abbreviations as in Table II.

obtained from hemodynamic and radionuclide data either alone or in combination were calculated as follows: cardiac index (liters/min/m²) = cardiac output/body surface area; stroke volume index (ml/m²) = cardiac index/heart rate × 1,000; pulmonary vascular resistance index (dynes·s·cm⁻⁵·m²) = 80 × (mean PAP − mean PCWP)/cardiac index; systemic vascular resistance index (dynes·s·cm⁻⁵·m²) = 80 (mean arterial pressure − mean right atrial pressure)/cardiac index; RV end-diastolic volume index (ml/m²) = stroke volume index/RV ejection fraction; RV end-systolic volume index (ml/m²) = RV end-diastolic volume index − stroke volume index; RV stroke work index (g·m/m²) = mean PAP × stroke volume index × 13.6/1,000.

Arterial and mixed venous oxygen saturations were measured using the Macro Reflexion Oximeter (American Optical,

mm Hg ($p < 0.01$), pulmonary capillary wedge pressure from 14 ± 3 mm Hg to 12 ± 3 mm Hg ($p < 0.05$), systemic arterial pressure from 112 ± 9 to 95 ± 7 mm Hg ($p < 0.001$), pulmonary vascular resistance index from 534 ± 152 to 450 ± 134 dynes·s·cm^{-5}·m^2 ($p < 0.01$) (Fig. 1). Heart rate was unchanged. Cardiac index, RV end-diastolic volume index, pulmonary vascular resistance index, and mean pulmonary artery pressure decreased in each patient. Nitroprusside decreased RV stroke work index (16 ± 5 to 11 ± 4 g·m/m^2, $p < 0.001$). After nitroprusside, there was no significant change in either right or left ventricular ejection fraction (Fig. 2).

Nitroprusside administration resulted in effects on gas exchange similar to nitroglycerin. Nitroprusside widened the alveolar-arterial gradient (35 ± 9 versus 41 ± 11 mm Hg ($p < 0.05$) and decreased arterial oxygen tension from 67 ± 12 to 63 ± 13 mm Hg ($p < 0.025$), and mixed venous oxygen tension from 34 ± 3 to 32 ± 3 mm Hg ($p < 0.025$) (Table III).

Hydralazine (Table V): After administration of hydralazine, there was a significant increase in heart rate from 81 ± 7 to 91 ± 10 beats/min ($p < 0.025$) and an increase in cardiac index from 2.4 ± 0.4 to 4.1 ± 0.7 liters/min/m^2 ($p < 0.05$). The pulmonary vascular resistance decreased substantially from 594 ± 232 to 362 ± 179 dynes·s·cm^{-5}·m^2 ($p < 0.01$); the pulmonary vascular resistance index decreased in all patients (Fig. 1). The decrease in pulmonary vascular resistance index correlated with baseline pulmonary vascular resistance ($r = 0.89$, $p < 0.01$), indicating that the greatest change occurred in those with highest initial levels. There was no significant change in mean right atrial pressure, RV end-diastolic volume index, mean or peak pulmonary artery pressure, or mean pulmonary capillary wedge pressure. RV stroke work index increased from 14.5 ± 4 to 20 ± 7 g·m/m^2 ($p < 0.05$). After administration of hydralazine, there also was a significant decrease in systemic arterial pressure from 110 ± 4 to 91 ± 8 mm Hg ($p < 0.01$).

After hydralazine administration there was a substantial increase in RV ejection fraction from 37 ± 5 to 45 ± 6% ($p < 0.01$) and in left ventricular ejection fraction from 63 ± 15 to 74 ± 13% ($p < 0.005$) (Fig. 2). However, the augmentation in ejection fraction for the right and left ventricles did not correlate ($r = 0.14$), indicating that improvement in RV performance was not dependent on augmentation of left ventricular function. Hydralazine increased the RV ejection fraction in all patients, and the increase in RV ejection fraction correlated well with the change in pulmonary vascular resistance index ($r = 0.89$, $p < 0.01$), but not with the baseline RV ejection fraction ($r = 0.05$) or changes in heart rate ($r = 0.04$). There was no significant correlation with the change in RV ejection fraction and the change in RV end-diastolic volume index ($r = 0.55$, difference not significant). Thus, the increase in RV ejection fraction after hydralazine was related well to the change in pulmonary vascular resistance but was independent of changes in heart rate (suggesting no baroreceptor reflex input) and changes in RV volume. A concomitant increase in stroke work index was observed.

After hydralazine there was no significant change in arterial oxygen tension or the alveolar-arterial oxygen tension gradient. However, there was a significant increase in mixed venous oxygen tension from 34 ± 3 to 39 ± 3 mm Hg ($p < 0.01$) (Table III).

RV stroke work: The interaction of RV stroke work index and end-diastolic volume for each of the 3 vasodilators is illustrated in Figure 3. Although hydralazine resulted in an increase in stroke work with no change in ventricular volume, nitroglycerin and nitroprusside resulted in a decrease in both stroke work and end-diastolic volume.

Discussion

The success encountered in using vasodilators for the treatment of left ventricular failure has increased interest in the application of the same principles and use of some of the same drugs for the treatment of the failing pressure-overloaded right ventricle.[4–11] The results of the present investigation indicate that acute administration of primary arterial vasodilators, such as hydralazine, result in substantial improvement in RV performance by virtue of decreasing pulmonary vascular resistance and impedance to ejection. Furthermore, in contrast to the other vasodilators studied, hydralazine increased mixed venous oxygen tension and did not decrease arterial oxygen tension. When coupled with an increase in cardiac output, this results in an increase in systemic oxygen delivery, a potentially beneficial effect, particularly in this disease state.

In contrast to hydralazine, the effects of nitroglycerin and nitroprusside were less salutary. Both drugs affect a significant reduction in venous return as a result of venous pooling, thereby decreasing preload. Nitroglycerin exhibited no effect on pulmonary vascular resistance, whereas nitroprusside resulted in a modest decrease. Nitroglycerin resulted in a small but significant increase in RV ejection fraction, whereas nitroprusside did not. This improvement in ejection fraction may have been the result of a secondary baroreceptor reflex response rather than a primary effect due to alterations in loading conditions of the right ventricle.

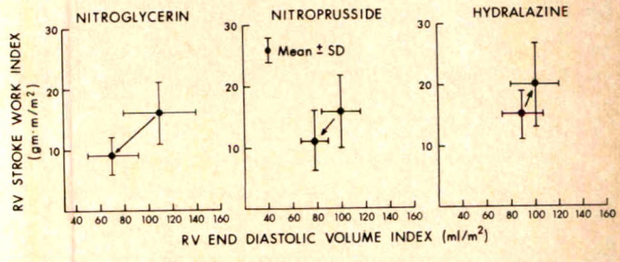

FIGURE 3. Relationship between right ventricular (RV) end-diastolic volume index and right ventricular stroke work index after administration of nitroglycerin, nitroprusside, and hydralazine. Nitroglycerin and nitroprusside produced statistically significant decreases in both right ventricular end-diastolic volume index and stroke work index. In contrast, hydralazine caused no change in right ventricular end-diastolic volume and a significant increment in right ventricular stroke work index. Results are expressed as mean ± standard deviation (SD).

Both nitroglycerin and nitroprusside resulted in a decrease in RV stroke work index and cardiac index. In addition, both agents induced a decrease in arterial oxygen tension and mixed venous oxygen and a widening of the alveolar-arterial oxygen tension difference. This phenomenon, noted previously with both drugs, coupled with a decrease in cardiac output, resulted in a substantial decrease in systemic oxygen delivery,[11,18,19] which may have important deleterious effects.[20]

On the basis of these data, it appears that in selected patients with mild to moderate secondary pulmonary hypertension, pulmonary arterial vasodilators may be potentially useful. This corroborates previous hemodynamic observations of Rubin and Peter[7,8] concerning hydralazine administration in primary pulmonary hypertension and in cor pulmonale both at rest and during exercise. However, not all patients will respond favorably to hydralazine and hemodynamic and functional characterization may help define those who will respond.[9,21] Recently, Lupi-Herrera et al[9] reported on the effects of hydralazine therapy in 12 patients with pulmonary hypertension of unknown cause. They subclassified patients into responders and nonresponders. Of relevance to the present data, hydralazine responders had baseline mean pulmonary artery pressures and resistances that were comparable with those observed in the patients in our study. Pulmonary artery pressure in nonresponders was significantly higher than observed in responders; all responders had baseline mean pulmonary artery pressures $\leq$46 mm Hg, whereas all nonresponders had baseline pressures $\geq$63 mm Hg. Of equal importance, acute hemodynamic results appeared to reflect more long-term effects. The results must be juxtaposed against the recent report of Hermiller et al[22] who noted no beneficial effects from hydralazine in a group of patients with primary pulmonary hypertension.

In contrast, agents with a more prominent preload effect, such as nitrates or nitroprusside, may result in potentially deleterious consequences with respect to both central hemodynamics and oxygen delivery. The latter observations highlight important differences between vasodilator therapy for diseases primarily affecting either the left or right ventricle. These differing therapeutic responses result from differences in the functional anatomy of the 2 chambers, the more marked afterload dependence of the right ventricle, and the basic pathophysiological mechanisms responsible for impaired ventricular performance in these differing disease states.[23–25]

Several additional points deserve emphasis. First, these observations were made only in the acute state. The patients studied were all stable at the time of evaluation and none manifested clinical evidence of significant heart failure. Additional long-term studies in a broader clinical spectrum of patients are necessary to establish therapeutic efficacy and clinical relevance. Second, these observations were obtained only in the resting supine state. It is important as well to demonstrate appropriate therapeutic responses under stress conditions such as exercise. RV ejection fraction may respond inadequately during exercise in patients with chronic obstructive pulmonary disease.[26] Third, vasodilator therapy also can have untoward effects in individual patients with pulmonary hypertension and result in systemic hypotension as well as a drug-induced increase in pulmonary artery pressure. This was demonstrated by Cohen and Kronzon[27] after administration of phentolamine. The mechanism of this phenomenon may involve insufficient pulmonary arterial vasodilation and predominating effects on the systemic circulation with either an uncompensated decrease in systemic vascular resistance, an increase in venous return, or both. Inadequate pulmonary vasodilation may occur when reversible vasoconstriction is not present and advanced pathologic lesions which are pharmacologically insensitive have developed in the pulmonary circulation. Recently, data have been presented indicating that hydralazine may be of little benefit and may frequently result in deleterious effects in patients with moderately severe primary and secondary pulmonary hypertension.[21] Differences between these results and those of our study as well as those of Rubin and Peter[7,8] and Lupi-Hererra et al[9] may be based on patient selection and the specific diseases evaluated. Nevertheless, the administration of vasodilator agents in patients with pulmonary hypertension clearly requires careful monitoring of intravascular pressures and RV performance in order to optimize therapy and detect unsuspected untoward effects. In the resting state, RV pump function correlates well with pulmonary artery pressure.[24] However, as evidenced by the data of this study, drug-induced changes in RV ejection fraction may not always reflect changes in pulmonary artery pressure, resistance, or flow. Ejection fraction may be augmented without a change in pulmonary resistance (as evidenced by the response to nitroglycerin in our patients). Fourth, additional pharmacologic agents may become available for the treatment of both primary and secondary pulmonary hypertension. Recently, Simonneau et al[10] demonstrated that nifedipine inhibits hypoxic pulmonary vasoconstriction in patients with acute respiratory failure. In this laboratory we have shown recently that terbutaline, a beta-2 agonist, exerts favorable effects on RV function similar to hydralazine in patients with pulmonary disease, pulmonary hypertension, and RV dysfunction.[28] These effects can at least in part be related to terbutaline-induced decreases in pulmonary vascular resistance. Clearly, these classes of drugs as well as arterial vasodilators and inotropic agents such as digitalis[29] will require more in-depth follow-up studies.

Reoperation for Isthmic Coarctation of the Aorta: Follow-Up of 26 Patients

PHYLLIS POLLACK, MD, MICHAEL D. FREED, MD, ALDO R. CASTANEDA, MD, PhD, and WILLIAM I. NORWOOD, MD, PhD

Twenty-six patients underwent reoperation for coarctation of the aorta (C of A) between 1972 and 1980. Most patients (73%) had undergone primary repair in infancy. The interval to reoperation was 5 months to 18 years (mean 8.2 years). Indications for reoperation included symptoms in 4, exercise systemic hypertension in 1, electrocardiographic changes of left ventricular strain in 1, arm hypertension in 21, and a C of A gradient at rest >30 mm Hg in all. Surgical procedures included patch aortoplasty (16 patients), bypass graft (6 patients), left subclavian angioplasty (3 patients), and end-to-end anastomosis (1 patient). There were no operative complications or mortality. There was 1 late death from aortic valve disease. Duration of follow-up in the remaining 25 patients was 2 weeks to 7 years (mean 2.5 years). All patients are asymptomatic. C of A gradients were significantly reduced from 30 to 132 mm Hg (mean 56) preoperatively to 0 to 48 mm Hg (mean 15) postoperatively. Right arm systolic blood pressure also was significantly improved from 120 to 237 mm Hg (mean 153) preoperatively to 100 to 160 mm Hg (mean 124) postoperatively. Systemic systolic hypertension persisted in 5 of 25 (20%). It is concluded that C of A reoperation is a low risk procedure that improves symptoms and reduces C of A gradient and arm blood pressure. However, systolic hypertension does not always resolve postoperatively. Patch aortoplasty appears to be a safe and effective surgical approach.

Although repair of isthmic coarctation of the aorta (C of A) is a common and safe procedure, inadequate relief or restenosis is not unusual. Several long-term follow-up studies have documented an incidence of 5 to 11% of persistent or recurrent C of A pressure gradients after primary repair in childhood,[1–4] with a substantially higher incidence, approximately 33%, after repair in infancy.[3–9] In some patients, the residual C of A has required a second operation to relieve the obstruction. The results of reoperation for C of A have been less well documented.[10,11] Therefore, we retrospectively reviewed our experience with reoperation for C of A, specifically assessing the results in terms of successful relief of residual obstruction and systemic hypertension, as well as the morbidity and mortality of reoperation.

From the Departments of Cardiology and Cardiovascular Surgery, Children's Hospital Medical Center, and the Department of Pediatrics, Harvard Medical School, Boston, Massachusetts. Manuscript received November 29, 1982; revised manuscript received March 3, 1983, accepted March 4, 1983.

Address for reprints: Phyllis Pollack, MD, Department of Cardiology, Children's Hospital Medical Center, Boston, Massachusetts 02115.

Methods

Between 1972 and 1980, 26 patients underwent a second operation for repair of C of A at our institution. Patients with complex intracardiac defects or those with interruption of the aortic arch were excluded. The charts were reviewed for the clinical information, catheterization data, and operative notes from both operations. The clinical status, arm blood pressure, and pressure gradients across the C of A before reoperation were recorded. If cardiac catheterization was performed within 6 months before surgery, the C of A gradient was defined as the pullback pressure differential. Otherwise, the C of A gradient was taken as the difference between the right arm and leg cuff pressures recorded immediately preoperatively. Right arm blood pressure and C of A gradients were noted at the time of discharge from the hospital, when available, and at subsequent follow-up visits. Postoperative clinical status was determined from clinic notes. Follow-up treadmill studies and cardiac catheterization results are included, when available.

Patients with right arm systolic blood pressure, on the most recent reading, exceeding the 95% percentile for age[12,13] were considered hypertensive. Statistical significance was evaluated by the t test for paired observations.

Primary repair: Of the 26 patients, 21 had their initial C of A surgery at our institution between 1954 and 1979. Five

* Surgery performed elsewhere.
Δ = pressure gradient between arms and legs; ASD = atrial septal defect; C of A = coarctation of the aorta; D/C = at hospital discharge; LSCA = left subclavian angioplasty; MR = mitral regurgitation; NA = data not available; PDA = patent ductus arteriosus; PPS = peripheral pulmonary stenosis; VSD = ventricular septal defect.

had primary repair performed elsewhere and full details were not always available. Altogether, 6 institutions and 10 different surgeons were involved. The details of the initial repair are summarized in Table I. There were 13 female and 13 male patients aged 6 days to 9 years (mean 2.1 ± 3.0 years) at the time of primary repair. Of the 26 patients, 19 (73%) were operated on at <1 year of age. Associated cardiovascular defects, primarily found in infants, included patent ductus arteriosus (15 patients), ventricular septal defect (9 patients), atrial septal defect (3 patients), mitral regurgitation (1 patient), and peripheral pulmonary stenosis (1 patient). Four of the 7 children who were >5 years of age at the time of primary repair had dysmorphic syndromes (William's syndrome, 2 patients; Turner's syndrome, 2 patients).

Initial surgical repair included resection with end-to-end anastomosis (17 patients), left subclavian angioplasty (3 patients), Blalock-Park procedure (2 patients), bypass graft from ascending to descending aorta (2 patients), and unknown (2 patients). Blood pressure recordings, available on hospital discharge after primary repair in 12 patients, revealed a C of A gradient (≥20 mm Hg) in 8 of 8 infants and in 9 of 12 of the entire group. Several other patients had paired pressures first recorded in follow-up clinic visits. Taken together, these documented a residual gradient ≥20 mm Hg within 6 months of surgery in 13 of 14 infants (93%) and in 17 of 20 of the entire group (85%). The gradients in 3 others were first detected at 6.3, 7.0, and 8.0 years postoperatively. Serial follow-up data were unavailable in the remaining 6 patients.

Reoperation: The details of reoperation are summarized in Table II. Age at reoperation ranged from 5 months to 20.8 years (mean 10.3 ± 6.2 years). The interval between the 2 operations was 5 months to 17.6 years (mean 8.2 ± 5.0 years). There was no difference in the interval to reoperation in the infant group (8.0 ± 5.5 years) versus the older children (8.7 ± 3.8 years).

The indications for reoperation in patients >1 year of age were symptoms in 3 (headaches in 2, claudication in 1), electrocardiographic changes of left ventricular strain in 1, exercise hypertension in 1, and upper extremity hypertension with a gradient of ≥30 mm Hg in the remaining 17. Reoperation was performed within the first year of life in 4 patients because of severe systolic hypertension (>200 mm Hg) in 3 and congestive heart failure in 1.

Cardiac catheterization and angiography were performed in 25 patients preoperatively and revealed discrete narrowing in 20, a long segment C of A in 2, multiple discrete areas of narrowing in 1, acquired isthmic aortic atresia in 1, and no discrete narrowing in 1.

Surgical approaches for secondary repair included patch angioplasty (16 patients), bypass graft (6 patients), left subclavian angioplasty (3 patients), and end-to-end anastomosis (1 patient). There were no operative complications or mortality.

Results

Follow-up: Follow-up results of reoperation are summarized in Table III. There was 1 late death from aortic regurgitation (case 20) 7 years after C of A reoperation. Follow-up in the remaining 25 patients ranged from 2 weeks to 7 years (mean 2.5 ± 2.2 years). All symptoms that were present preoperatively resolved. One patient developed mild hoarseness. The electrocardiographic changes of left ventricular strain that were present preoperatively in 1 individual persisted postoperatively.

Follow-up catheterization was performed in 3 patients primarily to evaluate associated congenital heart defects. Interestingly, one patient (patient 6) was found

to have a C of A proximal to the left subclavian artery that was not present on the angiogram before reoperation.

Coarctation gradient: The change in the C of A gradient from the preoperative period to the most recent follow-up examination is diagrammed in Figure 1. Preoperative C of A gradients at rest ranged from 30 to 132 mm Hg (mean 56 ± 26). On follow-up, the gradients were significantly reduced to 0 to 48 mm Hg (mean 15 ± 15), $p < 0.001$. There was a trivial resting gradient (0 to 10 mm Hg) in 10 (40%), a mild residual gradient (11 to 20 mm Hg) in 9 (36%), and a moderate residual gradient (30 to 48 mm Hg) in 6 (24%). The gradient was improved in 23, unchanged in 1, and increased in 1. Five of the 6 patients with moderate residual gradients underwent patch aortoplasty procedures, but this association was not significant because 16 of 26 patients (62%) in this series had this type of secondary repair.

Although the follow-up period is still relatively short (mean 2.5 ± 2.2 years), there has been no significant change in the postoperative C of A gradients from the time of hospital discharge (mean 11.6 ± 11.0 mm Hg) to the latest follow-up evaluation (15.3 ± 14.5 mm Hg). Gradients assessed during this period actually decreased in 9, increased in 11, and were unchanged in 3.

Hypertension: The distribution of systolic blood pressure in the preoperative period and on the most recent follow-up examination are diagrammed in Figure 2, showing age-adjusted norms. Systolic blood pressure in the right arm preoperatively ranged from 120 to 237 mm Hg (mean 153 ± 30). On follow-up, the pressures were significantly reduced, ranging from 100 to 150 mm Hg (mean 124 ± 14), $p < 0.005$. Although improved, systolic hypertension persisted in 5 of 25 (20%). Three patients continue to be treated with antihypertensive medications. The follow-up C of A gradients in the 5 hypertensive patients were 0, 2, 16, 20, and 30 mm Hg. Therefore, 2 patients have remained hypertensive despite no residual C of A gradient.

Discussion

Age distribution: In the past decade, several long-term follow-up studies have substantiated the problem of persistent or recurrent C of A after initial repair. The reported incidence has been 5 to 11% in children who had repair beyond the first year of life.[1–4] The incidence is substantially higher in the infant group (0 to 60%),[3–9] with most figures clustering about 20 to 36%. Thus, it is not surprising that reoperation is more commonly performed in children whose initial repair was performed during infancy. Infants comprised 73% of the patients in our series and 68% among the 44 children in 7 previously reported series[10,11,14–18] of reoperation for C of A.

In our series, no patients were between 1 and 5 years of age at the time of primary repair. This finding most likely reflects our experience that there is a bimodal distribution of surgery with infants with complicated coarctations frequently requiring surgery in the first year because of refractory congestive heart failure and the remainder electively repaired before starting school.

Causes of residual gradient: The residual obstruction found in postoperative coarctation patients has been attributed to several different causes, including inadequate relief, retention of abnormal ductal tissue,[13,29] insufficient growth of the anastomotic site,[22,23] fibrosis of the suture line,[23] and thrombosis and calcification of bypass grafts. Histologic data are unfortunately lacking because resection of the coarctation segment is rarely performed at the time of reoperation. Further discussion of etiologic factors remains essentially speculative on the basis of the chronologic reappearance of the coarctation gradient after the initial repair.

Multiple mechanisms are probably involved. The follow-up data that were available from the first operation documented a C of A coarctation gradient at hospital discharge in 9 of 12 patients (75%) of our group and within 6 months in 17 of 20 (85%). This finding suggests that the residual gradient was due in part to inadequate relief. The majority of these early gradients continued to increase substantially with time, suggesting progressive fibrosis or inadequate growth of the suture line, or both, as contributing factors.

Of some interest is that 57% of the children who were >5 years of age at the initial repair and required reoperation had either Turner or William's syndrome. Perhaps there is an intrinsic defect in the vascular connective tissue elements in these individuals that predisposes them to recurrent problems with C of A.

Residual hypertension: There has been much concern about residual hypertension after primary C

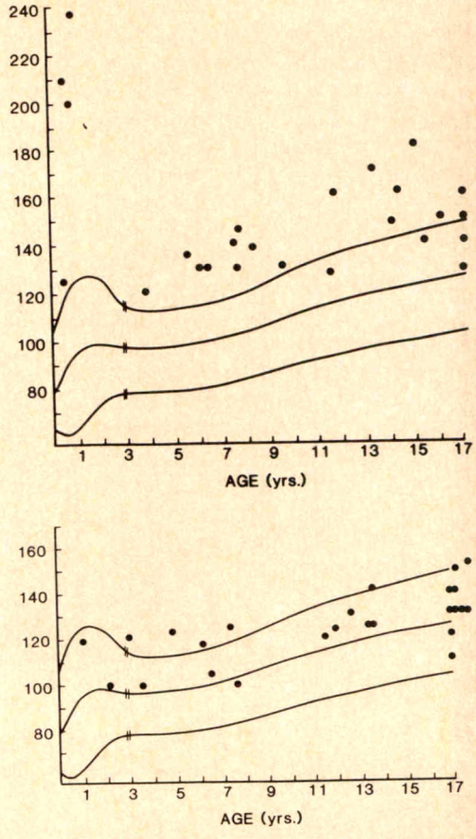

FIGURE 2. Top, arm systolic blood pressure at rest before reoperation for coartation of the aorta. Percentiles (5-50-95) are based on data of Nadas and Fyler[13] for 0 to 3 years of age and those of the National Institutes of Health Task Force[12] for those >3 years of age. **Bottom,** arm systolic blood pressure at rest on follow-up evaluation after reoperation for coarctation of the aorta.

of A repair. Figures for persistent hypertension, unexplained by a residual C of A coarctation gradient, vary with age of repair and duration of follow-up and have been reported at 8.4,[1] 12.3,[3] and 31%.[19] Unfortunately, different norms and cutoffs have also been applied. Liberthson et al[20] showed that persistent postoperative hypertension was progressively more common in patients who had repair at advancing ages from early childhood through adulthood. Nanton and Olley[2] demonstrated that in children aged 1 to 15 years, the earlier the age at operation, the greater the reduction in blood pressure.

In this series, after reoperation for C of A, 5 patients (20%) have persistent systolic hypertension. However, this does not correlate with age at primary or secondary repair. All 5 of these patients had initial repair in infancy (mean age 0.31 ± 0.37 years), with the interval to reoperation (4.7 ± 2.8 years) being shorter than that for the entire group (8.2 ± 5.0 years). The persistent hypertension cannot always be explained by residual hemodynamic obstruction. The mean gradient for these 5 patients was 13.6 ± 12.6 mm Hg as opposed to a mean of 15.3 ± 14.5 mm Hg for the entire group. There were no significant differences in preoperative blood pressure or C of A gradient or in the type of surgical repair. The only other long-term follow-up study on reoperation[10] reported a 29% incidence of postoperative hypertension.

Exercise testing: Exercise testing is useful in evaluating results after primary repair of C of A.[21] In this series, 8 patients had exercise studies after reoperation. Seven had graded treadmill studies according to the standard Bruce protocol, with arm and leg cuff pressures assessed immediately after peak exercise. The other was exercised during cardiac catheterization with the ergometer bicycle with the patient in the supine position. All 8 patients had a significant increase in C of A gradients, including the 3 individuals with no demonstrable gradient at rest. In addition, 2 patients had significant systolic hypertension of 190 and 210 mm Hg. Exercise testing can provide valuable information in counseling such patients to avoid strenuous activity.

Surgical results: Previously reported mortality rates for reoperation in C of A differ widely, but appear to be improving with time: Cerilli and Lauridsen 50% (1965),[18] Khoury and Hawes 17% (1968),[7] Ibarra-Perez et al 15% (1969),[11] Tawes et al 10% (1969),[8] Castaneda and Norwood 7.3% (1979),[16] and Beekman et al 4.8% (1982).[10] There was no morbidity or mortality in this series. (The previously published series by Castaneda combines his experience from 2 institutions and therefore has some overlaps with this series.)

Different approaches have been proposed for repair of coarctation of the aorta including resection,[22] patch aortoplasy,[23] bypass grafting,[24] and left subclavian angioplasty.[25] Balloon dilatation has recently been proposed as an alternative approach. Although transluminal angioplasty was reportedly successful in 1 infant with restenosis after C of A repair,[26] experimental studies question its feasibility.[27] Thus far, we have had no experience with this technique. Because of the theoretical problem of limited growth of circumferential suture lines, we currently favor the use of subclavian angioplasty in primary repair of C of A in neonates and infants and a Dacron® patch aortoplasty in older children. The approach to reoperation is primarily governed by anatomy. This series demonstrates that patch aortoplasty, when feasible, gives satisfactory results with low mortality. Because of potential long-term problems associated with patch grafting,[23] further follow-up is important.

Acknowledgment: We would like to thank Ann Marie Carpenito and Emily Flynn for their assistance with the graphics for the tables and figures.

Subxyphoid 2-Dimensional Echocardiographic Identification Of Left Ventricular Papillary Muscle Anomalies in Complete Common Atrioventricular Canal

ALVIN J. CHIN, MD, FREDRICK Z. BIERMAN, MD, STEPHEN P. SANDERS, MD, ROBERTA G. WILLIAMS, MD, WILLIAM I. NORWOOD, MD, PhD, and ALDO R. CASTANEDA, MD, PhD

Mitral valve dysfunction is probably the major cause of operative mortality from total repair of complete common atrioventricular (AV) canal in infancy. The presence of a solitary left ventricular (LV) papillary muscle appears to be 1 anatomic factor influencing the success of mitral reconstruction because suturing of the cleft between the superior and inferior components of the anterior mitral leaflet creates a parachute mitral valve deformity, which may result in stenosis or in unduly high tension on the components of the repair. This study reports on (1) the 2-dimensional (2-D) echocardiographic appearance of the LV papillary muscle architecture in patients with complete common AV canal compared with that in normal subjects, and (2) the incidence of solitary LV papillary muscle in patients with complete common AV canal.

Two-dimensional echocardiography was performed in 31 infants with complete common AV canal, 14 normal infants, and 9 infants with a large ventricular septal defect not involving the AV canal region. Of 31 infants with complete common AV canal, 26 (80%) had 2 LV papillary muscles on 2-D echocardiography, 3 (10%) had 3 LV papillary muscles, and 3 (10%) had 1 LV papillary muscle. In patients with 2 LV papillary muscles, the anterolateral papillary muscle was displaced posteriorly compared with that in normal subjects and in patients with ventricular septal defect, whereas the posteromedial papillary muscle was in its normal location.

Among the 25 patients with complete common AV canal with 2 LV papillary muscles, there was 1 operative death. Among the 6 infants with complete common AV canal with LV papillary muscle anomalies, 5 underwent surgical repair with 4 early deaths.

Subxyphoid 2-D echocardiography is a useful technique for evaluating LV papillary muscle architecture in complete common AV canal and permits identification of patients who may be at higher risk for unsuccessful mitral reconstruction.

The operative mortality rate for repair of complete common atrioventricular (AV) canal in patients <2 years of age is 17 to 25%.[1–6] Mitral valve dysfunction is probably the major cause of early postoperative death.[6] At least 4 anatomic factors influence the success of mitral valve reconstruction in complete common AV canal: quantity of AV valve leaflet tissue, the alignment of the common AV valve in relation to the ventricles, the presence or absence of double orifice mitral valve, and the presence or absence of a solitary left ventricular (LV) papillary muscle.[6] Preoperative detection of solitary LV papillary muscle should alert the surgeon to avoid extensive suturing of the "cleft" between the superior and inferior components of the anterior mitral leaflet which results in a parachute mitral deformity.[7,8] Intraoperatively, it is often difficult to examine the LV papillary muscle architecture from the left atrium.

This study reports on (1) the 2-dimensional (2-D) echocardiographic appearance of the LV papillary muscles in complete common AV canal as compared with normal, and (2) the frequency of LV papillary muscle anomalies in patients with complete common AV canal.

Material and Methods

Between January 1, 1977 and July 30, 1980, subxyphoid 2-D echocardiography was performed in 31 patients with the diagnosis of complete common AV canal confirmed at surgery (30) or autopsy (1). Two independent observers reviewed the examinations retrospectively along with those of 14 patients with no known cardiovascular disease (normal control subjects) and 9 patients with nonrestrictive ventricular septal defect confirmed at cardiac catheterization; this defect was confirmed at operation to be conoventricular, membranous, or muscular in location (morbid control subjects).

The 31 patients with complete common AV canal, aged 1 day to 13 months (median 4 months), included 27 with Down's syndrome. None of the 14 normal control subjects (aged 1 day to 22 months [median 17 days]), or the 9 morbid control subjects (aged 7 days to 13 months [median 2 months]) had Down's syndrome.

Subxyphoid 2-D echocardiography was performed using a Picker Echoview 80 CI system with a mechanical sector scanner. The intracardiac structures were displayed with a 45 to 60° sector angle and an image rate of 45 to 60 frames/s. All studies were performed with either a 5 mHz short-focus or 3.5 MHz medium-focus crystal with a 13-mm active element diameter.

The LV papillary muscle architecture was displayed in a subxyphoid transverse plane at the first appearance of the papillary muscles on the base to apex sweep. The number of LV papillary muscles was assessed at this level (chordal-papillary muscle junction) in all patients. The position of the center of each papillary muscle as well as the endocardial position of the anterior and posterior junctions of the ventricular septum with the LV free wall were marked on an acetate overlay for 3 consecutive cardiac cycles at end-diastole (Q wave in the electrocardiogram) (Fig. 1). From these tracings, a perpendicular from the mid-point of the chord connecting the anterior and posterior septum-LV free wall junctions was constructed as a reference line. Lines were then constructed from the origin of the reference line to the centers of the papillary muscles, and the angles between these lines and the reference line were determined (Fig. 2). Angles above the reference line were expressed as negative values and angles below the reference line as positive values. The angles were used as an index of the positions of the papillary muscles on the LV free wall.

All measurements were made by 2 independent observers to assess interobserver variability.

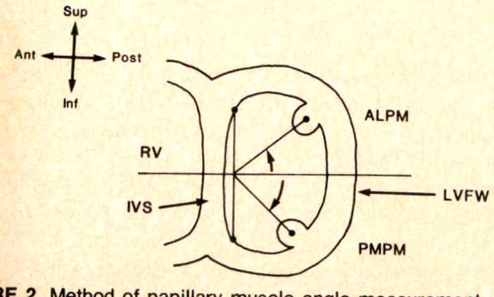

FIGURE 2. Method of papillary muscle angle measurement. A perpendicular passing through the midpoint of the chord connecting the ventricular septum-left ventricular free wall (LVFW) junctions served as a reference line. Lines between the origin of the reference line and the centers of the papillary muscles were then constructed. Angles **(unlabeled arrows)** between these lines and the reference line were determined; angles above the reference line were expressed as negative values, and angles below the reference line as positive values. IVS = interventricular septum; RV = right ventricle; other abbreviations as in Figure 1.

Results

Number of LV papillary muscles: In all cases, the findings of the 2 observers were concordant regarding the number of LV papillary muscles. Of the 31 patients with complete common AV canal, 25 had 2 LV papillary muscles on 2-D echocardiography, 3 had 3 LV papillary muscles, and 3 had a solitary LV papillary muscle (Fig. 3). All 14 normal patients and all 9 patients with ventricular septal defect had 2 LV papillary muscles.

Surgical or autopsy confirmation of the LV papillary muscle anatomy was available in all 3 patients with solitary LV papillary muscle seen on 2-D echocardiography. Of the 3 patients with 3 LV papillary muscles on 2-D echocardiography, there was postmortem confirmation in 2 and no record of surgical observations in the survivor. Of the 25 patients with complete common AV canal with 2 LV papillary muscles on 2-D echocardiography, none of the operative notes for the 23 survivors of repair comment on LV papillary muscle architecture. Autopsy confirmed the presence of 2 LV papillary muscles in the 2 who died.

Positions of left ventricular papillary muscles: The position of the LV papillary muscles could be determined in all 14 control patients and in 21 of the 31 patients with complete common AV canal. In the re-

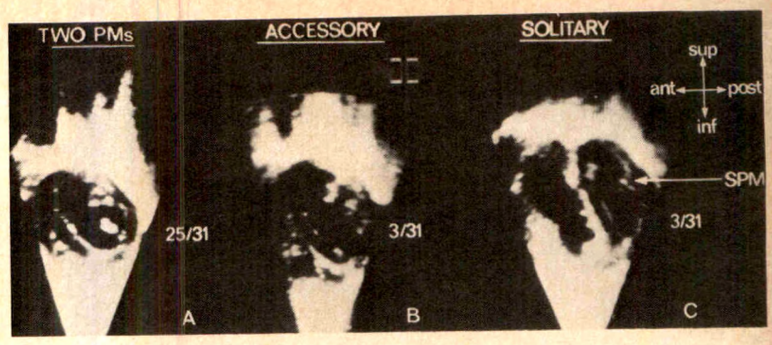

FIGURE 3. Two-dimensional echocardiograms demonstrating the 3 basic types of left ventricular (LV) papillary muscle (PM) morphology in complete common atrioventricular canal. **A,** in patients with complete common atrioventricular canal with 2 LV papillary muscles, the anterolateral papillary muscle is shifted posteriorly and inferiorly compared with that in normal subjects. See also Figure 4. **B,** complete common atrioventricular canal with 3 LV papillary muscles. **C,** complete common atrioventricular canal with solitary LV papillary muscle (SPM). The position of the SPM corresponds closely to the position of the anterolateral papillary muscle in patients with complete common atrioventricular canal and 2 LV papillary muscles.

maining patients with complete common AV canal, the anterior and posterior septum-LV free wall junctions could not be seen simultaneously on an end-diastolic stop frame, making construction of a reference line impossible.

Fifteen of the 21 patients with complete common AV canal in whom LV papillary muscle positions could be measured had 2 LV papillary muscles. The angle of the anterolateral papillary muscle was $-14° \pm 5°$ (mean ± standard deviation), whereas the angle of the posteromedial papillary muscle was $49° \pm 14°$.

The anterolateral papillary muscle position in the 14 normal patients was $-36° \pm 15°$; the posteromedial papillary muscle position was $+44° \pm 9°$.

The anterolateral papillary muscle position in the 9 patients with ventricular septal defect was $-26° \pm 9°$; the posteromedial papillary muscle position was $+44° \pm 11°$.

The maximum difference between the 2 observers for any measurement was 17°, with 92% of the measurements differing by $\leq 10°$.

The anterolateral papillary muscle in patients with complete common AV canal with 2 LV papillary muscles is shifted posteriorly when compared with that in normal subjects ($p < 0.001$, 2-tailed test) or in patients with large ventricular septal defect ($p < 0.001$) (Fig. 4). The position of the posteromedial papillary muscle in patients with complete common AV canal was not significantly different from that in normal subjects ($0.05 < p < 0.10$) or in patients with large ventricular septal defect ($p > 0.10$).

The position of the LV papillary muscles in the 3 patients with complete common AV canal with 3 LV papillary muscles was determined by the same technique. The position of the most superior LV papillary muscle was $-34°$, $-24°$, and 0° in these 3 patients. The position of the "middle" LV papillary muscle was +13°, +8°, and +21°, respectively. The position of the most inferior LV papillary muscle was +41°, +58°, and +38°, respectively.

In the 3 patients with complete common AV canal with solitary LV papillary muscle on 2-D echocardiography, the positions of the papillary muscles were +5°, +9°, and +25°. Thus, the position of the solitary LV papillary muscle corresponds closely to the position of the anterolateral papillary muscle in patients with complete common AV canal with 2 LV papillary muscles (Fig. 3).

Clinical course: Of the 3 patients with complete common AV canal with solitary LV papillary muscle, 1 died during induction of anesthesia before operation. (All other infants with complete common AV canal in this series underwent complete repair including suture of the cleft between the superior and inferior components of the anterior mitral leaflet.) The other 2 patients died early postoperatively. One acutely developed severe mitral regurgitation and died despite emergency mitral valve replacement; the other patient died from LV failure due to LV hypoplasia which was not recognized antemortem. Mild mitral stenosis was documented at early postoperative catheterization. All 3 of the patients with solitary LV papillary muscle had deficient left lateral leaflet tissue, verified by autopsy or surgical observation.

In 1 of the 3 patients with complete common AV canal with 3 LV papillary muscles, the LV papillary muscles coalesced toward the apex into a common base on the LV free wall. This arrangement theoretically functionally approximates a solitary LV papillary muscle. This patient died 10 days after repair because of disruption of the mitral cleft closure confirmed at autopsy. Of the other 2 patients with 3 LV papillary muscles, 1 died after acutely developing severe mitral regurgitation; autopsy revealed partial dehiscence of the anterior mitral leaflet from the septal patch. The remaining patient is alive and apparently well.

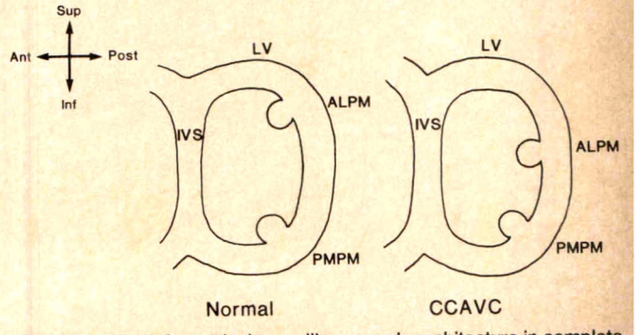

FIGURE 4. The left ventricular papillary muscle architecture in complete common atrioventricular canal (CCAVC) as compared with that in normal subjects. The anterolateral papillary muscle (ALPM) is shifted posteriorly and inferiorly in the CCAVC, whereas the posteromedial papillary muscle (PMPM) is in its usual location. LV = left ventricle; other abbreviations as in Figures 1 and 2.

Among the 25 patients with complete common AV canal with 2 LV papillary muscles, there was 1 operative death and 1 late death. Postmortem examination in both patients demonstrated that the mitral valve reconstruction was intact and did not appear stenotic or regurgitant.

Discussion

Axial angiography using the hepatoclavicular projection[9] has improved our preoperative delineation of several anatomic features relevant to complete common AV canal repair: alignment of the common AV valve in relation to the ventricles, the presence or absence of ventricular hypoplasia, and additional muscular ventricular septal defects. The projection orthogonal to the hepatoclavicular projection outlines the LV papillary muscles in some cases, but adequate visualization cannot always be achieved because of torrential shunting of contrast medium across the ventricular septal defect.

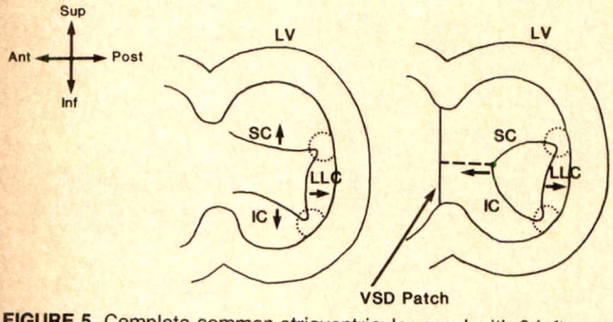

FIGURE 5. Complete common atrioventricular canal with 2 left ventricular papillary muscles pre- and postoperatively. Diagram of a transverse view during diastole at the level of the atrioventricular valve leaflets, the free margins of which are represented by the **solid line.** The papillary muscles are represented by **dotted lines** because they would be visualized in a transverse view at a different level. **Left,** preoperatively, the superior cushion (SC) and inferior cushion (IC) components of the common atrioventricular valve move superiorly and inferiorly, respectively, during valve opening. **Right,** suturing of the cleft during repair converts a trileaflet valve to a bileaflet valve. The 2 components of the anterior mitral leaflet now move anteriorly as a unit during valve opening. The motion of the left lateral cushion (LLC) is undisturbed. VSD = ventricular septal defect; other abbreviations as before.

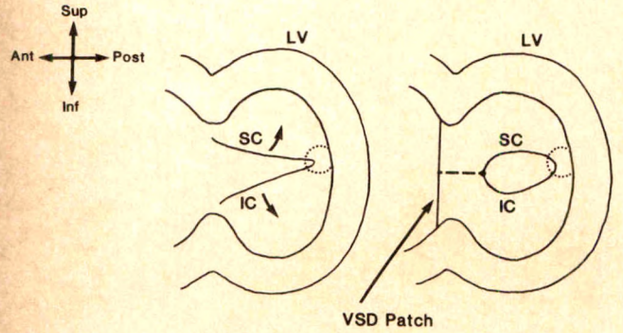

FIGURE 6. Complete common atrioventricular canal with solitary left ventricular papillary muscle pre- and postoperatively. Diagram of a transverse view, during diastole, at the level of the atrioventricular valve leaflets. **Left,** preoperative pattern of movement. The superior cushion (SC) and inferior cushion (IC) components of the common atrioventricular valve move superiorly and inferiorly, respectively, during valve opening. **Right,** suturing of the cleft during repair converts a bileaflet valve to a unileaflet valve (parachute mitral deformity). Abbreviations as before.

Subxyphoid 2-D echocardiography is a useful technique for identifying solitary LV papillary muscle in infants with complete common AV canal. There have not been any false positive diagnoses of solitary LV papillary muscle by 2-D echocardiography because in all such cases surgical observation or autopsy, or both, confirmed the findings. We cannot evaluate the false-negative rate of detecting solitary LV papillary muscle by 2-D echocardiography because all but 2 of the patients with 2 LV papillary muscles on 2-D echocardiography are still alive, and the LV papillary muscle architecture was not commented on in any of the operative reports of these survivors. A prospective series will be needed with systematic surgical observations in order to define the true incidence of solitary LV papillary muscle.

The significance of solitary LV papillary muscle in complete common AV canal lies in the observation that extensive suturing of the "cleft" between the superior and inferior components of the anterior mitral leaflet results in a parachute mitral deformity.[7,8] Suturing of this cleft in complete common AV canal patients with 2 LV papillary muscles converts a "trileaflet" valve into a "bileaflet" valve. The 2 components of the anterior mitral leaflet, which move apart in a superoinferior direction preoperatively, move as a unit in an anteroposterior direction postoperatively. (The motion of the lateral leaflet is undisturbed.) (Fig. 5). In patients with complete common AV canal with a solitary LV papillary muscle, suturing of the cleft converts a functional bileaflet valve to essentially a unileaflet valve (Fig. 6). Whether this parachute mitral deformity results in stenosis or in unduly high tension on the components of the repair should theoretically depend on how extensively the cleft is sutured. Acutely increasing the tension on leaflet tissue or drastically altering the distribution of tension may be major causes of dehiscence of the mitral reconstruction in the early postoperative period. Among the 5 patients with complete common AV canal and LV papillary muscle anomalies who underwent surgery, 4 died in the early postoperative period. Three of the deaths were due to the acute development of severe mitral regurgitation. It is possible that in patients with LV papillary muscle anomalies, dehiscence of the mitral reconstruction may actually be a more common surgical sequela than stenosis.

Carpentier[7] advocated leaving the cleft unsutured, thus preserving the geometry of the pattern of movement of the superior and inferior components of the anterior mitral leaflet and thereby presumably minimizing tension on the reconstructed region. Whether the mitral valve in patients with solitary LV papillary muscle can be satisfactorily repaired by leaving the cleft unsutured is unknown; late postoperative cardiac catheterization data in infants with solitary LV papil-

lary muscle repaired without cleft suture are not yet available.

This study also demonstrates that the anterolateral papillary muscle is situated more posteriorly in patients with complete common AV canal than in normal infants. This posterior displacement is not merely due to the presence of a LV volume overload because the anterolateral papillary muscle in patients with large ventricular septal defect not involving the AV canal region was not displaced posteriorly. The position of the posteromedial papillary muscle in patients with complete common AV canal does not appear to be different from that in normal subjects. Therefore, in patients with complete common AV canal with 2 LV papillary muscles, the interpapillary muscle angle is smaller than normal. Because papillary muscles are situated at the base of the valve commissures, the interpapillary muscle angle is an indicator of the size of the left lateral leaflet component (Fig. 4). Thus, the small interpapillary muscle angle in patients with complete common AV canal suggests that the left lateral leaflet is relatively small in such patients with 2 LV papillary muscles and is likely to be very poorly developed in those with complete common AV canal and solitary LV papillary muscle (interpapillary muscle angle, 0°).

Finally, although preoperative 2-D echocardiography appears to permit identification of LV papillary muscle anomalies in patients with complete common AV canal, the technique of intraoperative 2-D echocardiography promises to yield even better detail of the LV papillary muscle architecture.

Acknowledgment: We thank Jane Newburger, MD, for help with the statistical analysis, Barbara Cesaro and Ann Marie Carpenito for secretarial assistance, and Emily Flynn for her contributions to the graphics.

INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal.* All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

Journal: Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.

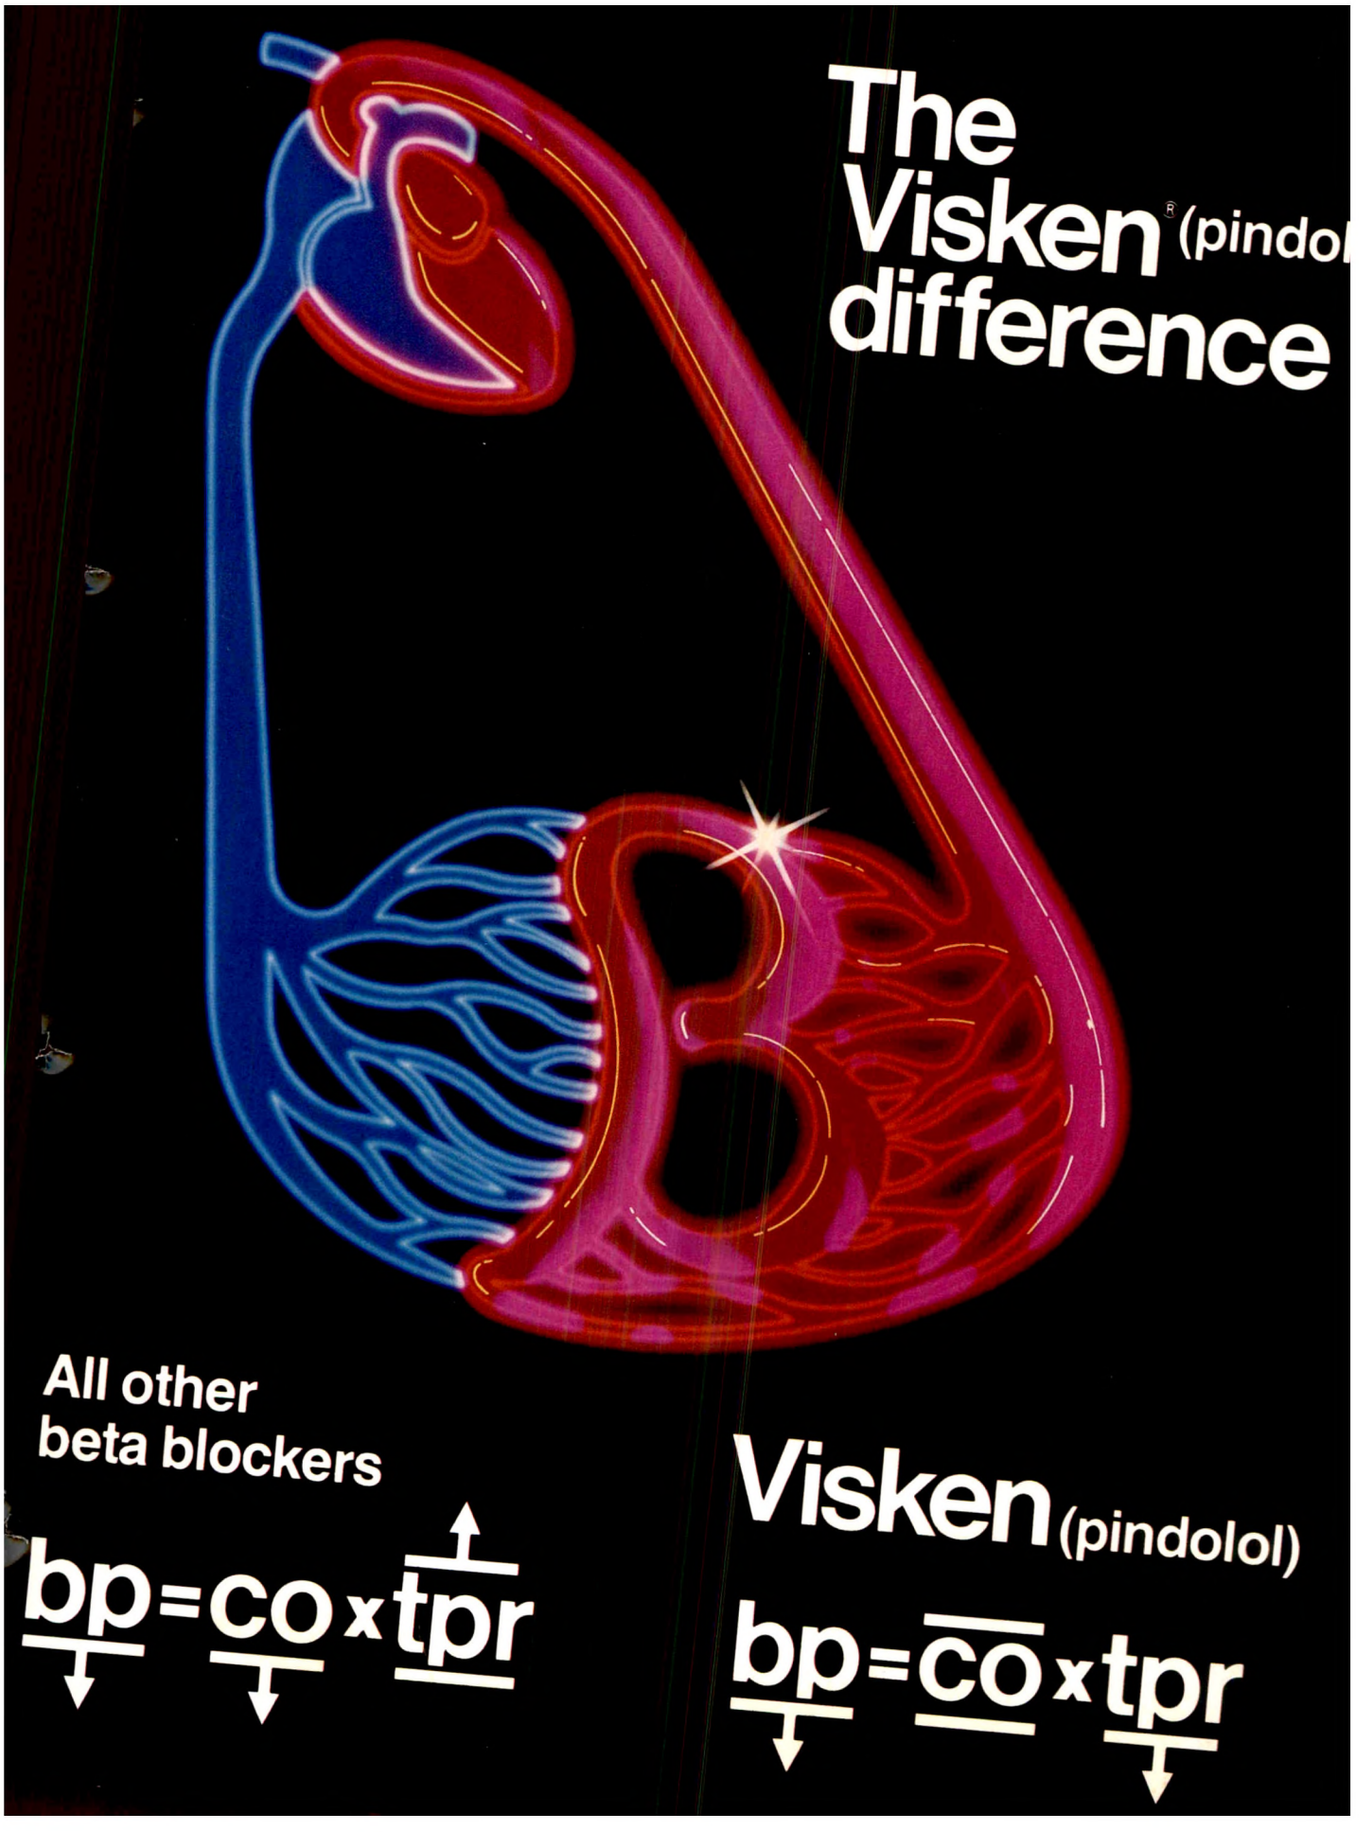
Chapter in Book: Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.

Book: Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

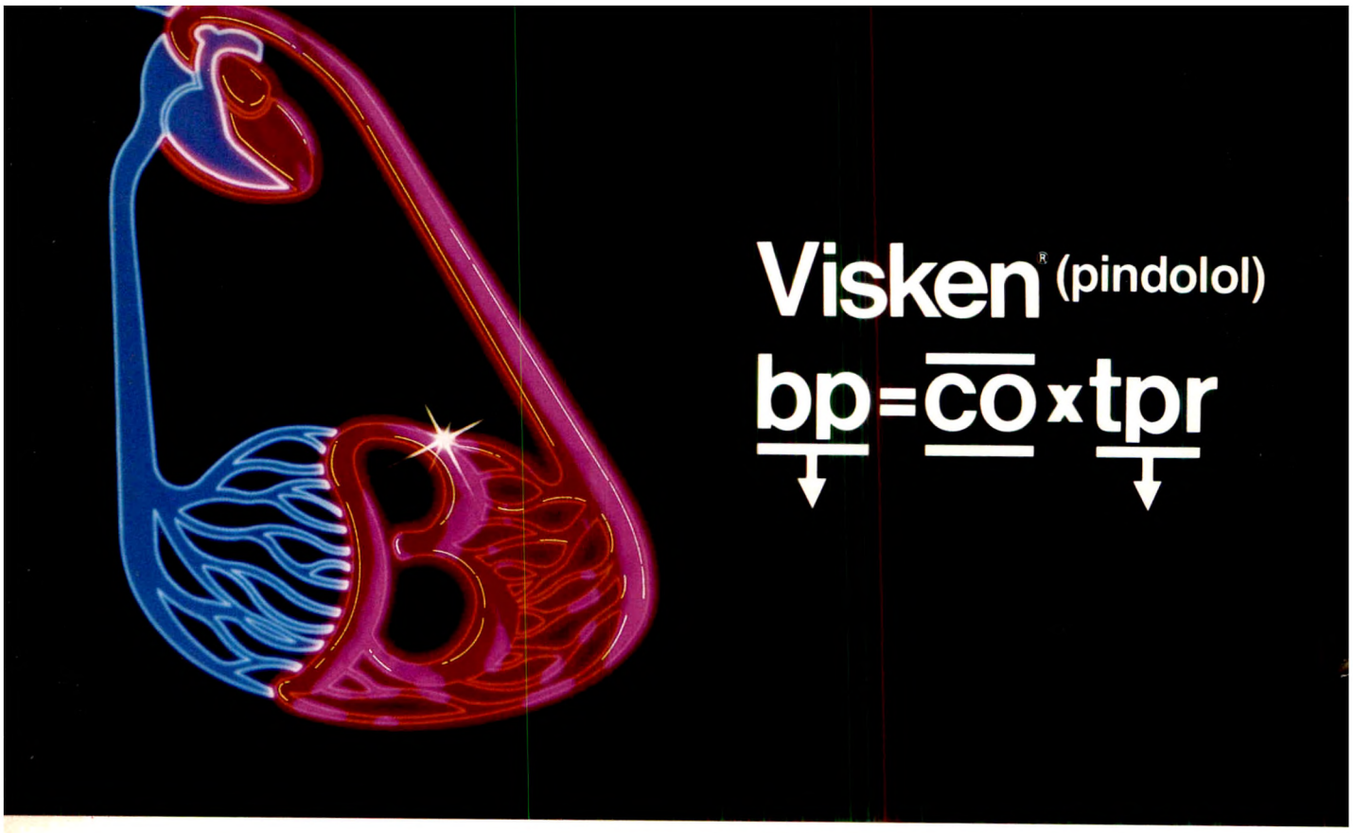
FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.



The Visken® (pindol difference
All other beta blockers
bp = co x tpr
Visken (pindolol)
bp = co x tpr



Makes hemodynamic sense in the treatment of hypertension

Reduces blood pressure

It's as effective as propranolol in normalizing blood pressure (dbp ≤ 90 mmHg) when used alone. It's also effective when used in combination with a diuretic.[1]

Has little effect on resting cardiac output

Unlike other beta blockers, Visken (pindolol) maintains resting cardiac output during long-term therapy. The clinical significance of this has not been evaluated.

Reduces total peripheral resistance*

Visken (pindolol) reduces one of the recognized components of hypertension: increased peripheral resistance.* Studies of 178 patients treated with Visken (pindolol) for at least two weeks have shown that Visken therapy reduces total peripheral resistance.[1]

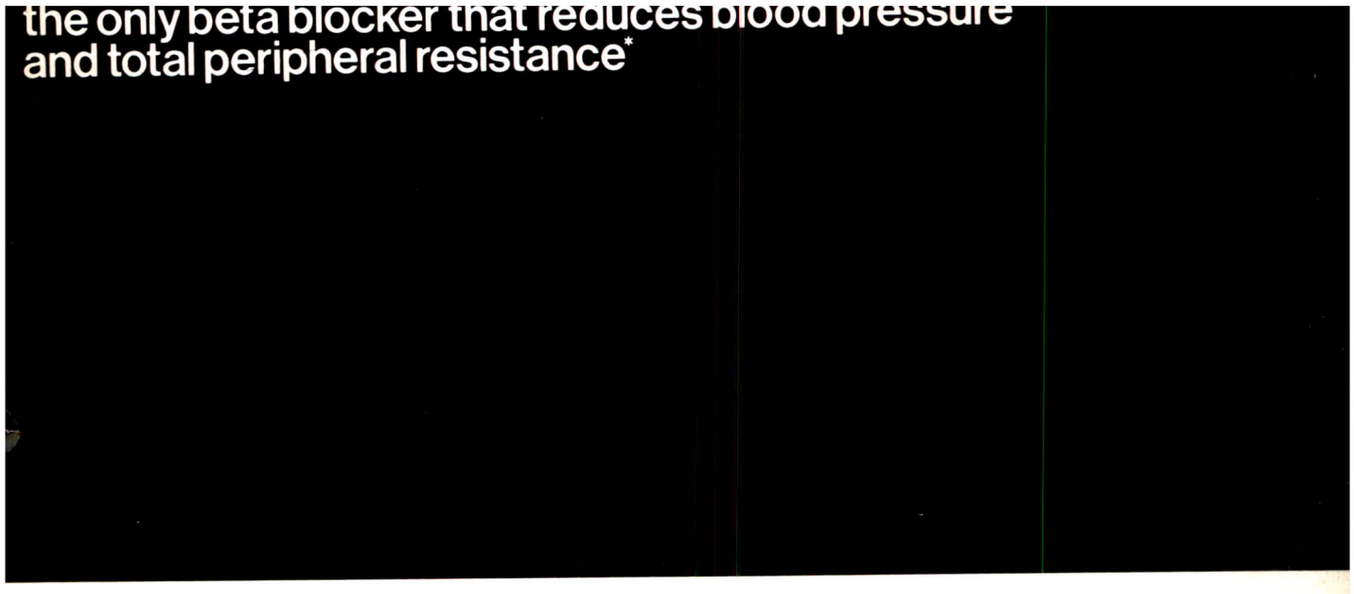
Reduces exercise-induced tachycardia

Like other beta blockers, Visken (pindolol) blocks stimulation by catecholamines to reduce exercise-induced increases in systolic blood pressure and heart rate.

© 1983 Sandoz, Inc.

*The clinical significance has not been evaluated. See clinical significance statement on facing page of this advertisement.

the only beta blocker that reduces blood pressure and total peripheral resistance*



Has little effect on resting heart rate

Visken® (pindolol) produces minimal changes in resting heart rate. Average reduction: 4-8 beats/minute.

The clinical significance has not been evaluated

The clinical significance of maintaining resting cardiac output, resting heart rate and reduced total peripheral resistance has not been evaluated and there is no evidence or reason to believe that exercise cardiac output is less affected by Visken (pindolol) than other beta blockers.

Maintains renal blood flow

Visken (pindolol) reduces supine and standing blood pressure while maintaining effective renal plasma flow and glomerular filtration rates.[2]

Favorable side effect profile

Low incidence of bradycardia

Low incidence of cold extremities

Visken (pindolol) is contraindicated in:

1) bronchial asthma
2) overt cardiac failure
3) cardiogenic shock
4) second- and third-degree heart block
5) severe bradycardia

*See clinical significance statement.

Please see next page of this advertisement for brief summary of prescribing information.

Visken® (pindolol)

Available in 5 mg and 10 mg tablets

Convenient bid dosage

Dosage should be titrated on an individual basis.
Many patients respond to 10-30 mg a day in divided doses.

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE
Visken (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS
Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of beta$_2$ receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS
Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

Body System/ Adverse Reaction	Total (Volunteered and Elicited) Visken (pindolol) (N = 322) %	Active Controls* (N = 188) %	Placebo (N = 78) %

*Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and nonthrombocytopenic purpura.

Gastrointestinal: Mesenteric arterial thrombosis; ischemic colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

OVERDOSAGE
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

Excessive Bradycardia: administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure: digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

Hypotension: administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a beta$_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ⩾80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 10 mg b.i.d. alone or in combination with other antihypertensive agents. Many patients will respond to 15 mg per day (5 mg t.i.d.). The antihypertensive response usually occurs within the first week of treatment. If a satisfactory reduction in blood pressure does not occur within 2-3 weeks, the dose may be adjusted in increments of 10 mg per day at 2-3 week intervals up to a maximum of 60 mg per day.

HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05). [VIS-Z2 9/1/82]

Anatomic Obstruction of the Right Ventricular Outflow Tract In Transposition of the Great Arteries

RUDOLF J. MOENE, MD, ARENTJE OPPENHEIMER-DEKKER, MD, and MARGOT M. BARTELINGS, MD

In 126 hearts with transposition of the great arteries (TGA), morphologic features of the right ventricular (RV) outflow tract were analyzed. Distinct anatomic outflow tract obstruction was found in 15 of the 55 hearts with a ventricular septal defect (VSD) (27%): 12 had a perimembranous defect (predominantly extending into the infundibulum), 2 had an inlet, and 1 had an infundibular defect. In 12 hearts, outflow tract obstruction was caused by anterior displacement of infundibular septum and ventriculoinfundibular fold; in 3 hearts, it was caused by bulging of the trabecula septomarginalis or ventriculoinfundibular fold, or both. Of 71 hearts with an intact ventricular septum, only 2 (3%) had RV outflow tract obstruction: 1 had a trabecula in front of the aortic ostium and in the other an aberrant hypertrophic muscle bundle crossed the RV cavity, obstructing the entrance to the infundibulum. Associated malformations included aortic arch malformations (6 cases) and tricuspid valve anomalies (6 cases). Thus, anatomic RV outflow tract obstruction may constitute a complicating factor in TGA, notably in cases with VSD. A systemic RV blood pressure may trigger hypertrophy, resulting in progression of the obstruction; establishing normal RV pressure by a "switch" procedure might prevent this progression.

The left ventricular outflow tract in complete transposition of the great arteries (TGA) has received extensive attention in numerous studies; several investigators have outlined the anatomic features of left ventricular outflow tract obstruction.[1,2] In contrast, the right ventricular (RV) outflow tract has received little attention and anatomic RV outflow tract obstruction has rarely been described in TGA.[3,4] More recently, Freedom et al[5] and Schneeweiss et al[6] reported angiocardiographic and pressure data from patients with TGA and subaortic stenosis. This study determines the frequency of RV outflow tract obstruction in specimens with TGA and characterizes its morphologic features.

Methods

Case material: One hundred twenty-six hearts with situs solitus, atrioventricular concordance, and ventriculoarterial discordance were available from the collection of the Laboratory of Anatomy and Embryology at Leiden: 71 with intact ventricular septum and 55 with ventricular septal defect (VSD). In all cases the pulmonary trunk was mainly committed to the left ventricle, thus excluding forms of double outlet right ventricle in which the RV outflow tract already has been studied and described by several workers.[7,8] In most specimens, the aortic valve was anterior and to the right of the pulmonary valve; in some cases there was a side-by-side relationship. Excluded were complicated hearts with so-called "posterior transposition" and with straddling atrioventricular valves.

The specimens were studied with special attention focused on the presence or absence of anatomic indications of RV outflow tract obstruction; 15 normal hearts of different ages served as controls.

Definitions: The RV muscular structures are described according to the terminology proposed by Anderson et al.[9] These investigators used the term *crista supraventricularis* only in the description of hearts with normal RV outflow tracts, those without anomalies which derange the alignment of the outflow musculature. It should be noted that some other workers, among them Schneeweiss et al,[6] do use the same term in hearts with outflow tract abnormalities. We agree with Anderson et al[9] that in hearts with outflow tract anomalies 3 separate structures warrant description: the infundibular septum, the ventriculoinfundibular fold (together constituting the crista supraventricularis in the normal heart), and the trabecula septomarginalis. The VSDs are described and classified according to the classification by Soto et al.[10] In the scope of the present study, we used in addition the term *displacement of the infundibular septum* because it emphasizes the morphologic features more adequately than the general term *malalignment* (this term does not figure into Soto's classification).

Results

The normal subaortic infundibular anatomy in TGA is depicted in Figure 1. Anatomic evidence of RV outflow tract obstruction was identified in 15 of the 55

hearts with VSD (27%) and in 2 of the 71 hearts with intact ventricular septum (3%). The 17 patients ranged in age from 1 day to 4.5 years (median 9.5 months). Of the 15 hearts with VSD, 12 had a perimembranous defect with predominant extension into the infundibulum, 2 had a muscular inlet defect, and 1 had a muscular infundibular defect. Among the 17 hearts with RV outflow tract obstruction, various outflow tract malformations were found which could be classified into 2 categories: (1) anterior displacement of the infundibular septum and ventriculoinfundibular fold, and (2) redundant muscle tissue.

Anterior displacement of the infundibular septum and ventriculoinfundibular fold (12 cases) was associated with 2 morphologic features (Fig. 2). First, it results in distance reduction between these structures on the one hand and the anterior RV wall on the other hand and thus in outflow tract narrowing. Second, it results in subpulmonary localization of the (perimembranous) VSD. The infundibular septum, merging with the trabecula septomarginalis, formed the anterior edge of the roof of the defect. The anteroinferior rim of the defect was formed by the trabecula septomarginalis. As viewed from the left ventricle, the posterior margin of the defect was the mitral-pulmonary fibrous continuity. Dual insertion of the medial papillary muscle was present in 7 cases with anterior displacement of the infundibular septum and ventriculoinfundibular fold, resulting in embracement of the subpulmonary VSD by 2 chordal groups: 1 group inserting into the trabecula septomarginalis, and the second chordal group inserting into the infundibular septum (Fig. 3).

Anatomic obstruction of the RV outflow tract by redundant muscle tissue was found in 5 cases. Three cases demonstrated bulging of the trabecula septomarginalis or ventriculoinfundibular fold, or both (Fig. 4); in 1 case, a trabecula was located ventral to the aortic ostium (Fig. 5) and in another case an aberrant hypertrophic muscle bundle crossed the RV cavity and obstructed the entrance to the outflow tract (Fig. 6). Associated malformations included aortic arch anomalies in 6 (35%) of the 17 hearts with RV outflow tract obstruction: isthmus hypoplasia in 3, local coarctation in 2, and interruption in 1.

In addition, the following anomalies of the tricuspid valve apparatus were identified: 2 hypoplastic valves (Fig. 7), 1 dysplastic valve, and 3 cases in which some chordae of the anterior tricuspid valve leaflet were connected to an accessory papillary muscle arising from the parietal wall of the right ventricle (Fig. 4). One mitral valve showed a parachute deformity. The aortic and pulmonary valves were normal in all 17 cases. Catheterization data were available from 4 patients. In 3 cases with a perimembranous subpulmonary VSD, the catheter was advanced from the right ventricle to the pulmonary artery; however, efforts to enter the as-

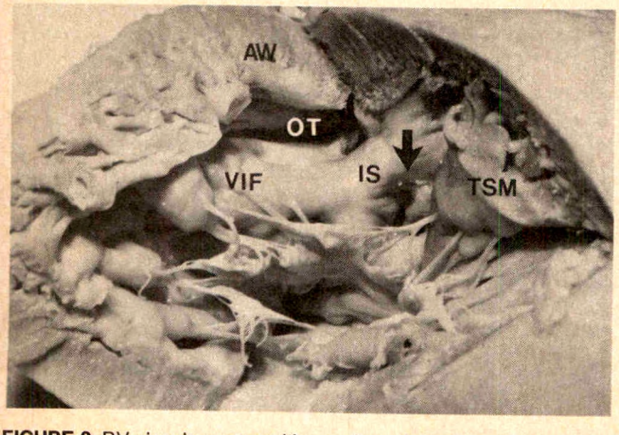

FIGURE 2. RV view in a case with a perimembranous, subpulmonary VSD (**arrow**) predominantly extending into the infundibular septum (IS). The infundibular septum and ventriculoinfundibular fold (VIF) are displaced anteriorly, thus narrowing the outflow tract (OT). AW = anterior wall of the right ventricle; TSM = trabecula septomarginalis.

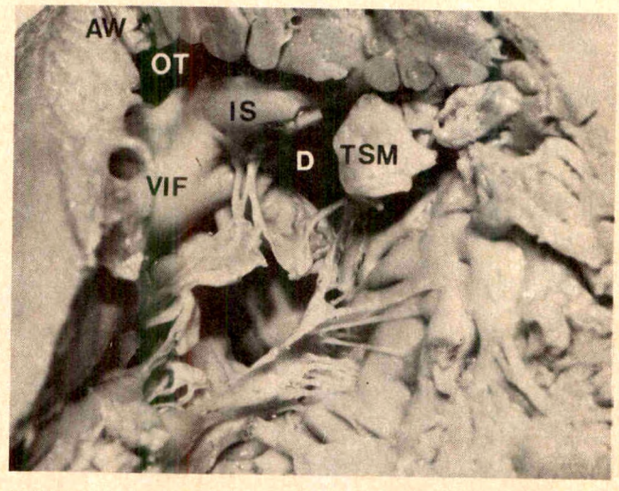

FIGURE 3. Conspicuous narrowing of the RV outflow tract (OT) by anterior displacement of the infundibular septum (IS) and ventriculoinfundibular fold (VIF). Dual insertion of the medial papillary muscle results in embracement of the perimembranous subpulmonary defect (D) by 1 chordal group inserting into the infundibular septum and another one inserting into the trabecula septomarginalis (TSM). AW = anterior wall of the right ventricle.

cending aorta from the right ventricle remained unsuccessful.

A pressure gradient of 30 mm Hg across the aortic outflow tract was diagnosed in the case with a bulging ventriculoinfundibular fold. In the hearts without RV outflow tract obstruction, hypertrophy of the ventriculoinfundibular fold, the infundibular septum, and the trabecula septomarginalis, separately or in combination, was noted in 20 specimens with a VSD and 17 specimens with an intact ventricular septum. One of those cases, with a hypertrophic ventriculoinfundibular fold, is shown in Figure 8.

Discussion

Data from the literature concerning the RV outflow tract in TGA are scarce and contradictory. Becu and Gallo[11] found abnormal muscular bands in the outflow tract of all their 67 studied hearts; this anatomic distortion was so marked in many instances that "the morphology of the subaortic chamber only superficially

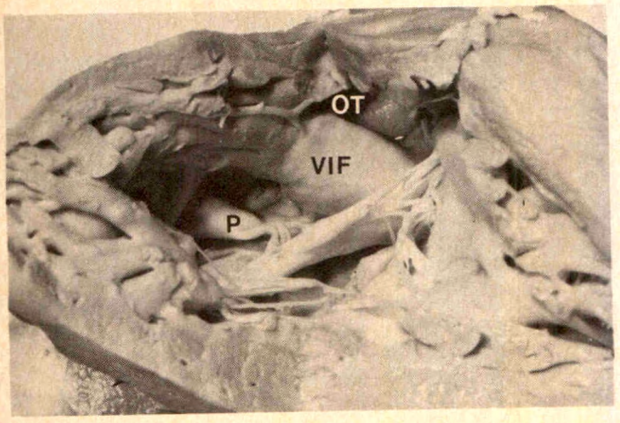

FIGURE 4. Narrowing of the RV outflow tract (OT) by a hypertrophic ventriculoinfundibular fold (VIF). Note the accessory tricuspid papillary muscle (P); the presence of a small inlet VSD is not visible in this view.

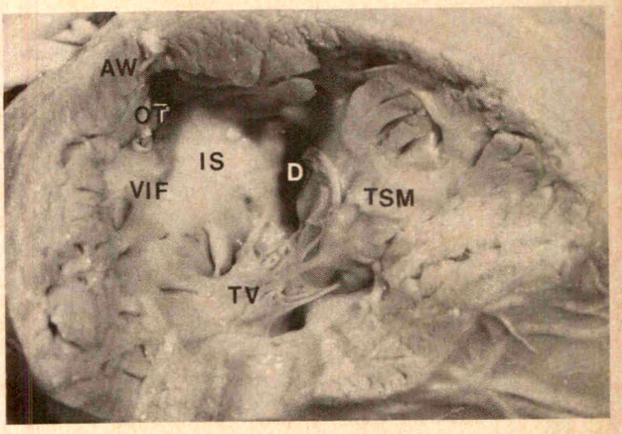

FIGURE 7. Narrowing of the RV outflow tract (OT) by anterior displacement of the hypertrophic infundibular septum (IS) and ventriculoinfundibular fold (VIF); the VSD (D) is perimembranous and subpulmonary. Note hypoplasia of the tricuspid valve (TV). AW = anterior wall of the right ventricle; TSM = trabecula septomarginalis.

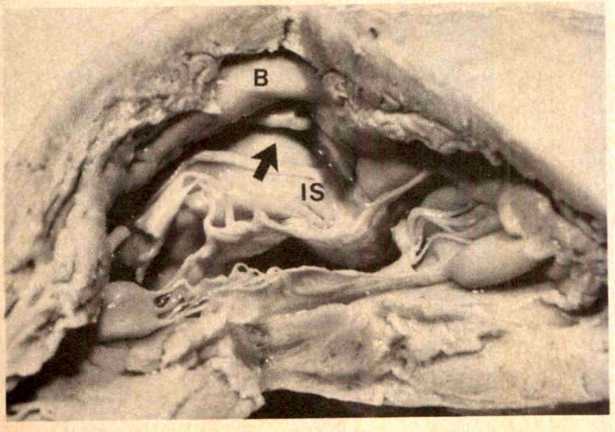

FIGURE 5. Narrowing of the outflow tract (**arrow**) by an aberrant hypertrophic muscle bundle (B) in front of the aortic ostium. IS = infundibular septum.

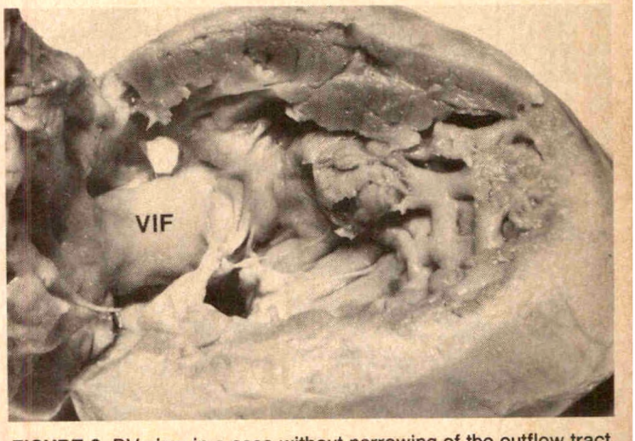

FIGURE 8. RV view in a case without narrowing of the outflow tract. Apart from the generalized hypertrophy, there is conspicuous bulging of the ventriculoinfundibular fold (VIF).

resembled a normal right ventricle." In contrast with those findings, Anderson and Becker,[12] in a recent review of the morphologic features of TGA, do not mention abnormal muscular bands. In their view, infundibular pathology is restricted to abnormal orientation of the infundibular septum in cases with intact ventricular septum, and to malalignment of the infundibular septum in case of an infundibular VSD. Malalignment (termed *displacement* by us) of the infundibular septum was also identified in the present material. However, in addition, our observations point to the presence of an abnormal, hypertrophic ventriculoinfundibular fold, infundibular septum, trabecula septomarginalis, or a combination of these in a considerable number of cases; this hypertrophy often exceeds the hypertrophy of the free wall of the right ventricle which is always present in cases with TGA.[13] Although the present observations are estimations since no quantitative methods are available to characterize size, shape, and alignment of the aforementioned structures, the differences from "normal" are distinct.

According to the literature, anatomic obstruction of the RV outflow tract in TGA seems to be rare. Elliott et al[3] found in 4 of 38 cases with intact ventricular septum slight obstruction of the subaortic area resulting from moderate enlargement of the crista supraventricularis, and in 3 of 22 cases with a VSD, stenosis of the subaortic area by a hypertrophied crista supraventricularis. Shaher[4] described a similar case and quotes another 2 cases from other studies. Clinical data concerning 5 patients with subaortic stenosis were reported by Schneeweiss et al[6]; in those patients, 4 of whom had a VSD and 2 a coarctation of the aorta, the stenosis was demonstrated by a pressure gradient of 30 to 55 mm Hg and by angiocardiography. In their control group of 67 patients without subaortic stenosis, various degrees of hypertrophy of what they termed *the crista supraventricularis* were identified by the angiocardiogram. Their findings suggest the presence of a sliding scale from minor to major pathology of the crista supraventricularis, which corresponds with the results of the present study, if we translate crista supraventricularis as ventriculoinfundibular fold and infundibular septum. Unfortunately, Schneeweiss et al[6] did not classify the VSDs in their patients. In 12 of our cases, a VSD was accompanied by anterior displacement of the infundibular septum and ventriculoinfundibular fold resulting in subpulmonary localization of the defect. This type of defect has been described as subpulmonary defect with overriding pulmonary trunk and malalignment of the infundibular septum by Huhta et al[14] in the scope of a study on tricuspid valve abnormalities in TGA.

Apart from tricuspid valve abnormalities, which were also present in 4 of our cases with this type of defect, the investigators refer to subaortic obstruction by a malaligned hypertrophic infundibular septum. Given the lack of sufficient pressure data to demonstrate the flow-obstructive character of the lesions observed, we are left with possible supportive evidence. In this respect, the incidence of 6 aortic arch malformations in the underlying 17 specimens is of importance, since the genesis of arch anomalies generally has been accepted as being the consequence of intracardiac obstructive factors. Having demonstrated anatomic obstruction of the RV outflow tract in hearts with subpulmonary VSD and anterior displacement of the infundibular septum, a similar problem may be expected in other anomalies with displacement of the infundibular septum to the right, as in the double outlet right ventricle with subpulmonary VSD. This is confirmed by several workers who established the close relationship between this malformation and subaortic stenosis.[7,8]

Together with data from the literature, the present study indicates that anatomic obstruction of the RV outflow tract in TGA does exist, and that it is usually characterized by anterior displacement of the infundibular septum and ventriculoinfundibular fold (in association with a perimembranous defect) or, in a minority of the cases, by redundant muscle tissue. More studies concerning the relation between anatomy and clinical data are needed to establish the functional implications and natural history of these anomalies. One practical consequence is mentioned by Huhta et al,[14] who pointed out that hypertrophy of a malaligned infundibular septum can add difficulty to the surgical creation of an unobstructed left ventricular outflow tract in case of a Rastelli approach. Next, it seems important to realize that a systemic RV blood pressure may trigger hypertrophy resulting in progression of the obstruction; one could speculate that normalization of the RV pressure by performing a switch procedure may prevent this progession.

Quantitative Angiographic and Morphologic Aspects of Aortic Valve Atresia

ALOIS R. HASTREITER, MD, RONALD L. VAN DER HORST, MD, IRA W. DUBROW, MD, and FRIEDRICH O. ECKNER, MD

Quantitative angiographic measurements were performed in 15 infants aged 1 to 35 days who had aortic valve atresia with intact ventricular septum and hypoplastic left ventricle. Thirteen infants had similar measurements performed at autopsy. The latter measurements were smaller than those found at angiography (because of shrinkage), but their relationship was predictable. Angiographic right ventricular (RV) volumes were 2 and 4 times normal in diastole and systole, respectively. The RV volume measured at autopsy was >3 times normal. Mean RV ejection fraction was 0.40; it was below normal in 10 infants. Maximal right atrial volume was >2 times normal, and mean left atrial maximal volume was two-thirds normal. The relation between circumferences of the aortic arch and ascending and descending aorta was similar at angiography and autopsy.

Aortic valve atresia (AVA) is the most malignant form of congenital heart disease.[1] Because of rapid clinical deterioration, infants with this lesion often are not extensively investigated. This study reports detailed angiographic measurements in infants with AVA with an intact ventricular septum and compares these with related autopsy measurements.

Methods

We studied 15 infants (12 male and 3 female) aged 1 to 35 days, all of whom had cardiac catheterization with biplane selective angiocardiography. The diagnosis was confirmed at autopsy in all infants.[2] Table I shows the clinical data. Birth weight was 2.8 to 4.1 kg. Symptoms appeared at 1 to 35 days of age. Eleven infants became ill in the first week of life, and 12 died within 3 days of the onset of symptoms. One became symptomatic at 19 days and lived 48 days after palliative surgery.[3] Eight infants had mitral valve atresia, and the remaining 7 had mitral stenosis. None had a ventricular septal defect, and the left ventricle was minute in all.

Cardiac volume and dimension was determined from biplane cineangiocardiograms as described previously.[4–6] Right ventricular (RV) and right atrial volume was calculated by Simpson's Rule and was corrected by regression equations obtained from plastic casts of the heart chambers.[4–6]

The following were measured at angiography: RV end-diastolic and end-systolic volume, stroke index, ejection fraction, and maximal right and left atrial volume; diameter of the ascending aorta (1 cm above the atretic aortic valve), aortic arch (proximal to the origin of the left subclavian artery), descending aorta (just distal to the ductus arteriosus), RV inflow and outflow tracts, and pulmonary and tricuspid valves, all measured in the lateral view. Spatial RV inflow (tricuspid valve to apex) and outflow (pulmonary valve to apex) tract lengths were calculated using the formula $\sqrt{x^2 + y^2 + z^2}$ from coordinates measured in the anteroposterior and lateral views. Normal values were obtained from our own laboratory and from Nakazawa et al[7] and Graham et al.[8–10]

Autopsy analysis was based on standard fixation by controlled pressure coronary perfusion as described elsewhere.[11,12] The following parameters were measured: heart weight; diameter of the tricuspid and pulmonary valves, ascending aorta (1 cm above the atretic valve), transverse arch (proximal to the origin of the left subclavian artery), and descending aorta (distal to the ductus arteriosus); RV inflow (tricuspid anulus to apex) and outflow (pulmonary anulus to apex) tract length; inflow (moderator band to base of anterior papillary muscle along free wall) and outflow (greater perimeter) diameter; and RV volume.[11,12]

Results

Autopsy findings (Tables I and II): These measurements were performed for comparison with the angiographic measurements.

Angiographic findings (Tables I and II): The right ventricle was dilated, was heavily trabeculated, and had reduced wall motion. RV end-diastolic and end-systolic volumes were 2 and 3 times normal, respectively, whereas the stroke index was near normal. RV ejection fraction was below normal in two thirds of the cases. Except for the length of the outflow and the diameter of the inflow tract, RV dimensions were significantly larger in patients with AVA than in normal control subjects. The left ventricle was usually not visualized. Maximal right and left atrial volume was more than twice and two-thirds normal, respectively. Both atria contracted forcefully. In Case 6, the interatrial communication became markedly restrictive during a 1-month period of observation.[3]

Comparison of angiographic and autopsy measurements: The dimensions of the various cardiac structures were consistently greater at angiography because of shrinkage of the autopsy specimens. When the latter was taken into account, angiographic measurements could be predicted with good accuracy from autopsy measurements.[5,6] The diameter of the RV outflow tract was an exception: angiographic and autopsy dimensions were similar. The mean RV volume measured at autopsy was smaller than the angiographic end-systolic volume. There was no significant difference between the RV inflow and outflow tract lengths measured by angiography or at autopsy. The tricuspid valve diameter measured at angiography was 1.6 times larger than that at autopsy, and the pulmonary valve 1.3 times larger. The ratio between the main pulmonary artery and descending aorta circumference was 1.9 on angiography and 1.8 at autopsy, respectively. At angiography, the mean ascending aortic circumference was 0.4 and that of the aortic arch 0.7 times that of the descending aorta. Autopsy measurements showed a similar relation, the ratios being 0.4 and 0.6, respectively.

Discussion

The only published angiographic measurements in AVA are those of Farooki et al,[13] who found an average of 0.38 ± 0.05 cm for the aortic root (range 0.29 to 0.44, n = 7) and 0.27 ± 0.05 cm for the ascending aorta (range 0.22 to 0.35, n = 7). The former measurements, made at the aortic sinuses, are not comparable with those of the present study. However, the size of the ascending aorta is virtually identical to the present data.

Infants with AVA and intact ventricular septum have a functional single right ventricle, subject to volume and pressure overload, resulting in extreme RV dilatation and significant hypertrophy in the newborn period. The present study confirms that most angiographic and pathologic measurements related to the right-sided cardiac structures are larger in patients with AVA compared with normal subjects.[11,12] Although the autopsy measurements are smaller than the angiographic measurements because of shrinkage, the latter can be predicted fairly accurately from the former. The ratios observed angiographically and at autopsy between the dimensions of the ascending aorta, aortic arch, and descending aorta are similar.

Pathologic studies suggest that longer term survivors with AVA and intact ventricular septum have a thicker left atrial wall, indicating progressive obstruction at the site of the foramen ovale.[2] Prolonged retention of angiographic contrast material in the left atrium corro-

Increased Left Ventricular Ejection Fraction After a Meal: Potential Source of Error in Performance of Radionuclide Angiography

JERRY M. BROWN, MD, CHRISTOPHER J. WHITE, MD, SAMUEL M. SOBOL, MD, and ROBERT J. LULL, MD

The effect of a standardized meal on left ventricular (LV) ejection fraction (EF) was determined by equilibrium radionuclide angiography in 16 patients with stable congestive heart failure but without pulmonary or valvular heart disease. LVEF was determined in the fasting state and 15, 30, and 45 minutes after a meal. Patients with moderately depressed fasting LVEF (30 to 50%), Group I, had a mean increase of 6.9 ± 2.9% ($p < 0.005$) in the LVEF at 45 minutes after the meal. Patients with severely depressed fasting LVEF (<30%), Group II, had no change after the meal. It is concluded that significant increases in LVEF may occur after meals in patients with moderate but not severe left ventricular dysfunction. Equilibrium radionuclide angiography studies that are not standardized for patients' mealtimes may introduce an important unmeasured variable that will affect the validity of data in serial studies of left ventricular function.

Postprandial increase in cardiac output is a well-recognized phenomenon in animals, but little is known about the effects of eating on cardiac performance in man. More specifically, no data are available to assess changes produced by eating on routinely measured indexes of ventricular function. The left ventricular (LV) ejection fraction (EF) is one of the most commonly used variables in assessing ventricular function. EF measurements by equilibrium radionuclide angiography have been shown to correlate well with values obtained by invasive left ventriculography and to be highly reproducible, with variations of <2.0 ± 2.1% in serial patient examinations.[1] This study determines the effect of a standardized meal on the resting LVEF in a group of patients with stable congestive heart failure.

Methods

The study group comprised 16 patients (14 men, 2 women), aged 29 to 78 years. All patients were normotensive. Thirteen had stable congestive heart failure secondary to atherosclerotic coronary heart disease, and 3 had idiopathic dilated cardiomyopathy. The patients were divided into 2 groups: Group I, patients with mild to moderately depressed resting EF (30 to 50%); and Group II, patients with severely depressed resting EF (<30%). No patient had a recent cardiac event or change in symptoms, therapeutic requirements, or functional class (New York Heart Association) within 6 weeks of the study. Patients with pulmonary or valvular heart disease were excluded from the study.

All patients were studied in the resting, supine state after fasting for 6 to 12 hours before examination, and all medications were withheld for at least 6 hours before testing. Red blood cells were labeled in vivo by an injection of 25 mCi (9.5×10^8 Bq) of technetium-99m pertechnetate preceded by an intravenous injection of stannous ion (2 mg). Patients underwent electrocardiographic gated equilibrium radionuclide left ventriculography before eating and at 15, 30, and 45 minutes after eating a standardized hospital breakfast composed of approximately 50% carbohydrate, 30% fat, and 20% protein and totalling 700 to 900 calories. No hot or iced liquids, coffee, or tea were included in the meal. Data acquisition was performed in a modified left anterior oblique projection by a gamma camera equipped with a general purpose collimator

TABLE I Comparison of Fasting and Postprandial Ejection Fractions

Group	Patients (n)	Ejection Fractions (%)					
			Postprandial				
		Fasting	15 Minutes	30 Minutes	45 Minutes	Change	p Value
I	10	37.7 ± 7.0	40.2 ± 7.0	43.1 ± 7.7	44.6 ± 7.3	6.9 ± 2.9	<0.005
II	6	23.6 ± 4.4	24.0 ± 4.7	23.6 ± 4.5	24.8 ± 5.0	1.2 ± 1.8	>0.10 (NS)

All values are means ± standard deviation.
NS = not significant.

(Picker Dynamo, South San Francisco, California) interfaced with a dedicated minicomputer (Medical Data Systems A^2, Ann Arbor, Michigan). All patients were in sinus rhythm. Heart rate and supine brachial arterial blood pressure were recorded. Stored data were processed by semiautomated computer system software using varying regions of interest for EF determinations. Statistical analysis was performed using analysis of variance with repeated measures.

Results

Analysis of the data revealed that the response to eating differed markedly between the 2 groups (Table I). Patients in Group I had an increase in average EF from 38% fasting to 45% at 45 minutes after eating. No Group I patient had an EF lower than the baseline fasting value during the performance of the test (Fig. 1). The mean increase in EF (6.9 ± 2.9%) was significant (p <0.005) (Fig. 2). The largest individual increase in this group was seen in Patient 3, whose EF increased 11% (from 36% to 47%), and the smallest incremental changes in EF occurred in Patients 7 and 8 (increases of only 2% and 3%, respectively). These 2 patients had had an acute myocardial infarction approximately 8 weeks before study.

Patients in Group II had no statistically significant change in EF after eating, with a mean fasting EF of 24% and a mean EF after eating of 25%.

There were no significant changes in blood pressure or blood pulse after eating in either group, and no patient had angina pectoris during study.

Discussion

More than 50 years ago, Grollman[2] reported that cardiac output increases in response to feeding. Subsequent studies confirmed an increase in cardiac output, pulse rate, and generalized organ blood flow in the

	$\overline{EF\Delta}$	SD	P
GROUP I	6.9	±2.9	<.0005
GROUP II	1.2	±1.8	NS

FIGURE 1. Fasting and after-meal ejection fractions (EF). NS = not significant.

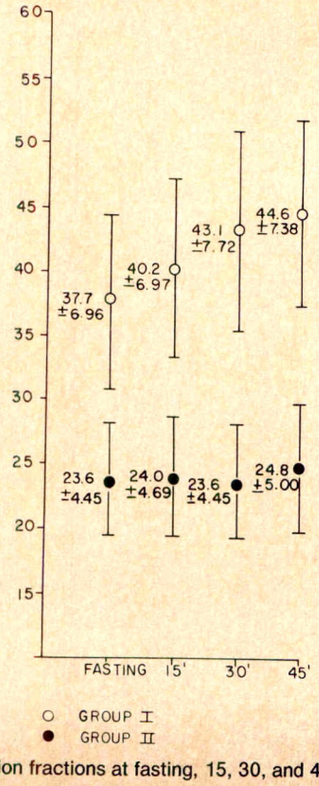

FIGURE 2. Ejection fractions at fasting, 15, 30, and 45 minutes.

postprandial state.[3,4] Further detailed observations in nonanesthetized animals have shown only a transient increase in cardiac output, pulse rate, and arterial blood pressure after eating,[5–7] with prolonged selective increases in mesenteric blood flow due to local vasodilation.[7] The cardiovascular effects of eating and digestion in man have rarely been subjected to investigation, either in the healthy person or in the presence of cardiac disease.[8,9]

Our study of patients who have stable congestive heart failure shows definite augmentation of LVEF after a meal in patients with moderate but not severe LV dysfunction. The mechanism by which this occurs may be a decrease in systemic vascular resistance as described in animal studies, resulting in LV unloading. In patients with more severe LV dysfunction, it can be speculated that chronically increased sympathetic nervous system tone may result in blunting or even preventing of the usual physiologic responses to a meal, or that these patients are less sensitive to the mild degree of afterload reduction induced by food intake because of continued high preload conditions.

Gated blood pool radionuclide angiography has gained widespread acceptance as a tool for assessing LV function. Ideally suited for serial longitudinal studies, it is both safe and noninvasive, with good reproducibility. However, to ensure the reproducibility of the test, factors that affect cardiac performance must be standardized for each examination. Our study demonstrates that significant increases in EF after eating exceed the accepted limits of EF variability utilizing radionuclide ventriculography.[1]

Thus, studies of cardiac performance that do not control mealtimes may introduce an important unmeasured variable. This uncontrolled variable may particularly affect the validity of data in serial comparative studies carried out at different hours of the day over several days, weeks, or months.

Diagnostic Accuracy of Indium-111 Platelet Scintigraphy In Identifying Left Ventricular Thrombi

MICHAEL D. EZEKOWITZ, MD, PhD, ROBERT D. BURROW, MS, PAUL W. HEATH, MD, TERRI STREITZ, BS, EILEEN O. SMITH, BS, and DONALD E. PARKER, PhD

This study defines the optimum imaging time window after injection of labeled platelet suspension for detection of left ventricular (LV) thrombi, identifies the most useful imaging views, and determines the reproducibility of this technique. A total of 662 images obtained from 64 patients were analyzed retrospectively on 2 separate occasions by 3 observers blinded as to patient identity, view (right anterior oblique, anterior, left anterior oblique, and left lateral), and time after injection of the platelet suspension that the images were obtained (0 to 2, 3 to 4, and 5 to 6 days). Images were categorized as either positive or negative. In every case surgical or autopsy verification of the presence or absence of LV thrombus was possible. The best combination of sensitivity, specificity, and diagnostic accuracy was found in the 3- to 4-day period in the left anterior oblique view and was 54 ± 5% (mean ± standard deviation), 98 ± 1%, and 85 ± 2%, respectively. Sensitivity, specificity, and diagnostic accuracy were not enhanced by adding additional views (right anterior oblique, left lateral, and anterior) to the left anterior oblique view in the 3- to 4-day time period. However, using multiple views, localization of thrombi to the left ventricle was facilitated. In a second retrospective analysis, a comparison of day 0 with day 3 to 4 images enhanced sensitivity and accuracy to 65 ($p < 0.001$) and 90% (not significant), respectively. Specificity was unchanged at 99%. Mean intra- and interobserver agreement was 91 and 88%, respectively. Thus, (1) indium-111 platelet scintigraphy is a reproducible and specific technique for identifying LV thrombus, and (2) we advise imaging on day 0 and again 3 to 4 days after injection of the platelet suspension in right anterior oblique, left anterior oblique, left lateral, and anterior views to maximize accuracy and to facilitate localization of LV thrombus.

Indium-111 labeled platelet scintigraphy has been used successfully to identify intravascular thrombi in various locations[1–16] including the left ventricle in man.[7,8] This report defines the optimum time window after injection of the labeled platelet suspension for detection of cardiac thrombi, identifies the most useful imaging views, determines the reproducibility of the technique, and provides illustrations of representative positive and negative studies including those that may be misleading or difficult to interpret.

Methods

The patient data base consists of 662 scintigraphic images obtained from 64 patients with left ventricular (LV) aneurysms (n = 38) or mitral valve disease (n = 23) and 3 patients with acute myocardial infarction who later died. Patients were imaged 7.5 ± 5.2 days (mean ± standard deviation [SD]) before aneurysmectomy, mitral valve replacement, or death. Of the 23 patients requiring mitral valve replacement, 3 had coronary artery bypass surgery and 8 had aortic valve replacement. Confirmation of the presence or absence of a thrombus was possible at surgery or autopsy in all studies. Injected platelets were labeled according to a method previously described.[7,17,18] Most patients were imaged in the left anterior oblique, right anterior oblique, anterior, and left lateral views on the day of injection of the platelet suspension and at least on alternate days thereafter for a maximum of 6

days. Patients were imaged on a large field-of-view gamma scintillation camera fitted with a medium energy collimator. The dual peak energy analyzers were centered on both photopeaks of indium-111 with 20% windows. In all patients, 200,000 counts over the field-of-view were obtained.

Analysis of data: Two retrospective analyses were performed. First, to determine optimum views and time windows for imaging, images were analyzed without knowledge of the surgical result, patient identity, view, and day from injection of the platelet suspension that the image was obtained. Three observers were used. They were instructed to make either a positive or a negative reading. A positive image was defined as an area of increased and abnormal activity in the region of the cardiac blood pool (Fig. 1). If the area of increased activity included the whole blood pool of the ventricle, images were read as negative (Fig. 2, panel 1). A series of representative negative images is shown in Figure 3. All images were read by the same observer on 2 different occasions. The 3 observers had varied academic backgrounds. Observer 1 was a computer person with extensive experience in nuclear cardiology. Observer 2 was a young faculty member with 6 months' experience in nuclear cardiology. Observer 3 was a cardiologist with an interest in nuclear medicine and the principal investigator. The data were decoded by a fourth investigator who was responsible for the analysis.

Image interpretation was categorized with respect to interpreted result (positive or negative), patient number (1 to 64), view (right anterior oblique, left anterior oblique, left lateral, and anterior), observer (1, 2, or 3), reading (1 and 2), and imaging window (days 0 to 2, 3 to 4, or 5 to 6 after injection of the platelet suspension). These categorized data along with the surgical results were entered into a file on a digital computer from which contingency tables were generated as desired. Sensitivity, specificity, and diagnostic accuracy were determined for each view and imaging time.

After analysis of these data, a second retrospective study was performed. Readers were blinded to patient identity and surgical or autopsy result and were unblinded for imaging time and views. Images from day 0 were compared with those from either day 3 or day 4. If the area of activity within the left ventricle increased from the day 0 image to the day 3 or 4 image, the study was considered positive. All doubtful images were read as negative. Sensitivity, specificity, and diagnostic accuracy were determined.

Surgical specimens were handled as follows: Findings at surgery were considered either thrombus positive or thrombus negative. In every case, this differentiation was unequivocal. Patients who had thrombi and who received injections within

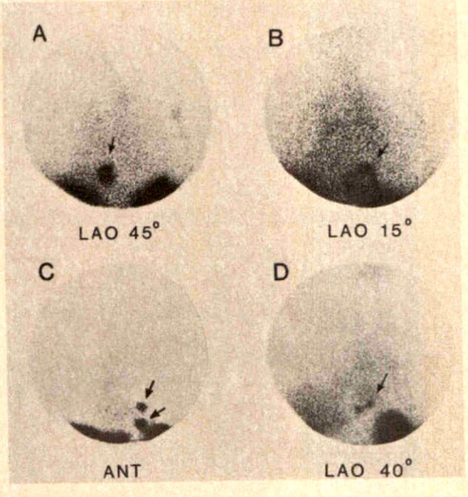

FIGURE 1. Scintiphotos obtained 72 hours after injection of the platelet suspension. Images are orientated with the top of the illustration cephalad. The increased activity in the right lower quadrant of each panel is from the spleen. The activity in the lower left quadrant in each panel is from the liver. The **arrows** point to areas of increased activity within the left ventricle and represent typical active thrombi within large anteroapical left ventricular aneurysms. These images were obtained from 4 different patients. ANT = anterior; LAO = left anterior oblique.

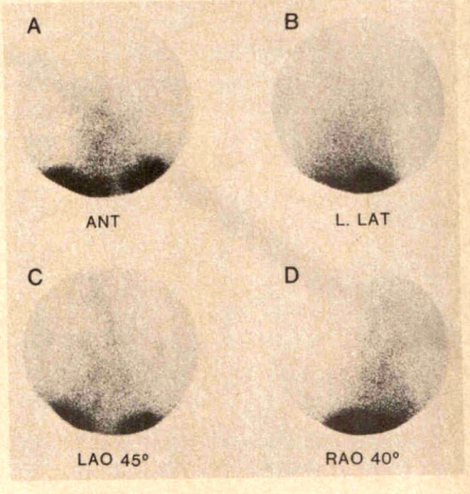

FIGURE 3. The orientation of this figure is the same as that in Figure 1. The area of increased activity in **panels A and C** in the right lower zone is due to the spleen and that in the left lower zone is due to the liver. In **panels B and D** there is superimposition of liver and splenic activity in the lower portions of both panels. This figure represents a typical series of negative images obtained 72 hours after injection of the platelet suspension. ANT = anterior; LAO = left anterior oblique; LLAT = left lateral; RAO = right anterior oblique.

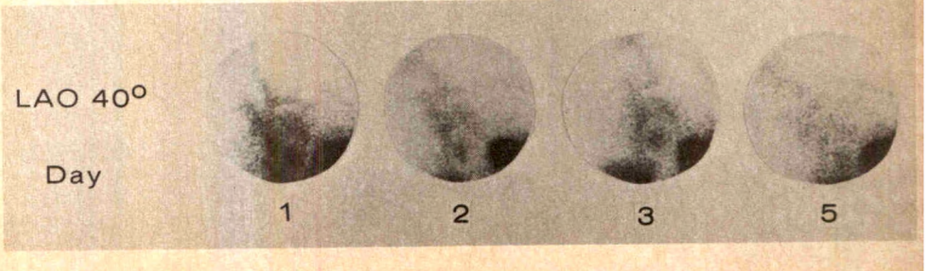

FIGURE 2. The orientation of these images is the same as in Figure 1. All images were obtained in the left anterior oblique (LAO) view on days 1, 2, 3, and 5 after injection of the platelet suspension. Note that the activity in the region of the left ventricle decreases with time.

8 days of surgery or autopsy had tissue levels of indium-111 measured. Thus, thrombus-positive patients were further subdivided, on the basis of surface thrombus indium-111 activity, into those with active and those with inactive disease. Inactive thrombi were arbitrarily categorized as those in which the surface activity was ≤6 times the adjacent blood activity normalized by mass. Three patients had inactive thrombi; in 3 others, tissue data could not be obtained. The data were analyzed by both including and excluding these 6 patients.

The reproducibility of the interpretations of the observers was assessed for each view and imaging window. The intraobserver agreement was calculated as the number of agreements between 2 different readings divided by the number of agreements plus the number of disagreements by the same observer.

The interobserver agreement was determined for each view and imaging window by dividing the number of agreements by the total number of images read.

Results

The sensitivity, specificity and diagnostic accuracy by view and imaging window for all observers and both readings are given in Figure 4. A total of 12 patients had LV thrombi at surgery or autopsy. The highest diagnostic accuracy was found in time period 3 to 4 days in the anterior (82 ± 1%, mean ± 1 SD, $p < 0.01$) and left anterior oblique views (85 ± 1.6%, $p < 0.01$). The specificity for all views in all time periods ranged from 97 ± 4% in the left anterior oblique view in the time period 0 to 2 days to over 98% in most of the other views in the various time windows. The sensitivity was highest in the left anterior oblique view in time period 3 to 4 days and was 54 ± 5% ($p < 0.01$). The significance values for the foregoing analysis was determined using the Duncan multiple range test.

By excluding patients with inactive thrombi from analysis, the following changes were seen (Fig. 5). The highest diagnostic accuracy was significantly ($p < 0.001$) enhanced to 88 ± 1.3% versus 82 ± 1% in the time period 3 to 4 days in the anterior view, and in the left anterior oblique (90 ± 2% versus 85 ± 2%), right anterior oblique (87 ± 4% versus 78 ± 3%, $p < 0.005$), and left lateral (87 ± 1% versus 78 ± 3%) views. The sensitivity was similarly enhanced in the 3 to 4 day time period in all views particularly the left anterior oblique view: anterior 57 ± 4% versus 44 ± 3%, $p < 0.001$; right anterior oblique 48 ± 5% versus 32 ± 3%, $p < 0.001$; left lateral 52 ± 5% versus 41 ± 4%, $p < 0.005$; and left anterior oblique view 67 ± 4% versus 54 ± 5%, $p < 0.001$. Specificity was unaltered at between 98 and 100%.

Because the foregoing indicates that the time period 3 to 4 days after injection of the platelet suspension was optimum for imaging, we combined the imaging views in that time period, considering a positive in any view as a positive. Sensitivity, specificity, and diagnostic accuracy were not altered. However, more reliable localization of increased activity to the left ventricle was possible using multiple views.

By comparing the 4 images on day 0 to those obtained on the third or fourth day of imaging, we could improve sensitivity and diagnostic accuracy to 65 ($p < 0.001$) and 90% (p not significant), respectively. Specificity was unaltered at 99%.

Overall intraobserver agreement was 91% with a range of 81% in the time period 0 to 2 days in the left anterior

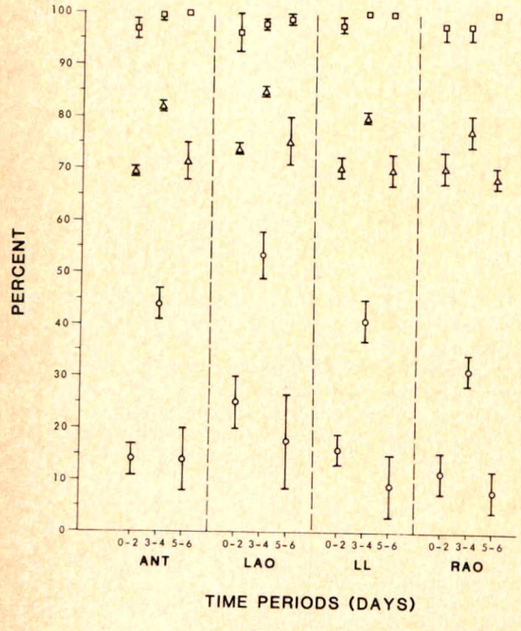

FIGURE 4. Percent sensitivity, specificity, and diagnostic accuracy in the anterior (ANT), left anterior oblique (LAO), left lateral (LL), and right anterior oblique (RAO) views for all images in time periods 0 to 2, 3 to 4, and 5 to 6 days. The data include patients with inactive thrombi. **Squares** = specificity, **triangles** = diagnostic accuracy, and **circles** = sensitivity. Mean ± standard deviation is for all observers and all readings (n = 6).

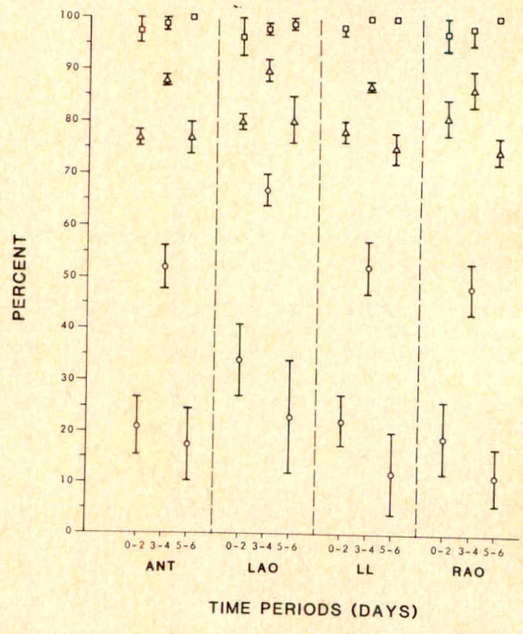

FIGURE 5. Analysis of these data is similar to that in Figure 4, except that inactive thrombi have been excluded. Inactive thrombi were defined as thrombi in which the surface indium-111 activity was ≤6 times the activity in the blood normalized by mass. Abbreviation as in Figure 4.

oblique view for observer 1, to 100% in the left lateral view in the time period 5 to 6 days for all observers. The interobserver agreement for reading 1 for all views and times ranged from 71 to 100%. For reading 2 the range was 77 to 100%. The mean interobserver agreement was 88%.

Discussion

In this retrospective analysis, we defined the diagnostic accuracy and reproducibility of indium-111 platelet scintigraphy in the diagnosis of LV thrombi. All 3 observers agreed that the left anterior oblique view in the time period 3 to 4 days after injection of the platelet suspension was the optimum time for imaging. By adding the right anterior oblique, left lateral, and anterior images to the left anterior oblique image, the parameters of accuracy were not significantly enhanced. However, imaging in multiple views allowed more reliable localization of thrombi to the left ventricle. There was significant enhancement of sensitivity and diagnostic accuracy when images from day 0 were compared with those obtained on the third and fourth day of imaging. Specificity remained high irrespective of the manner in which images were analyzed.

In a previous study in which multiple view images were acquired serially for 6 days and prospectively interpreted, the sensitivity was 71%.[19] In this retrospective analysis a comparison of day 0 with day 3 to 4 images resulted in a 65% sensitivity and a 67% decrease in imaging time with concomitant lowering of cost. Using day 0 with day 3 to 4 comparison, no reduction in specificity was noted.

There are 2 circumstances in which major difficulty occurs with the interpretation of images. Both are illustrated in Figures 2 and 6. In Figure 6, the patient had an elevated left hemidiaphragm with resultant elevation of the spleen, causing difficulty with interpretation of the anterior and right anterior oblique imaging views. The main point of differentiation is that activity due to the spleen characteristically accumulates early, that is, within minutes of injection of the platelet suspension, whereas increased activity due to a thrombus tends to be maximal 3 to 4 days after injection of the platelet suspension. To eliminate this difficulty, we advise interpretation of images only after a chest X-ray has excluded the presence of a raised left hemidiaphragm. Difficulty also might be encountered with the differentiation of increased blood pool activity due to a large LV volume or aneurysm, or both, from that due to a LV thrombus. Usually, increased activity from an enlarged blood volume is uniform in intensity, regular in shape, and much larger than the area normally occupied by a thrombus (Fig. 2). In addition, blood pool activity decreases with time, whereas activity due to a thrombus increases.

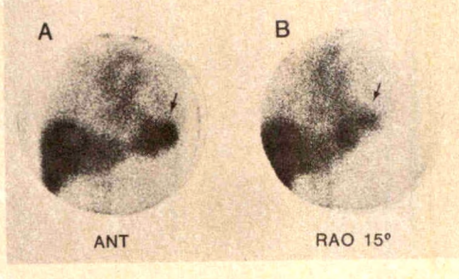

FIGURE 6. The orientation of this figure is the same as that of Figure 1. The activity in the left lower zone of both images is due to the liver. The **arrows** point to an area of increased activity that superficially resembles a thrombus but is due to the spleen which is raised as a result of an elevated left hemidiaphragm. ANT = anterior; RAO = right anterior oblique.

In most cases, the appearance of a thrombus is typical and little difficulty is experienced with its interpretation. Typical thrombi are illustrated in Figure 1. Most commonly, positive images are represented as a single hot spot (panel A, Fig. 1). Less commonly, multiple hot spots are seen (panel C, Fig. 1). The thrombus might be seen tangentially in which case a linear area of increased activity is seen (panel D, Fig. 1). In 2 patients, we have seen a circular increase in activity (panel B, Fig. 1), which is due to a laminated thrombus occupying most of the surface of the aneurysmal left ventricle. When scintiphotos (Fig. 1) are seen at any 1 time during the course of imaging, the interpretation is unequivocally positive. The strength of this technique is that it is highly specific.[7,8] Its limitation resides with its relatively low sensitivity. However, the series presented includes patients with chronic LV aneurysms and therefore old thrombi. We anticipate that studies designed to detect newly forming thrombi, as might occur during acute myocardial infarction, would be more sensitive than those in patients with chronic disease. This study also demonstrates that this technique is highly reproducible.

Apart from indium-111 platelet scintigraphy, several other noninvasive techniques have been used to identify LV thrombi. Two-dimensional echocardiography has the advantage of being suitable for repeated studies.[8,19–23] Its major limitation is image quality. Of the studies, 25% cannot be used for thrombus determination. With technically adequate studies, 2-D echocardiography carries a sensitivity and specificity of 77 and 93%.[19] Strict criteria should be used for clot detection. Either global or regional LV dysfunction must be present. The clot needs to be viewed in at least 2 transducer positions. The clot blood interface is usually echogenic, with the interior of the thrombus demonstrating a variable degree of echogenicity. Computerized tomography has recently been proposed as a means of identifying clot.[24,25] Image quality has improved with newer generation equipment. Motion artifact has been reduced. Preliminary studies are promising, but studies defining its diagnostic accuracy have not yet been reported. It is possible that platelet scintigraphy, a highly specific test that reflects thrombus activity, might be used to complement either 2-dimensional echocardiography or computerized tomography. Both of these later techniques reflect thrombus mass. Radionuclide angiography may also be used to detect intraventricular thrombi. It is widely available and like 2-dimensional echocardiography may be used in the simultaneous evaluation of global and regional LV function.[26]

In summary, the following are recommended concerning the imaging of LV thrombi using indium-111 labeled platelets. Imaging should only be performed on the day of injection and 3 or 4 days thereafter. On both imaging days, the left anterior oblique, right anterior oblique, left lateral, and anterior views should be used to facilitate the localization of LV thrombi, which is particularly important when studying patients during acute myocardial infarction when the possible sites of thrombi are multiple. All images should be interpreted only after chest X-ray has excluded the coexistence of a raised left hemidiaphragm.

Acknowledgment: We thank Mary Murray and Deborah Beauvais for typing the manuscript.

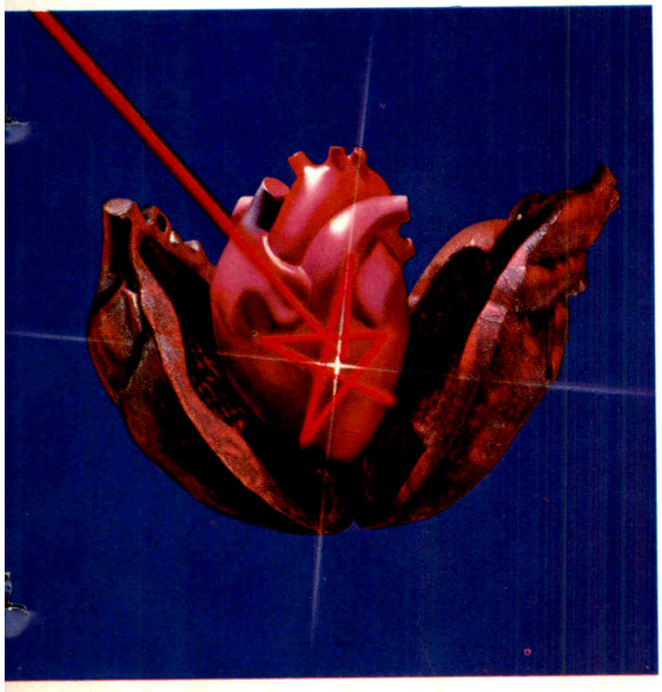
Heart failure makes
life more difficult

CAPOTEN®
(captopril tablets)
makes living
easier

SQUIBB

With the availability of CAPOTEN, heart failure† patients can enjoy an enhanced quality of life. Because, in patients who require more than digitalis and diuretics, CAPOTEN can improve their hemodynamic profile[1] and provide an opportunity to feel better.

- Eases principal heart failure symptoms[1]
- Restores patients' sense of well-being[1]
- Increases patients' capacity for exercise,[1] allowing them to participate more fully in the physical activities of everyday life



ACE* INHIBITOR

CAPOTEN®
(captopril tablets)

Can make the difference between merely existing and actively living

†CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

*Angiotensin Converting Enzyme

Please see brief summary of prescribing information on last pages of this advertisement.

ACE*INHIBITOR

CAPOTEN®
(captopril tablets)

CAPOTEN has been associated with the development of neutropenia/agranulocytosis (0.3% of 4,000 patients) or proteinuria (1.2% of 4,000 patients).† These serious side effects are more likely to occur in patients with predisposing conditions, such as renal impairment or autoimmune disease, or in patients receiving therapy known to suppress the autoimmune response.

The following precautionary guidelines are recommended for all patients receiving CAPOTEN:

- **Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.**
- **Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.**
- **Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.**
- **The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.**

*Angiotensin Converting Enzyme

†Please see brief summary of prescribing information on last pages of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

Reference: 1. Data on file, Squibb Institute for Medical Research.

CAPOTEN® TABLETS
Captopril Tablets

INDICATIONS: Hypertension — Because serious adverse effects have been reported (see WARNINGS), CAPOTEN is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects.

Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

WARNINGS: Proteinuria — Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients.

Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related. Most cases of proteinuria occurred by the 8th month of therapy. Patients should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine — the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

Neutropenia/Agranulocytosis — Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).

Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller. In these patients white blood cell counts should be performed every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Hypotension — Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).

In heart failure, where blood pressure was either normal or low, transient decreases in blood pressure >20% were recorded in about ½ the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTION: General: *Impaired Renal Function,* Hypertension — Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure — About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* — A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis, due to decreased afterload reduction.

Surgery/Anesthesia — If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension: Patients on Diuretic Therapy* — Precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose in hypertensive patients.

Agents Having Vasodilator Activity: In heart failure patients vasodilators should be administered with caution.

Agents Causing Renin Release — Captopril's effect will be augmented by

 (Continued on next page.)

(continued from preceding page)

antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity — The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium — Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Usage in Pregnancy: There are no adequate and well-controlled studies in pregnant women. Embryocidal effects were observed in rabbits. Therefore, captopril should be used during pregnancy only if the potential benefit outweighs the potential risk to the fetus.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving about 4000 patients.

Renal — One to 2 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic — Neutropenia/agranulocytosis occurred in about 0.3% of captopril treated patients (see WARNINGS). Two of these patients developed sepsis and died.

Dermatologic — Rash (usually mild, maculopapular, rarely urticarial), often with pruritus and sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 100 patients — reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular — Hypotension in about 2 of 100 patients. See WARNINGS (Hypotension) and PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia — About 7 of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice and hepatocellular injury with secondary cholestasis have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern in correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN should be taken one hour before meals. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 25, 50, and 100 mg in bottles of 100, and in UNIMATIC® unit-dose packs of 100 tablets.

Congestive Heart Failure

Mechanisms, Evaluation and Treatment
Dean T. Mason, M.D.

This rare treatment of such a multifaceted subject provides an unusual opportunity for the busy clinician to add to his knowledge in a minimum amount of time. Any area of immediate interest can be rapidly located and as much data as needed can be quickly extracted. The concentration on improved clinical management will be appreciated by every internist, cardiologist, generalist, and any professional involved in cardiovascular medicine.

Dean Mason, President of the American College of Cardiology, has organized this monograph within the three areas relevant to an understanding of congestive heart failure: *mechanisms, evaluation* and *treatment*. Fifty-six recognized authorities have been assembled by Dr. Mason, each contributing their expertise to make this book the foremost text covering the highly important and common disorders of abnormal heart function.

This presentation of recent advances in basic research and clinical progress has been highly acclaimed for its major contribution to the improvement of patient care. We invite you to see if you don't agree. Order and take 30 days to look over the book. If you're not totally satisfied, return it.

About the author . . . Dean T. Mason, M.D.

Professor of Medicine, Professor Physiology, Chief of Cardiovascular Medicine, University of California, School of Medicine, Davis.

President, American College of Cardiology; President, Western Society for Clinical Research.

Member of the American Board of Internal Medicine Cardiovascular Diseases.

Has authored more than 400 original articles on cardiovascular science and clinical cardiology.

Serves on the editorial boards of The American Journal of Cardiology, The Journal of Clinical Investigation, Circulation, Chest, Clinical Pharmacology and Therapeutics, Catheterization and Cardiovascular Diagnosis, and Heart and Lung.

Recipient of Experimental Therapeutics Award in 1973 from the American Society of Pharmacology and Experimental Therapeutics, the Research Awards in 1965 from the American Therapeutic Society, and the Theodore and Susan B. Cummings Humanitarian Awards in 1972, 1973, and 1975 from the U.S. State Department and the American College of Cardiology.

YORKE MEDICAL BOOKS Box C-757, Brooklyn, N.Y. 11205

Please send me a copy of CONGESTIVE HEART FAILURE for 30 days free examination and use. If I decide to keep it, your invoice will be honored ($45.00 plus shipping cost). Otherwise, the book will be returned for full credit or refund.

☐ Full payment enclosed, publisher absorbs shipping cost.
☐ Send invoice (U.S. and Canada only)

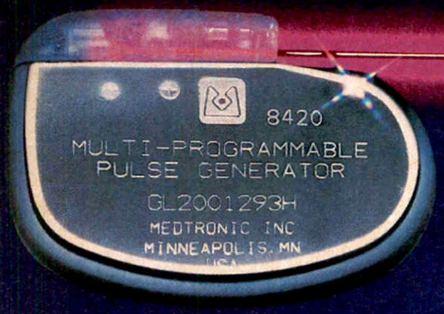
SPECTR

THE WORLD'S MOST PRESCRIBED PACEMAKER

THRESHOLD MARGIN TEST.

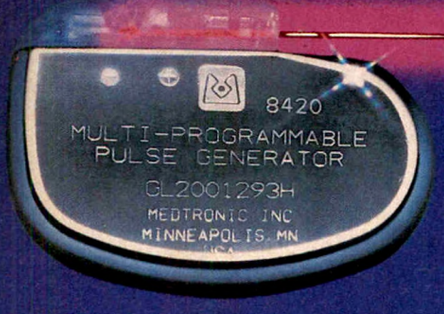
Insure adequate threshold safety margins—even over the telephon



A 66 year old female patient on vacation calls your office long distance for a routine pacer check. Are the pacing pulses sufficient to stimulate her heart? Here's how the unique Spectrax SXT™ **threshold margin test** helps you. Your patient simply positions the magnet she carries over her pacemaker and the Spectrax SXT automatically performs the test. Energy in the 3rd of 3 pulses emitted at 100 **ppm** is reduced 25% with no loss of capture, indicating an adequate safety margin. Long distance diagnosis is complete and your patient enjoys peace of mind.

AUTOMATIC THRESHOLD MEASUREMENT.

Determine pacing energy levels—fast.



You suspect loss of capture in a 62 year old male referral patient. What energy levels are needed for effective pacing stimulation of his heart? The exclusive **threshold measurement** built into his Spectrax SXT™ pacemaker gives you the answers fast. With the advanced Medtronic® CENSYS™ programmer, **automatic threshold measurement** is a simple pushbutton procedure. Reducing pulse width to the point of capture/loss tells you within 0.1 **ms** your patient's threshold. Restore original pulse width with no reprogramming needed and adjust to guarantee capture. Simple, convenient and electronically precise. That's Spectrax SXT's **automatic threshold measurement** feature.

PULSE GENERATOR BATTERY DEPLETION WARNING.

(EOL). 3 distinct warnings signal elective replacement.

Your 70 year old female patient has rushed to your office in alarm. During her routine pulse self-check test, she determined that her pacemaker had dropped 10% in rate. The implanted unit is a Spectrax SXT though, and you are able to reassure her. This rate change is simply a safeguard warning signalling elective replacement. Pulse width on the Spectrax SXT automatically increases to compensate for the gradual decline in battery voltage. She is in no danger of pacemaker battery failure or loss of capture. This fact is easily and visibly confirmed with Spectrax SXT's noteworthy telemetry which prints out battery status on command. In this case the print out has changed from **"Battery OK"** to **Elec. Replace Time!** Seeing is believing. You and your patient have several months in which to make her surgery decision. You can confidently relieve her anxiety.

Medtronic

Medtronic Implantable Pulse Generators and Leads

Intended Uses

Ventricular pacing using an implantable ventricular pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems. Cardiac pacing using an implantable A-V sequential pulse generator is for long-term therapeutic control of heart rate in patients where restoration of A-V synchrony is indicated to improve cardiac output or to protect against arrhythmias related to sequence of cardiac impulse propagation.

Contraindications

There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

Warnings

Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. See the specific precautions and warnings in the technical manuals included with the pulse generator.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

How thorough and unbiased is your drug reference?

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

Geigy

536-5763-A

A127

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings *Cardiac Failure:* Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions *Impaired Hepatic or Renal Function:* The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

Tissue Digoxin Concentrations During the Quinidine-Digoxin Interaction

NATALIE J. WARNER, MD, EDWARD B. LEAHEY Jr., MD, THOMAS J. HOUGEN, MD, J. THOMAS BIGGER Jr., MD, and THOMAS W. SMITH, MD

Digoxin concentrations in serum, myocardium, 3 separate skeletal muscles, kidney, liver, and 5 sites in the brain were measured in 26 dogs given 12-alpha ^{3}H-digoxin. Ten of the dogs also received 200 mg of quinidine sulfate orally 3 times daily for 3 days, and 6 others received 240 mg of quinidine gluconate intravenously every 3 hours for 24 hours. Mean serum quinidine concentration was 6.7 ± 1.5 μg/ml in the dogs treated with quinidine for 24 hours and 3.6 ± 2.3 in the dogs treated with quinidine for 3 days ($p < 0.01$). Mean serum digoxin concentrations were 2.72 ± 0.88 ng/ml in dogs treated with digoxin only, 2.61 ± 0.45 in dogs treated with quinidine for 24 hours (difference not significant [NS]), and 3.20 ± 0.92 in dogs that received quinidine for 3 days (NS). In dogs treated with quinidine for 3 days, serum digoxin concentration correlated significantly with serum quinidine concentration ($r = 0.76$), indicating that quinidine did affect the serum digoxin concentration. No differences in tissue digoxin concentrations were found between either of the groups of dogs that received quinidine and the group that received digoxin alone. Tissue-to-serum digoxin concentration ratios were significantly different in 4 of the tissues studied in the group of dogs that received quinidine for 24 hours. In this group, the ratio of myocardial-to-serum digoxin concentration was higher ($p < 0.01$) and ratios of renal ($p < 0.05$), occipital muscle ($p < 0.01$), and medullary brainstem ($p < 0.01$) digoxin concentrations were lower. The ratio of renal-to-serum digoxin concentration decreased as serum quinidine concentration increased ($r = -0.63$). No correlation was found between serum quinidine concentration and tissue-to-serum digoxin concentration ratio for other tissues.

Thus, in contrast to the findings in a previous study, there is no evidence of increased concentration of digoxin in the brain or of decreased digoxin concentration in the myocardium when quinidine is given to dogs receiving digoxin. The relationship of serum-to-tissue digoxin concentration changes in some tissues after 24 hours of quinidine administration. The decrease in the ratio of renal-to-serum digoxin concentration suggests that the decrease in renal digoxin clearance with quinidine is due to failure of digoxin to enter the kidney rather than to a block in the excretion of digoxin present in the kidney.

The serum digoxin concentration is used to infer cardiac concentrations of digoxin[1] and probable effects of digoxin on cardiac rhythm and contractility.[2,3] When quinidine is given with digoxin, the serum digoxin concentration increases as a result of decreases in digoxin clearance and volume of distribution.[4–8] Displacement of digoxin from binding sites in tissue, including myocardium, has been suggested as the mechanism of the quinidine-induced decrease in digoxin volume of distribution.[4–6,9] In order to manage patients receiving both digoxin and quinidine, it is important to know whether the relationship between serum digoxin concentration and myocardial digoxin concentration and effect is changed by quinidine.

Previous studies of the effects of quinidine on tissue concentrations of digoxin include a study of skeletal muscle digoxin concentration in patients and 2 studies done in animals. Schenck-Gustafsson et al[10] reported that the ratio of skeletal muscle-to-serum concentration of digoxin decreased in 8 of 10 patients after 4 days of

From the Departments of Medicine and Pharmacology, Columbia University College of Physicians and Surgeons, New York, New York, and the Cardiovascular Division, Brigham and Women's Hospital, the Department of Cardiology, Children's Hospital Medical Center, and the Departments of Medicine and Pediatrics, Harvard Medical School, Boston, Massachusetts. quinidine treatment. The decrease in skeletal muscle digoxin concentration completely accounted for the observed decrease in digoxin volume of distribution. Kim et al[11,12] gave intravenous tritiated digoxin to guinea pigs with and without simultaneous quinidine infusion. The serum digoxin concentration in animals given quinidine was higher than that of animals infused with digoxin alone, indicating that quinidine decreased the tissue uptake of digoxin. Doherty et al[13] gave tritiated digoxin to 11 dogs, 6 of which also received quinidine. The concentration of digoxin in the myocardium was lower in the quinidine-digoxin group than in the digoxin group. The mean serum digoxin concentration of the quinidine-digoxin group was also lower and there was no difference in the myocardial-to-serum digoxin concentration ratio.

The present study determines the effect of quinidine on tissue digoxin concentrations and on the ratio of tissue digoxin concentration-to-serum digoxin concentration in dogs.

Methods

Experimental preparation: Digoxin specifically labelled at the 12-alpha position with 0.2 μCi of tritium per microgram of digoxin was given to 26 mongrel dogs of either sex (14 to 27 kg) in doses of 40 μg/kg intravenously on day 1 and 20 μg/kg intravenously on days 2 and 3. Ten of the dogs received only digoxin. Ten received digoxin plus quinidine sulfate, 200 mg orally 3 times per day for the 3 days of the study. We used these regimens because preliminary studies in our laboratory showed that they produced steady-state serum drug concentrations. In an attempt to achieve higher and more predictable serum quinidine concentrations and to investigate the tissue digoxin concentration in the early phase of the quinidine-digoxin interaction, we gave 6 additional dogs 240 mg of quinidine gluconate intravenously every 3 hours for 24 hours after the third and final dose of digoxin. Tissue samples were obtained on day 4, 18 to 24 hours after the final dose of digoxin.

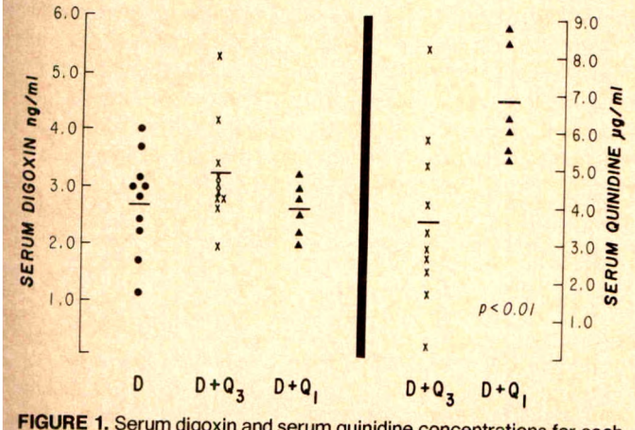

FIGURE 1. Serum digoxin and serum quinidine concentrations for each group of experimental animals. Dogs that received digoxin only are represented by **circles** and labelled D. Dogs that received digoxin and quinidine for 3 days are represented by **crosses** and labelled D + Q3, and dogs that received digoxin for 3 days and quinidine for 24 hours are represented by **triangles** and labelled D + Q1. Dogs that received intravenous quinidine for 24 hours had a mean serum quinidine concentration of 6.7 ± 1.5 μg/ml, which was significantly higher ($p < 0.01$) than the mean serum quinidine concentration of 3.6 ± 2.3 μg/ml of the dogs that received 3 days of oral quinidine. There were no statistically significant differences in mean serum digoxin concentration between any of the groups of dogs. Dogs that received digoxin alone had a mean serum digoxin concentration of 2.72 ± 0.88 ng/ml (standard deviation), dogs that received 24 hours of quinidine had a mean serum digoxin concentration of 2.61 ± 0.45 ng/ml, and dogs that received 3 days of quinidine had a mean serum digoxin concentration of 3.20 ± 0.92 ng/ml.

Tissue analysis: Serum samples were obtained from each dog immediately before it was killed. Three samples of approximately 50 mg each were obtained from the myocardium, 3 separate skeletal muscles (occipital, intercostal, and quadriceps femoris), kidney, liver, cerebral cortex, cerebellum, hypothalamus, pons, and medulla. Tissue samples were blotted dry, weighed, and dissolved by overnight incubation at 45°C in 0.5 ml of Protosol™ (New England Nuclear). Glacial acetic acid (0.02 ml) was added to each sample to make it less alkaline. After addition of scintillation medium (TT21, Yorktown Research), the samples were stored in the dark at 4°C for 1 week to reduce chemiluminescence. Duplicate samples of 500 μl of serum were added to scintillation medium and also stored in the dark for 1 week. Samples were counted in a liquid scintillation counter until there was no difference between 1 set of counts and the next, indicating that there was no remaining chemiluminescence. To permit correction for quenching, an internal standard containing approximately 5,000 cpm of tritiated digoxin was added to each sample and samples were again counted until there was no difference in counts per minute on successive determinations. By comparison with the counts per minute obtained from a known concentration of tritiated digoxin, the tissue or serum digoxin concentration was calculated in nanograms per gram of wet tissue weight or nanograms per milliliter of serum. The average digoxin concentration of the 3 samples from each tissue was calculated for each dog and used in the statistical analysis.

Serum quinidine concentration was measured by high pressure liquid chromatography after extraction by the method of Cramer and Isaksson.[14]

Statistical analysis: The ratio of tissue-to-serum digoxin concentration was calculated by dividing tissue digoxin concentration by the dog's serum digoxin concentration. Means and standard deviations of serum and tissue digoxin concentrations and of the tissue-to-serum digoxin concentration ratios were calculated for each tissue in all 3 groups of dogs. Student's t test was used to compare the mean serum quinidine concentrations of the 2 groups of dogs that received quinidine and to compare the mean serum digoxin concentration of each of the quinidine-treated groups to the mean serum digoxin concentration of the group that received digoxin alone. Hotelling's t test, a multivariate t test designed to avoid the possibility of making type I statistical errors by performing repeat t tests,[15] was used to compare tissue concentrations of digoxin between each of the groups of dogs that received quinidine and the group that received digoxin alone. Regression analysis was used to correlate serum digoxin concentration and tissue-to-serum digoxin concentration ratios with serum quinidine concentrations.

Results

Serum digoxin and quinidine concentrations: Serum quinidine and digoxin concentrations for the experimental animals are shown in Figure 1. The mean serum quinidine concentration was 3.6 ± 2.3 μg/ml (mean ± standard deviation) in the group that received 3 days of oral quinidine and 6.7 ± 1.5 μg/ml in the dogs that received intravenous quinidine for 24 hours. Despite the wide between-animal variability in the group

that received oral quinidine, these values are significantly different at the $p < 0.01$ level. Unexpectedly, no difference was found in the mean serum digoxin concentration between either group of dogs that received quinidine and the group that received only digoxin. The 10 dogs that received digoxin alone had a mean serum digoxin concentration of 2.72 ± 0.88 ng/ml. The average serum digoxin concentration in the 6 dogs that received digoxin and quinidine for 24 hours was 2.61 ± 0.45 ng/ml. The dogs that received quinidine sulfate for 3 days had an average serum digoxin concentration of 3.20 ± 0.92 ng/ml. Despite the fact that the mean is higher in this group than in either of the other 2 groups, there was wide between-animal variability in serum digoxin concentration in this group and there was no statistically significant difference between the mean serum digoxin concentration of this group and the mean serum digoxin concentration of the group that received digoxin only.

Figure 2 shows the relationship of serum digoxin concentration to serum quinidine concentration for the 10 dogs that received digoxin and 3 days of quinidine. There is a positive linear regression of serum digoxin concentration on serum quinidine concentration, indicating that a drug interaction between quinidine and digoxin occurred. No such relationship was seen between serum quinidine concentrations and serum digoxin concentrations in the dogs that received 24 hours of quinidine.

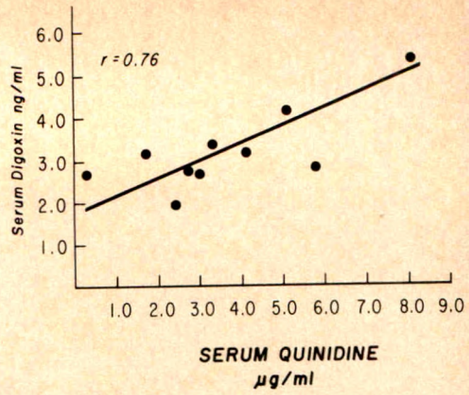

FIGURE 2. Serum digoxin concentration plotted against serum quinidine concentration as the independent variable for the 10 dogs that received 3 days of quinidine. The correlation coefficient for these 2 variables is 0.76 ($p < 0.01$).

Tissue digoxin concentrations: Table I shows the mean tissue digoxin concentration for each tissue type in the 3 groups of dogs. The tissue digoxin concentration varied widely from tissue to tissue. Kidney tissue samples had the highest digoxin concentration, followed by the heart, liver, skeletal muscle, and brain samples. We found no statistically significant differences in mean tissue digoxin concentrations between either of the 2 groups of dogs treated with quinidine and the group treated with digoxin alone.

Table I also shows the ratios of tissue-to-serum digoxin concentration for each tissue in the 3 experimental groups. Similar ratios of tissue-to-serum digoxin concentration have been reported in animals and patients treated with digoxin.[16–19] We found no significant differences in these ratios between dogs that received digoxin alone and those that received digoxin and quinidine for 3 days. However, there were differences in the ratio of tissue-to-serum digoxin concentration between the dogs that received digoxin alone and dogs that received digoxin and 1 day of intravenous quinidine. Using Hotelling's t test, which simultaneously tests the equality of the means of several variables, the chance that the tissue-to-serum ratios for the digoxin only and the digoxin and 24-hour quinidine group were equal was $p < 0.01$. (We used a critical value of $p < 0.05/2 = p < 0.025$ because we did 2 separate Hotelling's t tests.) Further analysis showed that there were differences between the 2 groups in 4 of the tissue-to-serum digoxin concentration ratios. Myocardial-to-serum digoxin concentration ratio was higher in dogs that received quinidine for 24 hours than in dogs that received digoxin only ($p < 0.01$). In contrast, the ratio of tissue-to-serum digoxin concentration was significantly lower in the kidney ($p < 0.05$), occipital muscle ($p < 0.01$), and the medullary portion of the brainstem ($p < 0.01$).

TABLE I Tissue Digoxin Concentrations and Tissue-Serum Concentration Ratios

	Tissue Digoxin (ng/g Wet Weight)			Tissue-Serum Digoxin		
	Digoxin	Digoxin + Quinidine, 3 Days	Digoxin + Quinidine, 1 Day	Digoxin	Digoxin + Quinidine, 3 Days	Digoxin + Quinidine, 1 Day

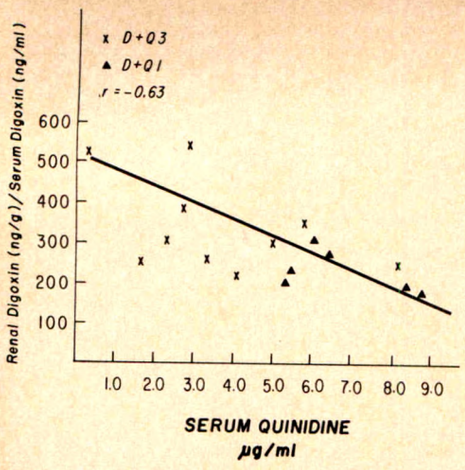

FIGURE 3. The ratio of renal-to-serum digoxin concentration plotted on the ordinate as the dependent variable against the serum quinidine concentration as the independent variable on the abscissa for all of the dogs that received quinidine. Dogs that received quinidine for 3 days are represented by **crosses.** Dogs that received quinidine for 24 hours are represented by **triangles.** The correlation coefficient between these 2 variables is -0.63 ($p < 0.05$). D + Q1 = digoxin for 3 days and quinidine for 24 hours; D + Q3 = digoxin and quinidine for 3 days.

We performed regression analysis on concentration ratio for these 4 tissues using serum quinidine concentration as the independent variable. There was no correlation between serum quinidine concentration and the ratio of tissue-to-serum concentration of digoxin for myocardial, skeletal muscle, or medullary brainstem. Figure 3 shows the relationship between renal-to-serum digoxin ratio and serum quinidine concentration. As the serum quinidine concentration increased, the ratio of renal to serum digoxin concentration decreased ($r = -0.63$, $p < 0.05$).

Discussion

Despite the fact that we could not demonstrate a statistically significant difference in mean serum digoxin concentration between either of the groups of dogs that received quinidine and the group that received digoxin only, we have evidence for the existence of a quinidine-digoxin interaction in both of these groups. Previous studies have shown a relationship between serum quinidine concentration and the magnitude of the effect of quinidine on serum digoxin concentration.[17] In the group of dogs that received quinidine for 3 days, regression analysis with serum quinidine concentration as the independent variable and serum digoxin concentration as the dependent variable (Fig. 2) showed a regression (serum digoxin concentration = 2.1 + 0.31 × serum quinidine concentration). Differences in tissue digoxin concentrations between the group of dogs that was treated with quinidine for 24 hours and the group treated with digoxin only was evidence that the quinidine-digoxin interaction was occurring after 24 hours of quinidine administration.

We did not confirm the findings of Doherty et al,[13] who reported that the concentration of digoxin in the myocardium was lower and the concentration of digoxin in the brain was higher in dogs that received digoxin and quinidine than in dogs that received digoxin only. Interpretation of both our study and that of Doherty et al is limited by the lack of a statistically significant difference in serum digoxin concentration between dogs treated with digoxin and quinidine and dogs treated with digoxin alone. We did find that the dogs that received 24 hours of high-dose intravenous quinidine (but not those that received 3 days of quinidine) had a statistically significantly higher ratio of myocardial-to-serum digoxin concentration than did the dogs that received digoxin only. Further work is necessary to determine the explanation for this finding.

Skeletal muscle accounts for 40 to 50% of the body digoxin stores in both dogs and humans.[10,17] A small change in the concentration of digoxin in the skeletal muscle would decrease the volume of distribution of digoxin sufficiently to explain the change in serum digoxin concentration seen with quinidine.[10] Neither of our quinidine regimens produced an increase in serum digoxin concentration (we did not directly measure volume of distribution) and we are unable to support the hypothesis that quinidine decreases digoxin volume of distribution and thereby increases serum digoxin concentration by displacing digoxin from skeletal muscle.

Quinidine causes a decrease in the renal clearance of digoxin, which occurs within hours of quinidine administration.[5–8,18–20] We measured the concentration of digoxin in the kidney after 24 hours of quinidine administration and found that it is less than expected based on the serum digoxin concentration. This finding suggests that decreased binding or uptake of digoxin by renal tubular cells, rather than a block in excretion of digoxin present in the kidney, accounts for the quinidine-induced decrease in renal clearance of digoxin. Previous studies have shown that the quinidine-induced decrease in the renal clearance of digoxin is quinidine dose-dependent.[7] When all 16 dogs that received quinidine in this study are considered together, there is a significant negative correlation between serum quinidine concentration and the ratio of renal-to-serum digoxin concentration.

In summary, this study reports the tissue concentrations and tissue-to-serum concentration ratios of digoxin during the quinidine-digoxin interaction in dogs. After drug doses calculated to produce steady-state serum drug concentrations, there were no differences in tissue digoxin concentrations or tissue-to-serum digoxin concentration ratios between dogs treated with quinidine and dogs treated with digoxin alone. Specifically, in contrast to a previous study,[13] we found no evidence that myocardial digoxin concentration was lower or brain digoxin concentration was higher with quinidine. In dogs that received 24 hours of intravenous quinidine, the ratio of myocardial digoxin concentration-to-serum digoxin concentration was higher and the ratios of renal, medullary brainstem, and occipital muscle-to-serum digoxin concentration were lower than in dogs that received digoxin only. The mechanism of the quinidine-digoxin interaction remains to be delineated further in studies in which the serum digoxin concentration increases substantially during quinidine treatment.

Effect of Atrial Fibrillation on Atrial Blood Flow In Conscious Dogs

PHILIP A. McHALE, PhD, JUDITH C. REMBERT, PhD, and JOSEPH C. GREENFIELD, Jr., MD

This study was undertaken to examine the independent effects of atrial tachycardia, ventricular tachycardia, and atrial fibrillation (AF) on atrial and ventricular blood flow in conscious, heart-blocked dogs using radioactive microspheres. Atrial blood flow averaged 0.54 ± 0.08 ml/min/g during the control period at an atrial rate of 124 beats/min and a ventricular rate of 90 beats/min. Atrial flow increased to 0.72 ± 0.12 ml/min/g during atrial pacing at 236 beats/min, but was not significantly altered by ventricular pacing at 200 beats/min. AF at a ventricular rate of 90 beats/min resulted in atrial flow values of 0.91 ± 0.08 ml/min/g. The ratio of atrial flow to left ventricular flow during AF averaged 1.18 ± 0.08. Administration of a maximal vasodilating dose of adenosine during AF further increased atrial flow to 2.18 ± 0.16 ml/min/g. Atrial tachycardia or AF did not significantly affect ventricular blood flow. These data indicate (1) that atrial blood flow increases significantly during AF, reaching flow values per gram of tissue comparable to those of the left ventricle, and (2) that this flow is regulated by the metabolic needs of the atrial tissue and does not represent maximal vasodilation.

The observation that coronary blood flow is regulated in direct response to metabolic need has been well established for the ventricular[1,2] as well as the atrial[3,4] myocardium. In conscious, heart-blocked dogs Neill et al[3] found that a change in atrial contraction rate from 92 to 201 beats/min increased atrial blood flow from 0.38 to 0.75 ml/min/g of tissue, thus establishing that atrial blood flow increases with increasing contraction rate, and is presumably the result of increased metabolic activity. White et al[4] observed in anesthetized dogs that atrial fibrillation (AF), with its more rapid and asynchronous pattern of contraction, increased atrial blood flow 2- to 3-fold above control values. These investigators also observed that rapid atrial pacing was a less potent stimulus for increasing atrial blood flow than was AF.[4]

The present study was designed to assess the independent effects of atrial and ventricular tachycardia and of acute AF on atrial and ventricular blood flow in a conscious dog model with complete heart block. This animal model eliminated the hemodynamic changes observed in open-chest preparations, and allowed the changes which normally occur in systemic hemodynamics due to the various interventions to be minimized. To test whether this blood flow increase represented maximal atrial vasodilation, adenosine was administered during AF. From these data, the relative maximal vasodilating capacity of atrial and ventricular vascular beds was determined.

Methods

Surgical preparation: Eleven adult mongrel dogs, weighing 20 to 28 kg, were anesthetized with sodium thiamylal (25 to 30 mg/kg, intravenously). After endotracheal intubation, respiration was maintained with an Emerson model 3-PV respirator. A left thoracotomy was performed through the fifth intercostal space. A heparin-filled polyvinyl chloride catheter (3.0 mm, outside diameter) was introduced into the arch of the aorta by way of the left internal mammary artery. The pericardium was opened and the heart was suspended in a pericardial cradle. A Medtronics model 6917A sutureless unipolar pacing lead and a bipolar pacing lead constructed in our laboratory were implanted on the free wall of the right ventricle. Complete heart block was produced by injection of <1 ml of 40% formaldehyde into the His bundle, using a modification of the method of Steiner and Kovalik.[5] The unipolar pacing electrode was tunnelled through the sixth intercostal space and the ventricular rate was maintained subsequently at 80 beats/min using a Medtronics model 5995

rate-adjustable ventricular inhibited pulse generator implanted in a subcutaneous pouch. A second bipolar pacing lead was implanted on the right atrial appendage. Additional heparin-filled polyvinyl chloride catheters were inserted into the left ventricle through the apex and into the left atrium by way of the left atrial appendage. The catheters and bipolar pacing electrodes were tunnelled dorsally into a second subcutaneous pouch but were not exteriorized until the day of the study to protect them from damage. The chest was closed, the pneumothorax evacuated, and the animal extubated. The implanted pacemaker was used to maintain heart rate throughout the postoperative period.

Experimental procedure: Studies were carried out 7 to 10 days after the initial surgery. All dogs were active and appeared to be in good health, were afebrile, and had hematocrits ranging from 38 to 46%. The dogs were placed on the study table on their right sides, and the laboratory was kept dimly illuminated. The subcutaneous pouch containing the catheters and pacing electrodes was anesthetized with 2% lidocaine infiltration. The catheters and wires were exteriorized through a 1 cm skin incision. The incision was closed in 2 layers around the catheters and wires, then sealed with Aeroplast spray dressing to prevent development of an acute pneumothorax. The ventricular rate was set at 90 beats/min using a Medtronics model 9600A rate controller and was left at that rate for the remainder of the study. The right ventricular bipolar electrode was connected to a Grass model S44 stimulator. The atrial pacing electrode was connected to a Digitimer model 3290 stimulator. The aortic, left ventricular, and left atrial catheters were cleared and connected to Statham model P23Db pressure transducers. All pressure measurements were referenced to zero at the mid-chest level. Data were recorded with a Hewlett-Packard model 3955-D magnetic tape recorder and model 7700 eight-channel direct-writing thermal recorder.

Microsphere technique: Regional myocardial blood flow and cardiac output were estimated by injecting 8 to 10 μm carbonized microspheres labelled with the gamma-emitting radionuclides cerium-141, chromium-51, scandium-46, strontium-85, and niobium-95 into the left atrium. Microspheres were obtained as 1.0 mCi of each nuclide in 10 ml of 10% dextran solution. This stock solution was diluted in 10% dextran solution so that 1.0 ml contained approximately 3,000,000 microspheres. The microspheres were mixed before injection by alternate agitation for at least 15 minutes in an ultrasonic bath and a Vortex agitator. Approximately 1.1 ml of microsphere suspension was drawn up into a preweighed 3 ml syringe, several drops of this suspension were placed into each of 5 preweighed plastic counting vials, and the syringe containing the microsphere suspension was reweighed. Blood flow measurements were made with approximately 1.0 ml of microsphere suspension injected over a 5 second interval into the left atrial catheter and the catheter was flushed with 10 ml of normal saline solution. A reference sample of arterial blood was collected into 6 plastic counting vials from the aortic catheter at a constant rate of approximately 20 ml/min by a withdrawal pump, beginning simultaneously with the microsphere injection and continuing for 90 seconds.

Experimental protocol: The atrial pacing rate was adjusted to obtain the slowest rate at which the atria could be paced without evidence of any escape beats; the ventricular rate was 90 beats/min. A microsphere injection was performed under these conditions to provide the control data. The atrial pacing rate then was increased at least 100 beats/min over the rate used during control conditions and another microsphere injection was performed. The atrial pacing rate was returned to its control value and the ventricular rate was increased to 200 beats/min by pacing the bipolar right ventricular electrode and thus inhibiting the implanted pacemaker. A microsphere injection was performed under these conditions. Bipolar pacing of the right ventricle was terminated and the ventricular rate returned to 90 beats/min and remained at that rate for the rest of the study. AF was induced by rapid (20 Hz) bipolar stimulation of the right atrial pacing electrode. In 8 dogs, AF was maintained spontaneously after a 5-min period of rapid atrial pacing; 3 dogs required continuous pacing at 20 Hz to maintain AF. A microsphere injection was made when AF or rapid atrial pacing had been present for at least 15 minutes. In 6 of the 11 dogs included in this report, an intravenous infusion of adenosine (1 mg/kg/min) was instituted while AF was present. A microsphere injection was performed under these conditions when all hemodynamic variables had been stable for at least 5 minutes.

Tissue preparation: The animals were killed at the end of data collection by intravenous administration of 30 mg/kg sodium thiamylal followed by 40 mEq of potassium chloride. The heart was removed and the atria were carefully dissected from the ventricular and venous tissues. The atria were separated into 3 pieces representing the right atrial free wall, the left atrial free wall, and the interatrial septum. Each atrial piece was weighed to the nearest 0.1 g. The left and right ventricles were separated and weighed to the nearest gram. All tissue was fixed in 10% buffered formalin for at least 24 hours. The 3 atrial pieces were cut into multiple small sections each weighing approximately 0.5 g. Care was taken to identify any samples that exhibited tissue damage due to formaldehyde injection and these samples were excluded from the blood flow determinations. Ten transmural samples weighing approximately 1 g were obtained from the free wall of the right ventricle midway between the apex and the pulmonary outflow tract. Each of these transmural samples was divided into an epicardial and an endocardial portion. The left ventricle, including the ventricular septum, was sectioned into 4 transverse rings of approximately equal thickness. The 2 middle rings were divided radially into 7 anatomic sections. Each radial section was further subdivided into 4 transmural layers of approximately equal weight from the epicardium (layer 1) to the endocardium (layer 4). Each tissue sample was weighed to the nearest milligram and was placed in a separate plastic vial for subsequent gamma counting.

Calculation of myocardial blood flow and cardiac output: Each tissue sample and the reference blood samples were counted for 10 minutes in a Packard model A5912 gamma spectrophotometer. Counts were accumulated in predetermined energy range windows selected to maximize activity from a given isotope while minimizing spillover from the other isotopes used in the study. Spillover ratios for each isotope into the lower energy windows were determined from locally prepared standards and used to correct the raw tissue counts obtained in each window by the standard stripping technique described by Rudolph and Heyman.[6] Total blood flow to each myocardial tissue sample (Q_m) in milliliters/minute was calculated using the formula: $Q_m = Q_r \cdot C_m/C_r$, where Q_r is the reference blood sample flow rate (milliliters/minute), C_m is the corrected count activity in the myocardial tissue sample, and C_r is the total count activity in the reference blood sample. Total myocardial tissue sample blood flow was divided by the corresponding tissue sample weight and expressed as milliliters/minute/gram of tissue.

Cardiac output (Q_{co}, milliliters/minute) was determined from the relation: $Q_{co} = Q_r \cdot C_i/C_r$, where Q_r and C_r are as defined previously and C_i is the total amount of activity injected into the left atrium. C_i was determined in the following manner: the 5 plastic counting vials containing several drops of microsphere suspension were reweighed and the weight of microsphere suspension in them was determined by subtraction. The empty syringe from the microsphere injection and the 5 vials were counted in the gamma spectrophotometer

TABLE I Anatomic Data

Body weight (kg)	24 ± 1 (11)
Right ventricular weight (g)	45 ± 2 (11)
Left ventricular weight (g)	111 ± 5 (11)
Right atrial free wall weight (g)	7.1 ± 0.5 (8)
Interatrial septum weight (g)	2.7 ± 0.1 (8)
Left atrial free wall weight (g)	6.2 ± 0.5 (8)
Total atrial weight (g)	16.0 ± 0.7 (8)
Left ventricular/body weight ratio (g/kg)	4.6 ± 0.2 (11)
Left atrial/body weight ratio (g/kg)	0.27 ± 0.02 (8)
Right atrial/right ventricular weight ratio	0.28 ± 0.02 (8)
Left atrial/left ventricular weight ratio	0.06 ± 0.01 (8)

Values are means ± standard error. Numbers in parentheses indicate the number of dogs in which these values were measured. Atrial free wall weights were used in ratio computations. Left ventricular weight includes the interventricular septum.

for 10 minutes each. An estimate of the counts/milligram of microsphere suspension was obtained by dividing the total number of counts in each vial by the weight of the microsphere suspension in that vial. The average counts/milligram for the 5 vials was determined and then multiplied by the difference between the full and empty syringe weights to obtain an estimate of the total number of counts contained in the syringe before injection. The total number of counts remaining in the empty syringe was subtracted from this value to determine C_i, the total number of counts injected into the left atrium. The coefficient of variation of the average counts/milligram of microsphere suspension was <5% for each injection. The percentage of the total number of counts contained in the full syringe that was injected into the left atrium ranged from 85 to 94%.

Data analysis: Right atrial free wall flow values were computed by averaging the data obtained from the individual right atrial samples. A similar procedure was used to obtain flow values for the left atrial free wall and the interatrial septum. In addition, a combined atrial flow value was obtained by computing the average flow for all atrial samples, including the interatrial septum. The endocardial/epicardial blood flow ratio for each left ventricular radial section was computed by dividing the blood flow value obtained for layer 1 into the value for layer 4. Data for all right ventricular samples were averaged to provide the right ventricular blood flow values; similarly, all left ventricular data values were averaged to obtain the left ventricular blood flow values. Thus, each dog contributed to the final analysis a single data value for each anatomic region for each intervention, irrespective of the actual number of atrial or ventricular tissue samples that were obtained.

Atrial rate, ventricular rate, aortic pressure, and left atrial pressure were measured from the graphic output obtained at the time of microsphere injection. These data were averages over several respiratory cycles before administration of microspheres and again after completion of reference blood sample collection. Atrial and ventricular vascular resistance indexes were computed by dividing the mean arterial pressure by the myocardial blood flow values determined by the microsphere technique.

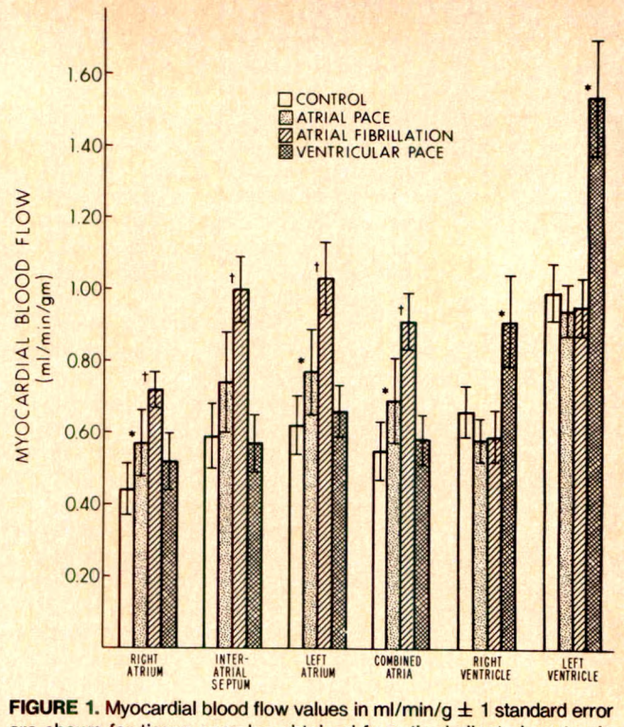

FIGURE 1. Myocardial blood flow values in ml/min/g ± 1 standard error are shown for tissue samples obtained from the indicated anatomic regions during the control period and during the interventions of atrial pacing, AF, and ventricular pacing. **Asterisks** denote a mean value that was significantly different ($p < 0.05$) from the control value; **daggers** denote a mean value during AF that was significantly different from the value obtained during atrial pacing.

Statistical analyses were carried out using multiple paired t tests. When appropriate, the Bonferroni method of adjusting the critical value of t for multiple comparisons was employed.[7] Throughout this report, a p value <0.05 was considered to represent a significant difference between 2 mean values.

Results

Specific anatomic weights and computed weight ratios for the atria and ventricles of the dogs included in this report are shown in Table I.

Hemodynamic data obtained in 11 dogs during control conditions and during the interventions of atrial

TABLE II Hemodynamic Data

	Atrial Rate (beats/min)	Ventricular Rate (beats/min)	Mean Aortic Pressure (mm Hg)	Left Ventricular End-Diastolic Pressure (mm Hg)	Cardiac Output (liters/min)
Control	124 ± 5	90 ± 1	95 ± 4	5 ± 1	3.0 ± 0.2
Atrial pace	236 ± 4*	90 ± 1	92 ± 4	4 ± 1	2.7 ± 0.2
AF	. . .	89 ± 1	94 ± 4	3 ± 1*	2.2 ± 0.2*
Ventricular pace	124 ± 5	199 ± 1*	98 ± 3†	. . .	3.2 ± 0.3

Values are means ± standard error of 11 dogs.
* Significantly different ($p < 0.05$) from control values.
† Significantly different ($p < 0.05$) from atrial pace and AF values.

pacing, AF, and ventricular pacing are summarized in Table II. Mean aortic pressure was 95 ± 4 mm Hg during the control period, and did not change significantly from the control value as a result of the interventions. Cardiac output was not changed from its control value by either atrial or ventricular pacing; however, a significant 26% decrease in cardiac output was observed during AF. Mean left atrial pressure was 4 ± 1 mm Hg during the control period and during the pacing interventions; a slight but significant decrease in mean left atrial pressure to 3 ± 1 mm Hg was observed during AF.

Atrial and ventricular blood flow data obtained in 11 dogs during control, atrial pacing, AF, and ventricular pacing are shown in Figure 1. Transmural distribution of flow in both the right and left ventricle was not affected by the atrial pacing interventions; thus, only combined values for ventricular flow are given. During the control period, right atrial flow averaged 0.44 ± 0.07 ml/min/g and was significantly lower than the average left atrial flow value of 0.62 ± 0.08 ml/min/g. Thus, right atrial flow per gram of tissue was approximately 71% of the corresponding flow in the left atrial tissue. In the combined atrial samples, atrial pacing significantly increased atrial blood flow by 28%, from 0.54 ± 0.08 to 0.72 ± 0.12 ml/min/g. AF further increased atrial blood flow to 0.91 ± 0.08 ml/min/g which represents a significant 26% increase over the blood flow observed during atrial pacing at 236 beats/min. This pattern of an increase in atrial flow with atrial pacing and a further increase with the onset of AF was observed in the individual samples obtained from the right atrium, left atrium, and interatrial septum. Further analysis of these data revealed that with AF the dogs fell into 2 distinct groups. In 1 group (6 dogs) there were no discrete atrial contractions that resulted in any change in atrial pressure; in the second group (5 dogs) discrete atrial pressure changes ranging from 1 to 3 mm Hg were generated at a rate of 500 to 800/min. In those dogs in which no discrete pressure changes were observed, the atrial flow increased an average of 0.47 ± 0.06 ml/min/g from the control value. In those dogs in which discrete pressure variations were observed, the atrial flow increased 0.25 ± 0.10 ml/min/g from the control value. While the difference in these 2 mean values failed to reach statistical significance ($p = 0.08$) it strongly suggests that AF without a definite organized atrial contraction induces a greater increase in atrial flow than occurs when a synchronized rapid atrial pressure wave is produced. Neither atrial pacing nor AF significantly changed the blood flow to the right or left ventricular tissue samples from that observed during the control period. A 39% increase in right ventricular and a 55% increase in left ventricular blood flow was observed with ventricular pacing at 200 beats/min compared with the control value. The left ventricular endocardial/epicardial blood flow ratio was 1.32 ± 0.03 during the control period and increased slightly but significantly to 1.47 ± 0.06 during ventricular pacing. However, ventricular pacing did not significantly alter blood flow to the atrial tissue samples in any of the regions examined.

These changes in atrial blood flow relative to ventricular blood flow can be examined further by computing several blood flow ratios. Figure 2 shows the right atrial/right ventricular, left atrial/left ventricular, and right atrial/left atrial blood flow ratios during the control period and during the interventions of atrial pacing, AF, and ventricular pacing. The left atrial/left ventricular blood flow ratio was 0.61 ± 0.05 at control, increased to 0.77 ± 0.06 with atrial pacing, and increased further to 1.18 ± 0.08 with AF. With ventricular pacing the ratio decreased to 0.43 ± 0.02. The right atrial/left atrial flow ratio was 0.69 ± 0.04 in the control period and did not change significantly with any of the interventions.

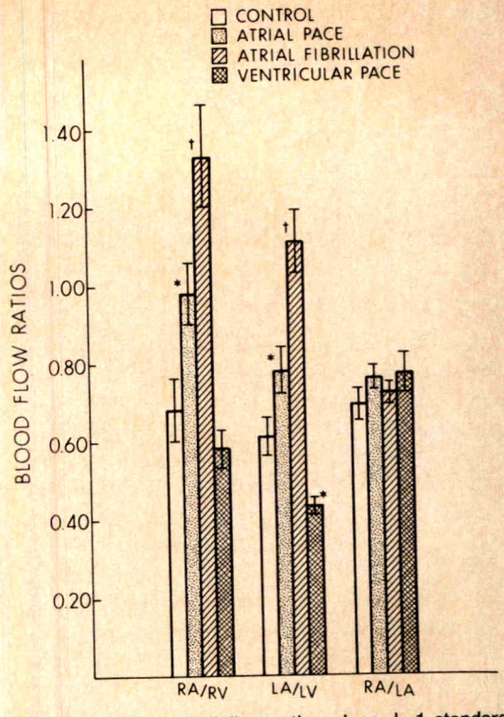

FIGURE 2. Myocardial blood flow ratio values ± 1 standard error computed between the indicated anatomic regions during the control period and during the interventions of atrial pacing, AF, and ventricular pacing. **Asterisks** denote a mean value that was significantly different ($p < 0.05$) from the control value; **daggers** denote a mean value during AF that was significantly different ($p < 0.05$) from the value obtained during atrial pacing. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

The hemodynamic effects of a maximal vasodilating dose of adenosine in 6 dogs are shown in Table III. In the presence of AF, adenosine administration decreased

† Significantly different from control and AF values.
‡ Significantly different from corresponding combined atria value.

mean aortic pressure from 96 ± 4 to 70 ± 3 mm Hg. Cardiac output increased 45% from its value during AF alone and reached a value (3.0 ± 0.2 liters/min) that was not significantly different from the cardiac output observed during the control period. Left atrial pressure was not altered by adenosine administration. Atrial and ventricular blood flows during the control period and during AF with and without adenosine are shown in Figure 3. With adenosine administration, atrial blood flow increased 146% from the value observed during AF alone. This atrial blood flow value of 2.18 ± 0.16 ml/min/g represents a 303% increase over the corresponding control value. For comparison, left ventricular blood flow increased from a control value of 1.02 ± 0.11 to 4.09 ± 0.27 ml/min/g with adenosine administration during AF. Thus, adenosine administration resulted in a 300% increase in ventricular blood flow.

Vascular resistance indexes computed for the control period and during AF with and without adenosine are shown in Table IV. Administration of adenosine during AF resulted in a 69 ± 4% decrease in the atrial resistance index while the right and left ventricular resistance indexes decreased 85 ± 4% and 80 ± 3%, respectively. This 69% atrial resistance index decrease is significantly lower than the 85% and 80% decrease in the ventricular vascular resistance indexes. Note that the vascular resistance index for the left ventricle is significantly less than for the combined atria during both the control period and during vasodilation secondary to AF and adenosine administration.

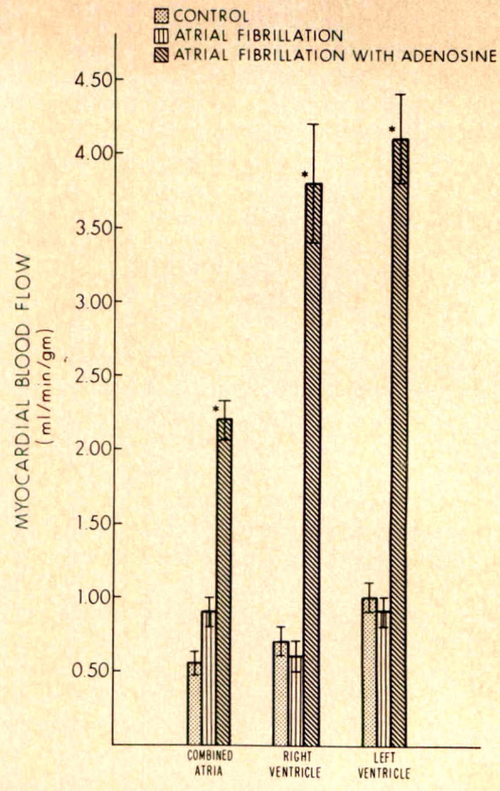

FIGURE 3. Myocardial blood flow values in ml/min/g ± 1 standard error are shown for tissue samples obtained from the indicated anatomic regions during the control period and during AF with and without adenosine. **Asterisks** denote a mean value obtained during AF with adenosine administration that was significantly different ($p < 0.05$) from the corresponding value obtained during AF alone. Note the change in scale from Figure 1.

Discussion

This study was carried out in conscious dogs to avoid the effects of acute surgical trauma and thus obtain the data in as physiologic a preparation as possible. Complete heart block was created so that a constant ventricular rate of 90 beats/min could be maintained during atrial pacing and AF, keeping the perfusion pressure of the atrial and ventricular vascular beds constant. As shown in Tables II and III, mean aortic pressure remained within a range of 6 mm Hg, except when adenosine was administered.

During the control period, atrial pacing at 124 beats/min resulted in atrial contractions that generated atrial pressure increases ranging from 2 to 12 mm Hg in all dogs. Atrial pacing at 236 beats/min also resulted in discrete atrial contractions that generated comparable pressure increases. During AF, the group of 5 dogs which exhibited discrete atrial pressure changes did not increase their atrial blood flow as much as the group of 6 dogs which exhibited no discrete atrial pressure changes. Thus, it seems fair to conclude that atrial blood flow is determined, at least in part, by the frequency of atrial contraction. In addition, Neill et al[3] observed in heart-blocked dogs that atrial vasomotion is independent of ventricular vasomotion, as demonstrated by the fact that atrial blood flow did not increase in response to ventricular pacing. This observation was confirmed in the present study.

The increased flow observed during AF could have resulted from an acute increase in atrial size, resulting in an increase in atrial wall stress. Atrial geometry was not measured in the studies included in this report. However, mean left atrial pressure was slightly decreased during AF and, unless there is a marked decrease in atrial compliance, it is unlikely that the atrium was larger. Henry et al,[8] using echocardiographic determinations of left atrial size in human subjects, observed no change in atrial size before and after an episode of paroxysmal AF.

In the present experiment it was not possible to obtain samples of atrial venous blood; therefore, we cannot directly address the question of whether the increased flow observed during AF represents a true increase in metabolic demand. However, White et al,[4] using a microspectrophotometric method in anesthetized dogs,

observed that the atrial O_2 extraction averaged 61% in their experiment when sinus rhythm was present and was not altered by AF. Thus, it is reasonable to assume in our dogs that the metabolic demands of the atrial muscle are significantly increased during AF and that these demands are met primarily in increasing blood flow. In a study which compared ventricular blood flow in the empty beating heart to the empty fibrillating heart, Kleinman and Wechsler[9] observed that an 82% increase in flow occurred when ventricular fibrillation was induced. This change is comparable to the 69% increase in atrial blood flow observed during AF.

It is important to know if the elevated blood flow observed during AF represents maximal atrial vascular vasodilation or if this vascular bed is simply regulating its blood flow at a level consistent with its metabolic demand. In the present study, administration of a maximal vasodilating dose of adenosine during AF resulted in a 146% increase in atrial blood flow from that observed during AF alone. This observation would indicate that atrial blood flow during AF is not maximal and thus appears to be under active vasomotor control.

The data obtained in our studies and in the study of White et al[4] clearly demonstrate that the acute onset of AF induced by electrical stimulation is associated with a significant increase in atrial flow. This does not answer the question of whether chronic AF is associated with a similar increase in atrial blood flow and, hence, it is somewhat premature to speculate on the clinical importance of these measurements. On the other hand, if the chronically fibrillating atria can be shown to maintain a high metabolic need per gram of tissue, especially in the hypertrophied atrium, then the presence of a flow-limiting stenosis proximal to the branching of the atrial arteries may create a hemodynamic impairment that has not been appreciated previously. That is, the increase demand for flow in the atria may act to further reduce the already compromised amount of flow available for ventricular perfusion, and hence accelerate symptomatic coronary artery disease.

Acknowledgment: We express our gratitude to Kirby Cooper and Eric Fields for surgical preparations, Donald G. Powell and the staff of the Durham Veterans Administration Medical Center Medical Media Production Service, J. Michael Taylor and the staff of the Durham Veterans Administration Medical Center Animal Care Facility, and Dianne Higginbotham for skillful preparation of the manuscript. We are especially grateful to Leigh Stubbs of Medtronics for assistance with the pacing technique and to Robert Murdoch for developing the techniques necessary for determining cardiac output from the radioactive microsphere injections.

Relation of Left Ventricular Mass to Geometry of the Proximal Coronary Arteries in the Dog

RICHARD S. STACK, MD, JUDITH C. REMBERT, PhD, BRUCE SCHIRMER, MD, and JOSEPH C. GREENFIELD, Jr., MD

Proximal epicardial coronary artery luminal diameters were measured from silicone casts formed in situ in freshly excised hearts under a constant pressure of 100 mm Hg. Twenty-five coronary arteries from 15 normal dogs and 22 coronary arteries in 13 dogs with either chronic pressure or volume overload hypertrophy were studied. Mean left ventricular (LV) body weight ratios were 4.75 ± 1.01 g/kg in the normal dogs, 8.4 ± 1.7 g/kg in the pressure-overload dogs, and 6.2 ± 0.6 g/kg in the volume-overload dogs. The cross-sectional area of the left circumflex (LC) coronary artery was determined at 11 branch sites. The ratio of the area of the branches to the area of the parent vessel was 1.095 ± 0.105, indicating that the cross-sectional area after a branch point increased.

A poor correlation existed between LV mass and coronary artery diameter in both normal and hypertrophy groups for the LC ($r = 0.44$), the left anterior descending (LAD) ($r = 0.63$), and the combined LC and LAD ($r = 0.52$). The mean cross-sectional area of the combined LC and LAD was 0.12 cm^2 in the normal group and 0.15 cm^2 in the hypertrophy group; this increase was not statistically significant ($p = 0.13$). When the mean cross-sectional area of the combined vessels was adjusted for heart weight, there was a decrease in the cross-sectional area/100 g of myocardium in the hypertrophy group compared with the control group. These data demonstrate that coronary artery luminal diameter in the dog does not increase commensurately with the increase in mass associated with myocardial hypertrophy.

The luminal diameter of the proximal coronary arteries is a major determinant of blood flow velocity. Shear stress at the blood-endothelial interface is directly proportional to blood flow velocity and is inversely proportional to the radius of the lumen.[1] Since myocardial blood flow increases proportionately with increasing ventricular mass,[2] the relation between coronary luminal diameters and left ventricular (LV) mass is of interest. In order for proximal blood flow velocity and hence the shear stress to remain unchanged in the presence of LV hypertrophy, the coronary arteries would have to increase in size commensurately with the increase in LV mass. If the coronary artery luminal diameters did not increase proportionately, the proximal blood flow velocity and shear stress would increase in the arteries supplying hypertrophied ventricles.

The dimensions of the epicardial coronary arteries at branch points also significantly influence coronary blood flow. The relation between the cross-sectional area of a vessel proximal to its branches and the total cross-sectional area of the branches determines the resistance to flow encountered at the branch site. The relation between the cross-sectional area of coronary arteries before and after major branching points has not been determined previously.

The purposes of the present study were (1) to examine the relation between proximal coronary artery luminal diameters and LV mass in chronic LV hypertrophy, and (2) to compare the dimensions of coronary arteries relative to the size of their major branches.

Methods

Thirteen dogs with chronic LV hypertrophy were studied. Ten had a modified coarctation-banding procedure[3] performed midway between the aortic valve and innominate artery at 7 weeks of age. The puppies recovered and were allowed to mature for 17 ± 8 months (mean ± standard deviation

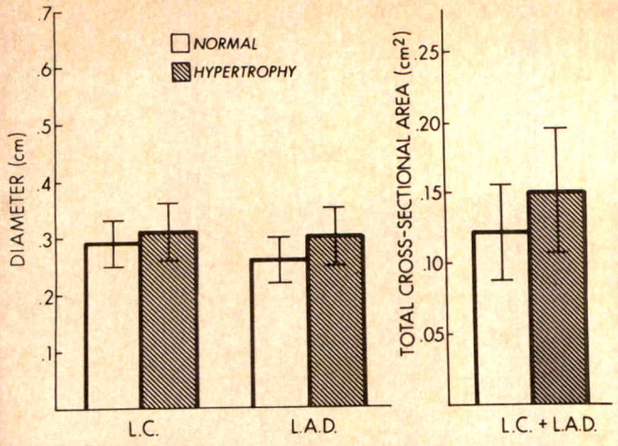

FIGURE 1. Comparison of left circumflex (LC) coronary artery diameter ($p = 0.64$), left anterior descending coronary artery diameter (LAD) ($p = 0.05$), and total cross-sectional area (LC + LAD) ($p = 0.13$) in normal and hypertrophied ventricles.

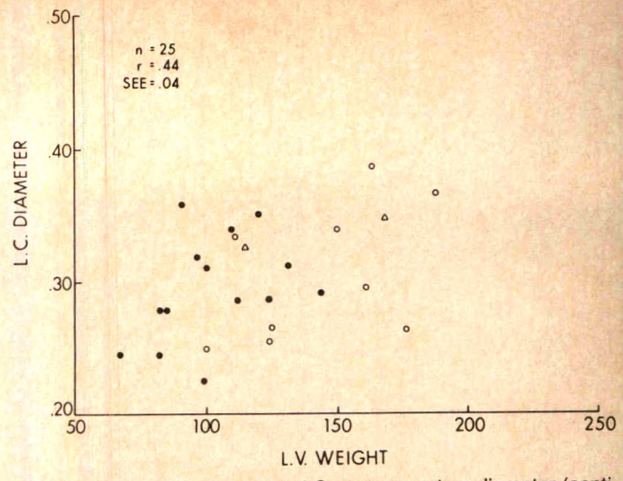

FIGURE 2. Correlation between LC coronary artery diameter (centimeters) and LV weight (grams). **Closed circles,** normal; **open circles,** modified coarctation-banding hypertrophy dogs; **triangles,** other hypertrophy dogs. SEE = standard error of the estimate.

[SD]) before being studied. The average arterial pressure measured proximal to the coarctation at the time of study was 182/88 mm Hg and the LV to body weight ratio (R) at the time of the study was 8.4 ± 1.7 g/kg.

The remaining 3 dogs in the hypertrophy group were adult mongrel dogs who underwent surgical procedures resulting in chronic volume overload hypertrophy ($r = 6.2 \pm 0.6$). In 2 of these dogs, a single chorda tendineae was surgically excised. The third adult dog had an aorto-caval fistula created between the abdominal aorta and the inferior vena cava. The average time interval from the surgery to the study in these 3 dogs was 15 ± 10 months.

Fifteen healthy adult mongrel dogs with a wide range of body weights ($r = 4.7 \pm 1.01$) served as controls.

After each dog was killed under barbiturate anesthesia by a lethal dose of potassium chloride, the heart and great vessels were removed and submerged in a bath of 0.9% normal saline solution. The left main coronary artery was cannulated from the ostium with an 8 cm section of high-pressure tubing connected by a 3-way stopcock to a Statham P23Db pressure transducer. Care was taken not to disturb the normal tethering of the vessel and there was no dissection around it. After the coronary arteries were flushed with saline solution, they were infused immediately with RTV-41 liquid silicone (General Electric) combined with adequate diluent and catalyst to ensure even flow and rapid solidification. The liquid silicone was infused until a continuous distending pressure of 100 mm Hg was achieved to approximate the mean diastolic pressure. The pressure was held constant until the silicone solidified. The coronary arteries then were removed from the heart and the vascular tissue was stripped from the silicone casts. The right ventricle, atria, and valvular tissues were excised and the stripped LV weights were recorded.

The diameters of the coronary artery casts were measured with a vernier caliper at a point just proximal to the first marginal branch of the left circumflex (LC) artery and at a point just proximal to the first diagonal branch of the left anterior descending (LAD) coronary artery. The diameter was measured 3 times at 2 perpendicular points around the circumference of each vessel and averaged to obtain the mean diameter.

The mean diameters (d) of 2 major proximal branches of the LC coronary artery casts from 4 normal dogs and 3 dogs with hypertrophy also were measured with a vernier caliper. Measurements were made within 1 mm of the branching point from the parent vessel. The diameter of the parent vessel just proximal and distal to the origin of the branch also was obtained. The cross-sectional areas (CSA) of the vessels at these points then were determined using the following relation: $CSA = \pi(d/2)^2$. The branching ratio of each branch site was computed as the combined cross-sectional areas of the 2 branches divided by the cross-sectional area of the parent vessel proximal to the branch.

To test for possible volume changes after solidification, liquid silicone was allowed to solidify in a volumetric container and was shown to maintain a constant volume after hardening. Standard parametric statistical techniques were employed to evaluate the data.

Results

The mean diameters of the proximal LAD and LC coronary arteries in the normal and hypertrophied hearts are shown in Figure 1. Although the hypertrophied hearts had increased coronary artery diameters, only the LAD coronary artery was significantly different ($p = 0.05$) from the coronary artery diameter of the normal dogs. When the LAD and the LC coronary arteries were combined to obtain the total cross-sectional area of the main vessels that supply the left ventricle in dogs, there was no significant difference between the normal and hypertrophy groups ($p = 0.13$).

The correlation between proximal coronary luminal diameter and LV weight in the normal and hypertrophied hearts is shown for the LC artery in Figure 2 and for the LAD artery in Figure 3. The total cross-sectional area of the combined vessels is plotted against the LV weight in Figure 4. Although there is a weak positive correlation in each of the comparisons, indicating a trend for a greater coronary diameter in the bigger hearts, a high degree of scatter among the data was found. This trend is apparent both for the normal dogs in whom a wide range of heart weights was obtained and the dogs with LV hypertrophy. When the total cross-sectional area of both vessels (Fig. 4) is adjusted per 100

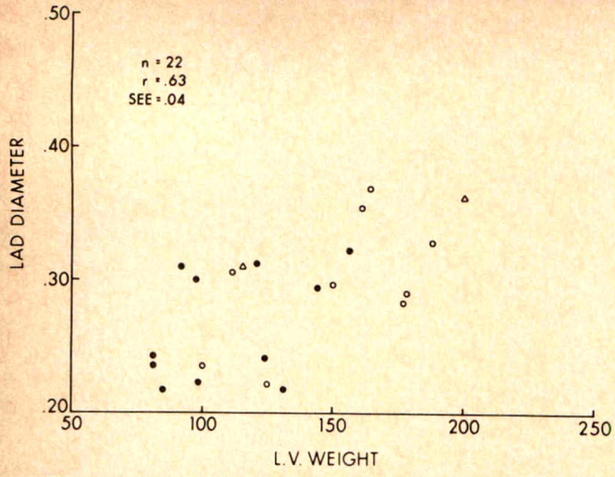

FIGURE 3. Correlation between LAD coronary artery diameter (centimeters) and LV weight (grams). **Closed circles,** normal; **open circles,** modified coarctation-banding hypertrophy dogs; **triangles,** other hypertrophy dogs. SEE = standard error of the estimate.

g of LV myocardial weight, there is a decrease in the relative size of the vessels from hypertrophied hearts (9.91 mm^2/100 g) compared with those from the normal hearts (11.4 mm^2/100 g).

Eleven branching ratios were calculated from the first or second (or both) major branches in 7 typical circumflex casts. Four were from the normal group and 3 were from the hypertrophy group. The mean branching ratio was 1.095 ± 0.105 (mean ± SD). This ratio was significantly greater than unity, $p = 0.014$, indicating that the total cross-sectional area of the vessel increased after a branching point. This result was found in all 7 dogs, whether they were in the normal or the hypertrophy group.

Histologic evaluation of the proximal coronary arteries fixed under physiologic pressure was carried out in 8 additional dogs with either pressure or volume overload hypertrophy and compared with those from 2 normal dogs. There was no evidence of abnormal thickening or fibrosis of either the intimal or medial layers.

TABLE I Coronary Size Corrected for Heart Weight in Normal and Hypertrophied Ventricles

Study	Normal Group	Hypertrophy Group
Roberts and Roberts[4]	1.61*	1.31

Wilens et al[6]	7.0‡	5.1
Current study	11.4§	9.91

Comparison of the result of 3 previous studies and the current study. Note that there is a decrease in cross-sectional area of the vessels per 100 g of myocardium in the hypertrophy group in each study when the results are adjusted for heart weight.

* Mean cross-sectional area of LC, LAD, and right coronary arteries (mm^2/100 g [heart weight]).

† Sum of left and right coronary ostia (mm^2/100 g [heart weight]).

‡ External coronary surface area (cm^2/100 g [heart weight]).

§ Total cross-sectional area LC and LAD coronary arteries (mm^2/100 g [stripped left ventricular weight]).

Discussion

Proximal coronary blood flow velocity is determined by the coronary blood flow and the cross-sectional area of the proximal coronary arteries. The present study shows that while there is a trend toward an increase in coronary artery luminal diameter with LV hypertrophy, it is not proportional to the increase in LV mass. Since the blood flow per gram of myocardium during resting conditions either remains the same or is slightly increased in enlarged ventricles,[2] the proximal coronary blood flow, blood flow velocity, and intimal shear stress all must be increased in LV hypertrophy.

Previous studies comparing the size of the major coronary arteries with myocardial mass using various techniques generally have reported a trend toward an increase in luminal cross-sectional area with increased heart size. Whether or not the coronary arteries increase in size parallel to the increase in myocardial muscle mass has remained controversial.[4–6] One way to examine this question is to compare the coronary diameter in normal and hypertrophied hearts per 100 g of myocardium supplied by the vessels. A comparison of the results of 3 previous studies, when adjusted for the reported heart weights, and the results of the current study are shown in Table I. When the mean cross-sectional area of the vessels is corrected for the heart weight in normal and hypertrophied hearts, there is a decrease in the cross-sectional area of the vessels per 100 g of myocardium with increased myocardial mass. This indicates that the small increase in coronary size that occurs with increased heart size is not proportional to the increase in myocardial mass.

To test whether this decrease in relative coronary size is physiologically significant, the intimal shear stress in the proximal circumflex coronary artery of a small (75 g) and a hypertrophied (150 g) ventricle was calculated using blood flow data previously reported from our laboratory.[2] The cross-sectional area of the LC artery of a 75 g and 150 g heart was determined from the data in Figure 2. The predicted shear stress at the blood intimal interface in the individual vessels may be obtained

from the following equation[1]: $\tau = 4\zeta\bar{V}/r_i$, where τ is the shear stress, ζ is the blood viscosity in poises, $\bar{V}$ is the mean blood velocity, and r_i is the internal radius of the vessel. Increases in shear stress are directly proportional to increases in mean blood flow velocity and inversely related to the internal radius of the vessel. Estimations of the intimal shear stress in the representative 75 g and 150 g hearts for the LC coronary artery are 9.6 and 16.1 dynes/cm^2 respectively. This shear stress would be expected to increase still further under conditions of increased blood flow, such as with exercise or other physiologic stress. For example, the average peak blood flow recorded during reactive hyperemia in similar hypertrophy dogs in our laboratory is 302 ± 72 cm^3/min.[2] This degree of flow results in a markedly elevated shear stress of 62.9 dynes/cm^2 when calculated for a 150 g heart.

The relation of the cross-sectional area of a coronary artery to that of its major branches has not been determined previously. The average ratio of the change in total cross-sectional area due to branching (branching ratio) found in the present study was 1.095. By applying a similar analysis to the data of Patel et al,[7] who studied the relation between the aorta and its major divisions, an average branching ratio of 1.11 is obtained. Blum,[8] who studied the mesenteric arterial system, compared the mass of parent and branching vessels. He calculated an average branching ratio of 1.26 in the excised postmortem state and a ratio of 1.38 when the vessel segments were stretched to the in situ length.

The change in resistance to blood flow after branching into vessels of equal size is given by the relation[9]: $P_1/P_2 = d^2/n$, where P_1 represents the pressure gradient (proportional to the vascular resistance) before a bifurcation, P_2 is the pressure gradient distal to the bifurcation, d is the branching ratio, and n is the number of branches. Therefore, for any bifurcation (n = 2), the branching ratio must be at least equal to the $\sqrt{n}$, 1.41, if the resistance to blood flow after a branching point is not to increase. The results of the present study show that resistance to flow in a single coronary artery is increased after a bifurcation. If all parallel branches are considered, however, the resistance will decrease when the overall cross-sectional area is sufficiently increased, such as at the level of the capillaries.[10] These considerations are based on the Poiseuille relation which assumes steady laminar flow in a rigid tube. A more precise analysis would involve the measurement of the impedance due to branching under conditions of pulsatile flow and would consider branches of variable size.

If the difference in coronary artery shear stress between normal and hypertrophied hearts is clinically significant, it may help explain the fact that chronic essential hypertension is a risk factor in the development of coronary artery disease. LV hypertrophy from chronic hypertension could cause increased blood flow velocity with a resulting increase in shear stress in the proximal coronary vessels, especially during periods of physiologic stress. In support of this theory, Wilens[6] reported a 7-fold increase in the prevalence of myocardial infarction when the size of the coronary arteries decreased to below 6 cm^2 of external surface area per 100 g of myocardium.

If hypertrophy itself is sufficient to cause a significant increase in the incidence of atheromatous lesions, then other disorders such as chronic valvular disease or dilated cardiomyopathy also would increase the risk of developing coronary artery disease. Since this association has not been made, the increase in blood pressure that accompanies chronic hypertension also may be important. An experiment that could have bearing on this discrepancy was carried out by Carew and Patel.[1] They evaluated the relative importance of circumferential tensile stress and shear stress in causing an increase in endothelial permeability to dye-tagged albumin in coronary arteries. These investigators found that increased circumferential tensile stress was more important than elevated shear stress. Elevated shear stress (>21.6 dynes/cm^2) became an important determinant of endothelial permeability only under conditions of high circumferential tensile stress. Hence, the combination of increased shear stress and increased circumferential tensile stress that accompanies the elevated arterial pressures in patients with LV hypertrophy due to hypertension theoretically could predispose to an increase in endothelial permeability and the subsequent development of atherosclerotic heart disease.

Quantitative Detection of Regional Left Ventricular Contraction Abnormalities by 2-Dimensional Echocardiography

Comparison of Myocardial Thickening and Thinning And Endocardial Motion in a Canine Model

JOSEPH E. O'BOYLE, BS, ALFRED F. PARISI, MD, MARKKU NIEMINEN, MD, ROBERT A. KLONER, MD, PhD, and SHUKRI KHURI, MD

Myocardial infarction (MI) was produced in 27 dogs by ligation of the left anterior descending coronary artery. Two-dimensional (2-D) echocardiograms were performed through the closed chest before and serially after coronary ligation, in both the acute and healing stages of MI. Two-dimensional echocardiographic studies performed before the animals were killed were analyzed for left ventricular (LV) contraction defects by 2 algorithms—1 involving systolic myocardial thickening and thinning and the other by determining the extent of endocardial motion to derive cavity area shrinkage. Using the thickening algorithm, myocardial dysfunction was detected in 93% of the animals with MI; with the area shrinkage method, contraction abnormalities were detected in 96% of the animals with MI. When the heart was divided from base to apex into 3 short-axis sections, the thickening algorithm showed a trend toward better identification of normal regions than the area shrinkage algorithm. However, in predicting the circumferential extent of MI, the thickening-thinning method of analysis showed no advantage over the endocardial motion method ($r = 0.77$, standard error of the estimate = 0.16 versus $r = 0.76$, standard error of the estimate [SEE] = 0.16; p = not significant [NS]).

These observations support the concept that either algorithm can be used effectively to detect the presence and quantify the circumferential extent of MI.

The use of 2-dimensional (2-D) echocardiography to detect regional left ventricular (LV) contraction abnormalities has been well documented.[1–4] Increasingly sophisticated technology has prompted a recent trend toward quantitative analysis of 2-D echocardiography. Nearly all of the studies dealing with the quantification of regional LV function have been based on analysis of LV endocardial motion.[5–11] However, evaluation of regional LV function by endocardial motion ignores the ability of echocardiography to assess transmural thickening and thinning, which is an intrinsic feature of myocardial performance independent of the swinging of the heart.[12–16] This attractive feature has led to a preference among echocardiographers for mural thickening analysis despite the fact that there has only been 1 study, performed in an open-chested canine model, which has demonstrated an advantage to thickening analysis as compared with measurement of endocardial motion by 2-D echocardiography.[17] In a closed-chest subject, particularly in the clinical setting, epicardial targets are not always detected with sufficient accuracy to allow thickening analysis. Hence, it becomes important to define in a model more analogous to the clinical situation just what is gained and lost in attempting to define regional contraction defects by each of these methods. The present study was designed to compare the relative merits of endocardial motion and mural thickening analyses in association with both acute and healing myocardial infarction (MI).

Area of MI is shown by **stippling.** A = the angle on the basal side of the pathologic slice which defines its circumferential extent of MI; B = angle on the slice's apical side which defines its circumferential extent of MI; C = maximal transmural thickness of the MI on the basal side of the slice; D = point used to measure myocardial thickness of the slice's basal side; E = the maximal transmural thickness of the MI on the slice's apical side; F = point used to measure the myocardial thickness of the slice's apical side.

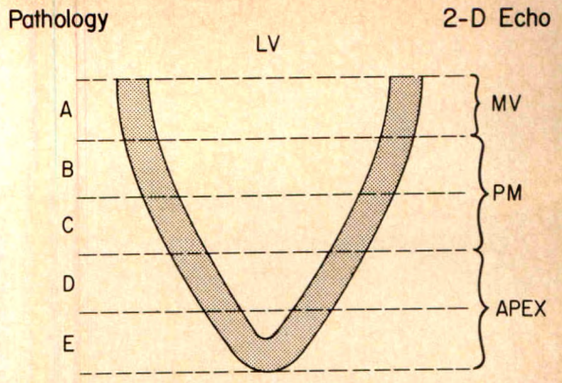

FIGURE 2. Relationship of the pathologic slices to the 2-D echocardiographic short-axis views. The left ventricle (LV) was imaged by 2-D echocardiography at 3 short-axis levels: mitral valve (MV), papillary muscles (PM), and cardiac apex (APEX). At pathologic examination, the isolated left ventricle was sliced in bread loaf fashion at 1 cm intervals—A, B, C, D, E, and so forth (see text for further explanation).

2-D echocardiographic examination which showed clear definition of LV epicardial and endocardial targets.

MI was produced through an open thoracotomy incision by ligation of the left anterior descending coronary artery. The chest was then closed and the animals were studied again by 2-D echocardiography before being killed. Animals were studied in 2 groups: an acute series in which they were killed 48 hours after coronary ligation, and a delayed series in which animals were killed periodically at intervals beyond 48 hours.

At postmortem, the heart was excised and cut into transverse, 1 cm thick sections from base to apex, parallel to the atrioventricular groove. These sections were then incubated for 15 minutes in triphenyl tetrazolium chloride (TTC) to assess size and location of the infarct; they were photographed and the normal and infarcted regions were traced on acetate sheets.[19,20]

From these pathologic tracings, the following indexes were determined for each slice: mean circumferential extent of MI, maximal circumferential extent of MI, and maximal transmural extent of MI as shown in Figure 1. The circumferential extent of MI on each side of each slice was measured as an angle, the vertex of which was located at the center of the LV cavity with rays directed tangentially along the edges of the infarcted area. The mean circumferential extent of MI for each slice was calculated as the average of the circumferential extent of MI measured on its basal and apical sides. The maximal circumferential extent of MI for each slice was defined as the greater circumferential percentage of MI on either its basal or apical side. The maximal transmural extent of MI was determined by the greater percentage of myocardial thickness that was infarcted on either the basal or apical side of each pathologic slice.

Since 2-D echocardiographic examinations were performed on a closed-chest canine model, in a manner analogous to clinical studies, it was impossible to obtain 2-D echocardiographic short-axis views that corresponded *exactly* to the thickness and number of the pathologic "bread-loaf" slices. Therefore, in order to compare the pathologic findings in the LV myocardium with the results obtained by 2-D echocardiographic examination, the pathologic slices were grouped by their anatomic landmarks in the following manner (Fig. 2). Section A, the pathologic specimen at the base of the heart, was related to the 2-D echocardiographic short-axis section which showed mitral valve elements. Pathologic sections B and C, which contained the papillary muscles, were related to short-axis echoes at the mid-left ventricle, in which the papillary muscles were visualized. The pathologic specimens D, E, and so forth were below the papillary muscles and were related to the lowest portion of the 2-D echocardiographic LV image, which did not show the papillary muscles. Thus, when comparing the circumferential extent of MI found at pathologic examination with the regional wall motion abnormality obtained by 2-D echocardiography, the papillary muscles' extent by pathologic examination was composed either of the mean of sections B and C (for mean circumferential extent) or the maximal extent found on either sections B and C (for maximal circumferential extent). In a similar fashion, we determined the mean and maximal circumferential extent of MI at the cardiac apex. The maximal transmural extent of MI was determined as the maximal percentage of myocardial thickness infarcted on either side of sections B and C for papillary muscles' extent, and on either side of slices D and E for the apical extent.

Image analysis was performed from studies recorded on a reel-to-reel video recorder (Panasonic NV3160) using ½-in videotape (Scotch 361). In all instances, outlines were traced from stop-frame images and were confirmed by playing through preceding and succeeding beats using both real-time and slow-motion playback. Cross-sectional images were traced from the video monitor onto clear acetate sheets. End-diastole was defined at the first deflection of the QRS complex, and end-systole was measured as the smallest ventricular cavity image during the last half of the T wave. These outlines were entered into a computer (PDP 11/05, Digital Equipment) by way of a light-pen digitizer (Electronics for Medicine) previously described (Fig. 3).[21] The outlines were analyzed as previously described by 2 different algorithms—thickening and cavity area shrinkage (Fig. 4)—for each of 8 octants at the mitral valve, papillary muscle, and apical cross-sectional levels.[16,21] In brief, the midpoint of the ventricular septum was

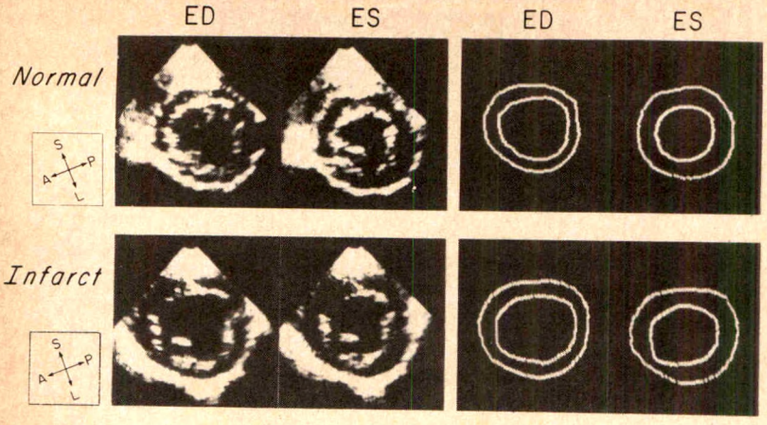

FIGURE 3. Two-dimensional echocardiograms at the level of the papillary muscles and their corresponding computer-generated epicardial and endocardial outlines. **Top left,** baseline (preligation) 2-D echocardiograms at end-diastole (ED) and at end-systole (ES). **Top right,** corresponding computer-generated outlines: ED (left); ES (right). **Bottom left,** 2-D echocardiography at ED and at ES 7 days after coronary ligation. **Bottom right,** their corresponding computer-generated outlines: ED (left); ES (right). A = anterior; L = lateral; P = posterior; S = septal.

defined as the point on the right ventricular-septal endocardial surface equidistant from the junctions of the right ventricle with the ventricular septum of LV free wall. Because of the lack of a right ventricular cavity at the cardiac apex, an equivalent point corresponding to the septal midpoint was defined. This point was placed in the same position on the circumference of the LV cavity as occurred with the septal midpoint in the immediately superior short-axis level, which was confirmed by scanning from the cardiac apex through the level of the papillary muscles. From the septal midpoint, an initial line was constructed to the lateral wall so as to divide the LV cavity into anterior and posterior halves of equal areas. From the midpoint of this line, the image was then subdivided at 45° angles into octants.

Twenty healthy dogs were used to define the normal range (mean ± 2 standard deviations) in each octant for both thickening and area shrinkage analyses. For the experimental group, an octant was considered abnormal if its contraction value was less than the lower limit of the normal range (mean − 2 standard deviations) of that octant. The circumferential extent of MI seen by 2-D echocardiography was defined as the number of abnormal octants in a short-axis view divided by 8 octants ×100%.

Previously in our laboratory, interobserver variability for the cavity area shrinkage method was extensively addressed and averaged 7.6%.[21] In a subsequent study, the intraobserver reproducibility of the myocardial thickening analysis in assessing infarct size showed a mean difference in paired observations of 4.9%.[16]

Statistical analyses were performed with a programmable Monroe 325 desk-top calculator. Sensitivity was defined as the number of 2-D echocardiographic short-axis views with abnormal contraction values which corresponded to infarcted pathologic cross-sections divided by the total number of infarcted pathologic cross-sections. Specificity was defined as the number of 2-D echocardiographic short-axis levels with normal contraction values which correspond to noninfarcted pathologic cross-sections divided by the total number of noninfarcted pathologic cross-sections. Accuracy was defined as (the number of 2-D echocardiographic short-axis sections with abnormal contraction values which corresponded to infarcted pathologic cross-sections plus the number of 2-D echocardiographic short-axis levels with normal contraction values which corresponded to noninfarcted pathologic cross-sections) divided by (the total number of pathologic cross-sections). Means, standard deviations, standard errors of the estimate, and correlation statistics were calculated using Monroe's Alpha 315 Univariate Statistics Pak and Regression Analysis Pak, respectively. Statistical significances were determined for proportions and standard errors of the estimates by the following tests: (1) the comparison of proportions in paired samples, and (2) a test of the equality of 2 variances, respectively.[22]

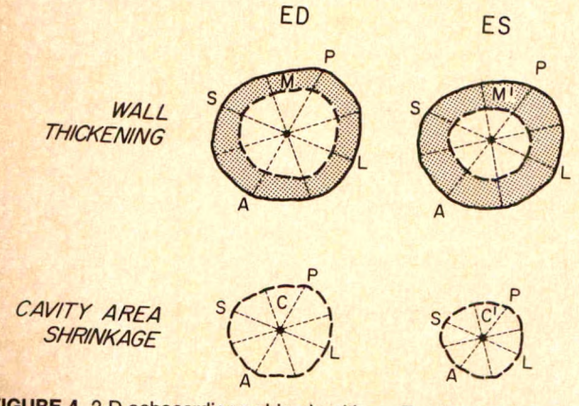

FIGURE 4. 2-D echocardiographic algorithms. Tracings of 2-D echocardiographic short-axis views were entered into a computer system that analyzed them both by the thickening method and by the cavity area shrinkage algorithm. Both algorithms utilize a floating axis format which rotates and translates the systolic outline so that the center point and the axes are superimposed upon the diastolic outline. Percent myocardial thickening in an octant is defined as $(M' - M) \div M \times 100$; percent cavity area shrinkage in an octant is defined as $(C - C') \div C \times 100$. **Continuous line,** epicardium; **heavy broken line,** endocardium; **thin broken line,** computer-generated axes; **blackened point,** computer-generated midpoint of S–L axis. A = anterior; C = LV cavity octant area at ED; C′ = LV cavity octant area at ES; ED = end-diastole; ES = end-systole, M = myocardial thickness at ED; M′ = myocardial thickness at ES; L = lateral; P = posterior; S = septal.

Results

A total of 27 dogs were studied: 14 were studied at 48 hours (acute series) and 13 were studied at intervals beyond 48 hours (evolving series). Of the 13 dogs in the evolving series, 2 were killed at 1 week, 2 at 2 weeks, 5 at 3 weeks, 3 at 6 weeks, and 1 at 8 weeks.

Pathologic examination: Of the 27 hearts, 21 were sliced into six 1-cm thick transverse sections. Four hearts were so small that they could only be sliced into five 1-cm thick sections; 2 were so large that they were sliced into seven 1-cm thick sections. In evaluating these pathologic sections, the most apical slice (the tip of the left ventricle) did not contain a cavity and as a result could not be compared with the 2-D echocardiographic

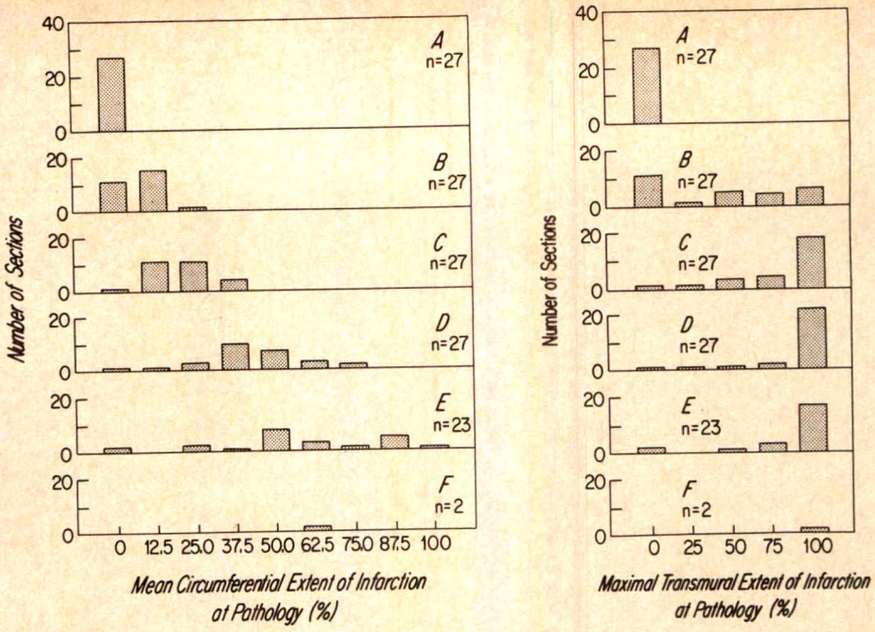

FIGURE 5. Left, Frequency distribution of mean circumferential extent of MI in the pathologic bread-loaf slices (calculated to the nearest 12.5%). Section A is the only slice that was totally free of myocardial damage in all the excised hearts. As the left ventricular apex (sections D, E, and F) was approached, the circumferential extent of MI was more heterogeneous. **Right,** frequency distribution of the maximal transmural extent of MI (calculated to the nearest 25%) found in the different pathologic segments. Section A was totally free from myocardial injury. As the left ventricular apex (sections D, E, and F) was approached, maximal transmural extent skewed toward 100%.

short-axis view of the LV apex. In most hearts, sections D and E were combined as described above. In the 4 hearts with only 5 slices, section D was equated to the cardiac apex. In the 2 hearts with 7 sections, slices D, E, and F were equated to the LV apex.

At postmortem examination, all excised hearts were found to have MI present in 1 or more of the "bread loaf" slices. Figure 5, left shows the frequency distribution of the mean *circumferential* extent of MI in the pathologic slices. In all 27 hearts, pathologic section A was found to be free of MI. In 1 of the excised hearts, both slices B and C were free of myocardial damage; in another, sections D and E were found to be free of MI. Therefore, after grouping the pathologic specimens to correspond to 2-D echocardiographic tomographic levels (see Methods and Figure 2), 52 of 54 combined slices below the level of section A had some degree of MI present; alternatively, 29 combined slices were free of infarction. As the LV apex (sections D, E, and F) was approached, the circumferential extent of MI became more heterogeneous.

Figure 5, right shows the frequency distribution of the maximal *transmural* extent of MI. Of these pathologic slices with MI (sections B to F), 28% had maximal transmural extent of MI of ≤50%. When the findings in these slices were combined for comparison with the 2-D echocardiographic short-axis views, only 6 of 52 (11.5%) had maximal transmural extent of MI of ≤50%. The maximal transmural extent of MI skews to the right (toward 100% transmural extent) as the LV apex (sections D, E, and F) was approached.

Two-dimensional echocardiographic examination: *Detecting and localizing the presence or absence of myocardial infarction:* Sensitivity was analyzed by (1) considering individual dogs, and (2) considering individual cross-sections. With the area shrinkage method, 26 of 27 dogs (96%) were assessed correctly; using the thickening-thinning algorithm, 25 of 27 dogs (93%) were assessed correctly (p = NS). In detecting MI at a particular cross-sectional level, the cavity area shrinkage algorithm identified 40 of 52 2-D echocardiographic short-axis sections (77%) correctly, and the thickening method identified 42 of 52 short-axis sections (81%) correctly (p = NS).

Since all dogs had MI present at pathologic examination, specificity could not be assessed for individual animals. However, specificity was evaluated on the 29 pathologic sections that were free of MI. Utilizing the cavity area shrinkage method, 24 of 29 2-D echocardiographic short-axis views (83%) had all octants within the normal contraction range; with the thickening algorithm, 29 of 29 2-D echocardiographic short-axis views (100%) had all octants within the normal contraction range (p = NS). Of the 232 octants from these 29 pathologic slices, the area shrinkage method correctly assessed 225 octants (97%); the thickening algorithm correctly identified all 232 octants (100%) ($p < 0.05$).

The accuracy of algorithms assessed both infarcted and noninfarcted regions; thus, comparing all the 2-D echocardiographic short-axis views with all pathological cross-sections, the accuracy of cavity area shrinkage analysis was 64 of 81 (79%) and that of the thickening-thinning method was 71 of 81 (88%) (p = NS).

Figure 6A shows the frequency distribution of pathologic sections with MI which were not identified by each method. Of those missed by the thickening al-

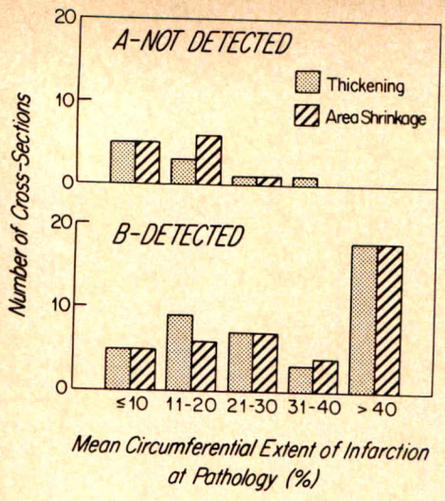

FIGURE 6. A, frequency distribution of the mean circumferential extent of MI at pathologic examinations *not detected* by 2-D echocardiographic algorithms. **B,** frequency distribution of mean circumferential extent of MI at pathologic examination detected by 2-D echocardiographic algorithm.

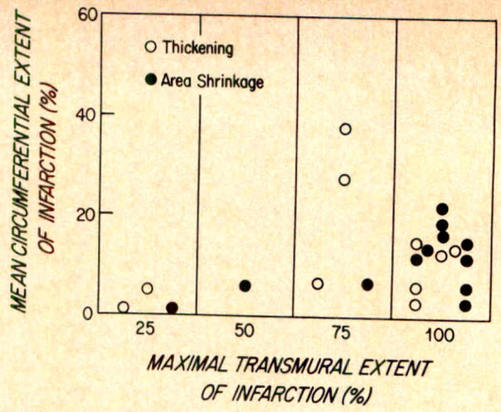

FIGURE 7. Plot of mean circumferential versus maximal transmural extent of MI for those infarcted 2-D echocardiographic short-axis levels *not detected* by 2-D echocardiographic algorithms. **Open circles,** the thickening method; **solid circles,** the area shrinkage algorithm.

ogirthm, 80% had mean circumferential extents of MI ≤20%. Of those not detected by the area shrinkage method, 92% had a mean circumferential extent of MI ≤20%. For each method, the areas of MI not detected were almost equally divided between the acute and the evolving series. Figure 6B shows the frequency distribution of infarcted cross-sections that were correctly identified by the 2-D echocardiographic algorithms.

For those areas of MI *not detected*, we evaluated the relationship of the circumferential to transmural extent of myocardial damage (Fig. 7). Though limited (usually <20%) in circumferential extent, the majority of the regions of MI which were not detected by either method were transmural.

Evaluating the circumferential extent of myocardial infarction: Figure 8 shows the relationship of the circumferential extent of MI determined by each 2-D echocardiographic method to the mean circumferential extent of MI at pathologic examination. With the area shrinkage algorithm, there was a more systematic overprediction by 2-D echocardiography of the circumferential extent of MI. The thickening analysis had a regression equation: Pathology = 0.72 2-D echocardiography + 0.08 (r = 0.77, SEE = 0.16). The regression equation for the relationship of mean circumferential extent of MI by pathology and the area shrinkage analysis was as follows: Pathology = 0.49 2-D echocardiography + 0.08 (r = 0.76, SEE = 0.16). These SEE pairs were not significantly different. When the maximal circumferential extent of MI by pathology was compared with the circumferential extent by each 2-D echocardiographic method, the correlation coefficients and SEE pairs were very similar to those for the above analysis (thickening: r = 0.75, SEE = 0.18; area shrinkage: r = 0.73, SEE = 0.19; p = NS).

Discussion

The problem of detecting and quantifying MI using ultrasonic methods is receiving increased attention as high quality, portable 2-D echocardiographic imaging units are progressively introduced into the critical care setting. Previous studies, in experimental animals, have utilized devices such as ultrasonic micrometer crystals,

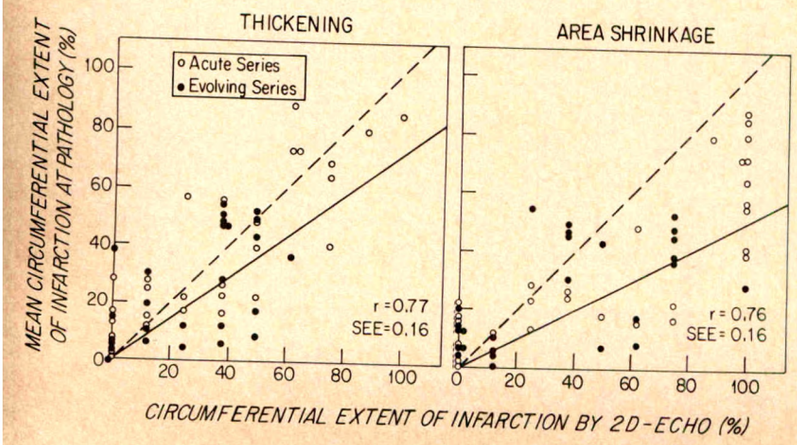

FIGURE 8. Plots of circumferential extent of MI: mean pathologic versus 2-dimensional echocardiographic (2-D echo). **Left,** thickening method. **Right,** area shrinkage method.

piezoresistive force gauges, and epicardial surface transducers to evaluate the regional wall motion changes associated with acute MI.[17,18,23–27] Although ultrasonic crystals can evaluate a precise site of dysfunction associated with MI and an epicardial surface transducer can match 2-D echocardiographic short-axis views with pathologic "bread-loaf" slices, these approaches are not directly applicable in a clinical setting. In a closed-chest model, the ultrasonic transducer is further away from the heart and the beam must penetrate greater amounts of tissue. Under these circumstances, information may be less accurate due to beam divergence and beam attenuation.

As increasingly sophisticated 2-D echocardiographic analysis equipment emerges, particularly computerized digital acquisition and automated edge detection techniques,[28] there arises a need to establish the attributes and limitations of systematically developed algorithms for measurement. In this study, LV cavity area shrinkage and myocardial thickening and thinning were evaluated because these 2 algorithms have been used most extensively in independent studies.

With some qualifications, our results extend to the closed-chest animal recent studies in an open-chest model. Lieberman et al[17] compared an endocardial motion algorithm and a myocardial thickening algorithm with the pathologic extent of MI. They reported that the thickening-thinning algorithm was superior because it produced less overlap between the remote normal zones, normal zones adjacent to areas of MI, and the infarct zones. Our results suggest that while this is indeed the case, endocardial motion is still a valid means of identifying some degree of MI in the injured whole heart.

In this study, there were a number of small circumferentially infarcted zones that were not detected by either method. Since our computer analysis divided each short-axis view into octants, infarcts <12.5% of the circumference might not, theoretically, be detected. Thus, a system which subdivides short-axis views further might improve sensitivity. Besides the circumferential extent of MI, the transmural extent must be considered. Since there were very few cross sections in this study with transmural extents of MI <50%, nothing conclusive can be inferred from our data about the degree of systolic thickening and thinning in relation to transmural extent of MI. The detection and quantification of subendocardial MI would be studied more properly in a model in which most zones of myocardial damage were <50% of the mural thickness.

The problem of assessing infarct size is more complex than just the overprediction or underprediction of the area of MI. Wall motion or contraction abnormalities do not necessarily reflect the extent of myocardial necrosis. Nieminen et al[16] showed that, in a canine model 2 to 48 hours after coronary artery ligation, 2-D echocardiographic estimation of infarct size from wall motion abnormalities decreased. Thus, there is a dynamic aspect to the evolution of wall motion abnormalities, particularly early after MI. While this may be due, in part, to slow evolution of histologic changes associated with MI and developing collateral blood flow which promotes some functional recovery, a system which will simultaneously integrate myocardial contraction defects with the assessment of tissue characteristics is needed to enhance detection of tissue necrosis.

In conclusion, the mechanical and computerized approach used in this study is a valid alternative to the subjective visual inspection techniques successfully used by others.[1,3–5] Our results indicate that (1) a statistically significant difference in the detection of the presence of MI either by the cavity area shrinkage algorithm or by the thickening-thinning algorithm could not be demonstrated in this series; (2) both algorithms *failed to detect* some areas of MI, but these segments were were usually limited in the circumferential extent, though not necessarily limited in the transmural extent; (3) when the cross-sections *free* of MI were evaluated by the 2-D echocardiographic algorithms, there was a trend toward better identification with thickening than with the area shrinkage algorithm, but only when specificity was evaluated by subdividing into octants did a statistically significant difference emerge; and (4) when used to quantify the circumferential extent of MI, although the thickening method tended to overestimate infarct size less, both algorithms had nearly identical correlation coefficients and estimating errors.

Pharmacologically Induced Changes in Wall Thickening Dynamics and Mid-Ventricular Volumes in Dogs Assessed by Prospectively Gated Computed Tomography

G. B. JOHN MANCINI, MD, WALLACE W. PECK, MD, ROBERT A. SLUTSKY, MD, ROBERT F. MATTREY, MD, and CHARLES B. HIGGINS, MD,
With the technical assistance of STEPHEN A. LONG

Assessment of regional wall thickening dynamics is important for monitoring the response of normal and ischemic myocardium to pharmacologic interventions. Because regional wall thickness can be measured on computed tomographic (CT) scans of the heart, the ability of electrocardiogram-gated computed tomography to determine the effects of pharmacologic agents on global and segmental left ventricular (LV) function was assessed. Eight conditioned dogs were studied at a control state and during drug-induced changes in contractility and loading conditions brought about by the use of isoproterenol (0.15 μg/kg/min), phenylephrine (0.3 μg/kg/min), and verapamil (0.2 mg/kg infused over 10 minutes). Ten contrast-enhanced CT slices (1 cm thick) at the same mid-LV level were reconstructed for each 10% of the R-R interval throughout an average cardiac cycle using prospectively gated CT scans. End-diastolic and end-systolic frames were selected and analyzed for the following: septal, apical, and lateral wall thickness, percent wall thickening, end-diastolic and end-systolic mid-LV volume, and percent change in mid-LV volume.

During control, end-diastolic and end-systolic LV wall thicknesses (in millimeters) were 12 ± 2 and 15 ± 2 for the septal wall, 8 ± 1 and 11 ± 2 for the apical wall, and 10 ± 1 and 12 ± 1 for the lateral wall, respectively. The percent thickening in these respective segments was 24 ± 8, 36 ± 10, and 28 ± 13. The control end-diastolic and end-systolic mid-LV volumes were 16 ± 3 and 12 ± 3 ml, resulting in a percent change of 27 ± 7%. Phenylephrine induced significant thinning of the walls and impairment of systolic thickening, whereas isoproterenol induced opposite effects. Verapamil produced a significant decrease in mean blood pressure (123 ± 9 versus 99 ± 23 mm Hg, $p < 0.025$), but end-diastolic wall thicknesses were mildly thicker or showed no change and end-systolic wall thicknesses showed no change compared with those in the control state. Similarly, mid-LV volumes and percent change in mid-LV volumes were not different from those during control. Thus, electrocardiogram-gated computed tomography can be used to assess the effects of pharmacologic interventions on global and segmental LV function.

Dynamic features of wall thickening are important in evaluating the mechanical performance of the left ventricle.[1–4] Numerous techniques are available for the quantitative measurement of this important parameter,[5–15] but only a few are noninvasive or semiinvasive and hence potentially of widespread clinical use in man.[16–18] Noninvasive assessment of regional wall thickening dynamics is important for monitoring and comparing the regional myocardial response to interventions in coronary heart disease. The currently available cross-sectional imaging techniques, echocardiography and computed tomography, can be used to measure left ventricular (LV) wall thickness throughout the cardiac cycle,[19–26] but the use of computed tomography in assessing the dynamic effects of pharmacologic agents has not been evaluated. This study determines the use of prospectively gated computed tomography in assessing directional changes in wall thickening dynamics in dogs. We sought to define the effects of alterations in contractile state and loading conditions on global and regional function as produced by infusions of isoproterenol, phenylephrine, and verapamil.

Methods

Protocol: Eight conditioned dogs weighing 26 ± 5 kg (mean ± standard deviation) were premedicated with morphine sulfate (3.6 ± 0.6 mg/kg), anesthetized with sodium pento-

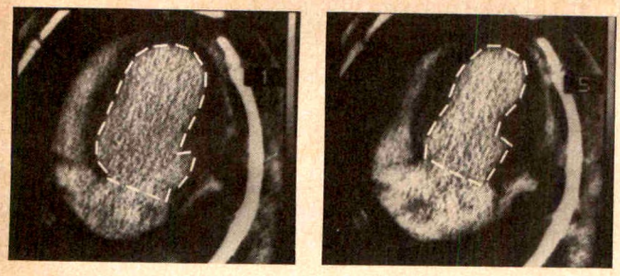

FIGURE 1. Mid-ventricular endocardial outlines. Planimetered areas at end-diastole (**left**) and end-systole (**right**) are demonstrated.

barbital (22 ± 5 mg/kg), and paralyzed with succinylcholine (1.7 ± 0.3 mg/kg). Respirations were maintained at a rate of 16 breaths/min with a Harvard respirator. A femoral artery cannula was connected to a Statham P23dB pressure transducer. Two separate peripheral veins were cannulated for infusion of drugs and contrast material.

Renografin®-76 (sodium meglumine diatrizoate) was infused with a Harvard infusion pump at 6.1 ml/min for 10 minutes and then at 4.4 ml/min for the duration of the experiment. A control scan, described subsequently, was taken once the heart rate and blood pressure were stable after initiation of the contrast infusion. Subsequently, scans were taken during steady-state administration of phenylephrine (0.3 μg/kg/min) and isoproterenol (0.15 μg/kg/min), and 5 to 10 minutes after verapamil administration (0.2 mg/kg given over a 10-minute period). All scans were taken once the heart rate and blood pressure had attained a new, stable level which did not change during the scan acquisitions. The dogs were allowed ample time to attain control heart rate and blood pressure after cessation of each intervention and before initiation of subsequent drug infusions, so that no residual drug effects were present.

Imaging technique: Imaging was performed using a 2020 Technicare scanner with a prototype prospective gating system.[26] Gated computed tomographic scans were obtained by acquiring X-ray data in relation to a preselected fraction of the electrocardiographic R-R interval width, called the biologic window. The biologic window was set at 10% of the R-R interval in this study. The prospective gating technique programmed sequential scans, one 2-second scan each 7 seconds, to obtain all 360° of data for each 10% fraction of the cardiac cycle. A prospective monitoring program updated the display immediately after each scan to show the gaps still present in the angular (360°) X-ray data for 1 biologic window. After the initial scan the prospective gating system sets the launching of the X-ray tube at the appropriate time to position the next preselected portion of the R-R interval in the largest gap in the angular data. Six to 8 scans were required to obtain a full complement of gated angular data for the preselected biologic window. Because each scan actually collected data during the entire 360° rotation of the gantry, when the biologic window was filled, it was possible to reconstruct multiple images (10 per R-R interval in this study) all having the same preselected interval width depicting the cardiac cycle from end-diastole to end-diastole. Unlike retrospective gating, prospective gating minimizes the time and the number of scans necessary to image the preselected fraction of the R-R interval width with small or no gaps in the angular data. Because each biologic window was 10% of the R-R interval and the animals sustained a heart rate of 90 to 190 beats/min during scanning, the end-diastolic and end-systolic gating intervals were 32 to 67 ms in duration.

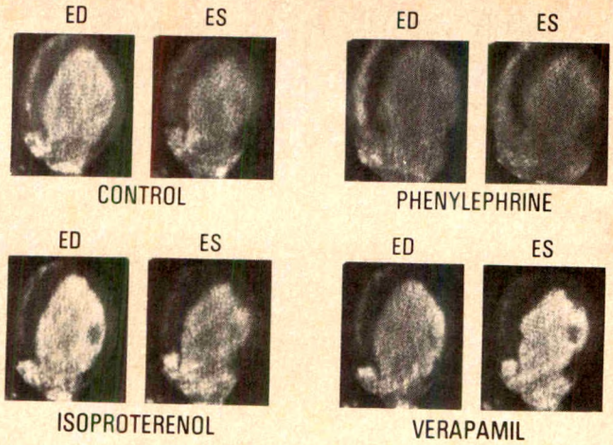

FIGURE 2. End-diastolic (ED) and end-systolic (ES) frames obtained during control state and during pharmacologic interventions, demonstrating changes in wall thickness and mid-LV volume.

Gated scans were performed over the mid-LV level during held inspiration. The scans were acquired during a steady state of contrast infusion, while heart rate and blood pressure remained stable. The scanning technique was set at 120 kVp, 100 mA, 10 mm slice thickness, and a 25 cm scanning circle. The approximated midline radiation dose for a gated series of scans (approximately 8 scans) was 1 to 2 rads in a precisely collimated X-ray beam of 1 cm thickness.

Each of the 10 images, comprising a single cardiac cycle, was displayed on the TV monitor using a 512 × 512 image matrix. A 12.5 × 12.5 cm square was placed over the heart and magnified to fill the entire 512 × 512 matrix. Each pixel thus represented 0.24 × 0.24 mm in real life. A variable region of interest was drawn over the LV wall and the average Hounsfield units (HU) and standard deviation were obtained. The mean Hounsfield units of the LV wall measured approximately 60, whereas the enhanced LV lumen measured 175, thus providing a clear edge. The window was set at approximately 500 HU such that each 8 HU was compressed into 1 gray level. The center was set at the average Hounsfield unit measured over the LV wall. The window and center were then maintained constant for the entire series.

Measurements: The 10 frames at the mid-LV level representing 10% portions of the average heartbeat were displayed along with reference distance markers, and the end-diastolic and end-systolic frames were selected. The end-diastolic figure was the initial frame which corresponded to the 10% interval encompassing the QRS complex, whereas the end-systolic frame was identified as the one with the smallest luminal area. End-diastolic and end-systolic areas were planimetered (Fig. 1) and converted into mid-LV volumes in cubic centimeters, each slice being 1 cm thick. The percent change in mid-LV volume was calculated as the difference between end-diastolic and end-systolic volume divided by end-diastolic volume and expressed as a percentage, referred to as the "mid-LV ejection fraction."

LV wall thickness was measured by placing a movable cursor, available as a display function, across the LV wall. The measurement was given automatically by the display program. The septum was measured directly across from the papillary muscle identified on the lateral LV wall. The anterior wall was measured at the apex of the LV lumen. The lateral wall was measured just below the papillary muscle. The same position was measured on the end-diastolic and end-systolic images (Fig. 2). The percent thickening was calculated as the differ-

TABLE I Summary of Study Parameters

	Control	Phenylephrine	Isoproterenol	Verapamil

ence between end-systolic and end-diastolic thickness divided by end-diastolic thickness and expressed as a percentage.

Wall thicknesses and mid-LV volumes were calculated by 1 observer on 2 occasions separated by >3 weeks and by a second independent observer. Data were analyzed by the paired Student's *t* test. All thickness values are given in millimeters.

Results

The results of the study parameters are summarized in Table I and Figures 3 and 4. Phenylephrine induced predictable increases in blood pressure and a decrease in heart rate. These changes were associated with significant thinning of the LV walls at both end-diastole and end-systole and a decrease in percent thickening from 24 ± 8 to 12 ± 6 ($p < 0.001$) in the septum, from 36 ± 10 to 25 ± 8 ($p < 0.025$) in the apex, and from 28 ± 13 to 19 ± 9 ($p < 0.05$) in the lateral wall. Mid-LV volumes increased significantly as well, but although the mid-LV ejection fraction decreased modestly, the change from control was not statistically significant (27 ± 7 versus 23 ± 3%, p not significant [NS]).

Isoproterenol produced characteristic increases in heart rate and a decrease in mean blood pressure. Wall thicknesses and percent thickening increased substantially; however, the increased thickness of the lateral wall at end-diastole was not quite statistically significant (11 ± 2 versus 10 ± 1 mm at control, p = NS). Percent thickening increased from 24 ± 8 to 33 ± 9 ($p < 0.001$) in the septal wall, from 36 ± 10 to 66 ± 27 ($p < 0.025$) in the apex, and from 28 ± 13 to 38 ± 17 ($p < 0.05$) in the lateral wall.

Verapamil caused a decrease in systemic pressure without any significant change in heart rate compared with the control value. Although the septal and apical end-diastolic wall thickness was slightly thicker than that of the control, the lateral wall thickness at end-diastole was not statistically different from that of the control. Percent thickening for each segment was: septum, 23 ± 13 (p = NS versus control); apex, 35 ± 20 (p = NS versus control); lateral, 11 ± 12 ($p < 0.05$ versus control). Thus, despite the decrease in blood pressure, and with comparable heart rates, systolic thickening was not enhanced and was compatible with an overall impairment of systolic function. In fact, impaired systolic function was detected in the lateral wall. This change in systolic function was also reflected by the LV volumes; that is, despite the substantial decrease in afterload, the end-diastolic and end-systolic volume as well as the mid-LV ejection fraction were not different from the control.

The intraobserver variability was as follows: wall thickness, ±1.2 mm (±10%), range −1 to +2 mm; LV volume, ±0.6 ml (±3%), range −0.6 to +1.4 ml. The interobserver variability was: wall thickness, ±1.0 mm (±9.2%), range −2 to +2 mm; LV volume ±0.5 ml (±5%), range −1.0 to +1.6 ml.

Discussion

This study demonstrates that gated computed tomography of an intact canine model can be used to detect changes in segmental wall thickening dynamics and cross-sectional (global) LV function in response to pharmacologic interventions. The directional changes in response to isoproterenol and phenylephrine are in close agreement with the results from other investigators using invasive sonomicrometer techniques,[3] and the percent thickening in the control state (range of means 24 to 36% in all segments) agrees with results obtained with a variety of other techniques.[3,5,14,18,21,27,28] Furthermore, the present results were obtained in a relatively noninvasive fashion without limitations on the number of segments that could potentially be analyzed

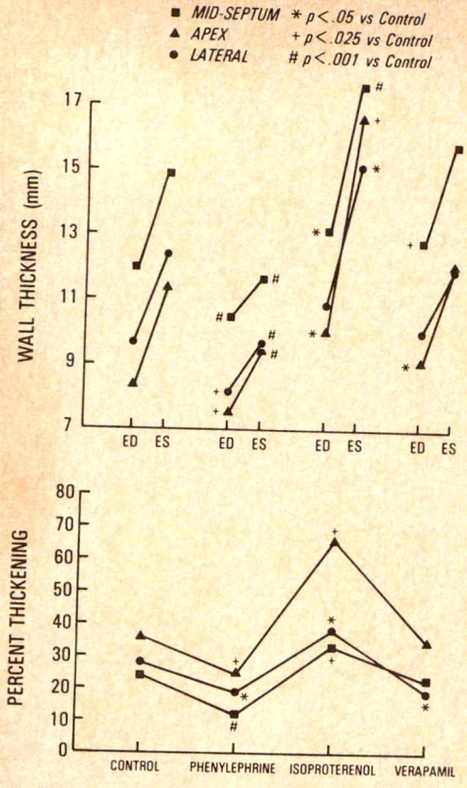

FIGURE 3. Computed tomographic wall thickening dynamics with pharmacologic interventions. ED = end-diastole; ES = end-systole.

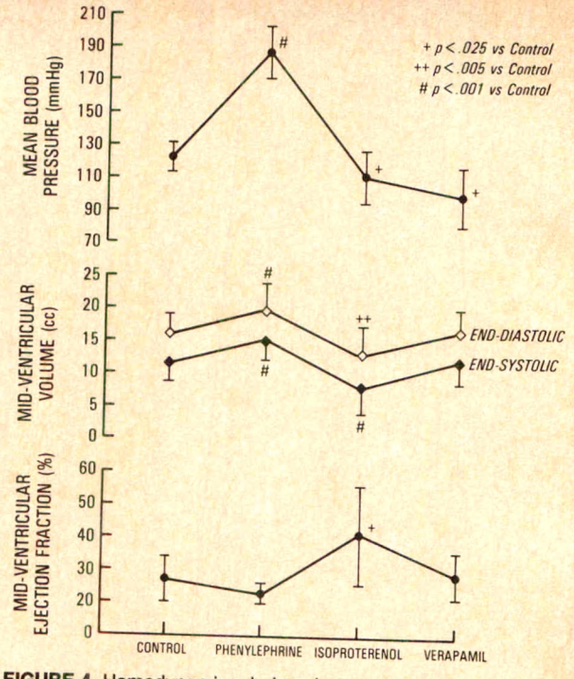

FIGURE 4. Hemodynamics during pharmacologic interventions.

and with the additional ability to assess global function.

Inotropic stimulation of isoproterenol induced a predictable increase in heart rate and a slight decrease in blood pressure in association with increased wall thickness and percent segmental thickening as well as a decrease in LV volume and an increase in mid-LV ejection fraction. Similarly, the known effects of phenylephrine were readily detected, that is, an increase in blood pressure and concomitant reflex bradycardia in conjunction with LV dilatation and wall thinning, and a depression in global and regional systolic function.

Verapamil is a slow channel antagonist with more complex properties than isoproterenol or phenylephrine. It simultaneously causes peripheral vasodilation and depression of myocardial contractility as well as inhibition of the slow response tissues of the sinoatrial and atrioventricular nodes.[29,30] The depression of contractility is largely offset both experimentally and clinically by the reduction in impedance to ventricular emptying and reflex sympathetic activation.[31,32] These effects were also demonstrated in the present study. In particular, although blood pressure decreased, there was little reflex tachycardia because of inhibition of sinoatrial nodal function. In the presence of this reduced afterload, systolic wall thickening remained the same or deteriorated, and the mid-LV end-diastolic volume and ejection fraction showed no change when compared with the control. This finding is in keeping with a depression of the contractile state induced by verapamil.[29–33]

There is a paucity of reports regarding the use of gated computed tomography to assess myocardial wall thickness, and there are no reports that assess its ability to study changes in LV wall thickening dynamics in response to pharmacologic interventions. Skioldebrand et al[19] showed that septal wall thickness measured by nongated computed tomography demonstrated an excellent correlation with autopsy measurements in dogs, although there was a consistent 10 to 20% underestimation of the actual thickness. They were able to detect significant differences in wall thickness in normal animals compared with those with aortic coarctation. Lackner and Thurn,[34] using gated tomography in man, demonstrated a decreased thickness of the ventricular wall in ischemic heart disease and an increase in aortic stenosis. More recently, Mattrey and Higgins[26] demonstrated changes in canine wall thickening dynamics in response to ischemia that could be shown with gated computed tomography and that were corroborated by implanted sonomicrometers.

Several current limitations of gated computed tomography merit discussion. Imaging requires the cessation of respiration and this time interval will depend on the desired number of images per R-R interval as well as the intrinsic heart rate. Imaging time in this canine model was <50 seconds but would be longer in human subjects with slower heart rates, and this would also entail a higher radiation exposure. In addition, a single, mid-LV image provides limitations in measuring true, global ejection fraction. Technical advances will largely eliminate these problems.[35] Contrast enhancement with ionic contrast material was used in this study

in large volumes primarily because of the length of the study. Clinically, doses of contrast material would be smaller with less protracted investigations in human subjects; in addition, newer nonionic contrast agents may prove more acceptable.[36–38]

The inter- and intraobserver variability of the measurements in this study were quite good and compare favorably with echocardiographic techniques even at this early stage of technical development.[39–41] We also previously showed small variability in sequential analysis of cardiac chamber function (end-diastolic and end-systolic volume as well as ejection fraction) when sequential imaging is performed.[42] However, imaging with computed tomography is not affected by lung disease, pericadial effusion, absence of an adequate interspace window, or variable transducer positioning which are all problems with echocardiography. Nevertheless, both of these 2-dimensional imaging techniques are prone to errors in determining absolute wall thickness at specific levels because of the complex nature of cardiac motion outside the plane being imaged.

Measurements of apical and lateral wall thickness in this study depend on detection of the epicardial surface at the heart-lung interface. Skioldebrand et al,[43] in assessing myocardial mass, demonstrated that the potential source of measuring error at this interface is very small. Relative changes in systolic wall thickening should be unaffected by this small error because this potential effect will be similar in both the end-diastolic and the end-systolic frames.

Coronary Blood Flow During the Development and Regression of Left Ventricular Hypertrophy in Renovascular Hypertensive Rats

PIERRE WICKER, MD, ROBERT C. TARAZI, MD, and KIMINARI KOBAYASHI, MD

Left ventricular (LV) coronary flow (CF) was determined by left atrial injection of microspheres in conscious rats during the development and after the reversal of LV hypertrophy in 2-kidney, 1-clip Goldblatt hypertension. Two groups of untreated renal hypertensive rats (RHR) were studied, the first (RHR_1, n = 17) at 10 weeks and the second (RHR_2, n = 9) at 24 weeks after clipping. Beginning 9 weeks after clipping, 2 other groups were treated either with captopril (40 to 60 mg/kg/day) in drinking water (RHR-C, n = 8) or left nephrectomy (RHR-N, n = 9) and followed for 15 weeks. Sham-operated animals followed for similar periods of time served as controls (Sham-1, n = 12, as a control for RHR_1, and Sham-2, n = 11, as a control for RHR_2). In all groups, LV mass increased or decreased in close correlation with changes in arterial blood pressure, and minimal total LV coronary resistance remained unchanged. The development of hypertrophy was associated with a tendency toward reduction in CF reserve (defined as maximal CF/unit mass); this flow reserve was restored with reversal of hypertrophy. The importance of the relation between pressure and LV mass as a determinant of CF reserve was investigated in a second study in which this relation was changed by altering the periods of captopril therapy; in these cases, CF reserve correlated significantly with the ratio of arterial pressure to LV mass ($r = 0.76$, n = 12, $p < 0.01$). The results suggest that maintenance of CF reserve in LV hypertrophy depends on an appropriate balance between arterial pressure and LV mass, and might be disturbed by antihypertensive therapy that leaves LV hypertrophy unchanged.

Most studies of left ventricular (LV) hypertrophy report that coronary flow (CF) per unit of LV mass is normal at rest,[1–6] although some investigators note either increased[7–10] or decreased[11–13] values. However, measurements of resting CF are of limited value in determining whether hypertrophied ventricles are at increased risk of ischemia. Resting myocardial perfusion is generally autoregulated according to metabolic needs.[14] Therefore, more fruitful as regards the potential risk of ischemia in cardiac hypertrophy is the concept of CF reserve. This concept describes the ability of the coronary circulation to augment flow and therefore to maintain an adequate metabolic supply when presented with increased myocardial requirements. CF reserve determined after maximal vasodilation, induced either pharmacologically or by exercise, usually remains within the normal range in pressure-overload hypertrophy[3,4,15,16] unless the latter is excessive.[10] However, CF in LV hypertrophy may be diminished in the subendocardial layers.[6,14,17]

In contrast to these many studies of developing or established LV hypertrophy, there have been few reports on myocardial perfusion after reversal of cardiac hypertrophy. Because chronic myocardial ischemia might be an aggravating factor for heart failure in cardiac hypertrophy, any information on the possibility of reversing potential coronary abnormalities with therapeutic intervention is of great interest. Therefore, these studies were designed to determine possible alterations in CF after reversal of LV hypertrophy as well as in situations in which blood pressure and LV mass are dissociated by therapeutic manipulations. This second step was designed because we have previously shown that some antihypertensive medications may control arterial pressure without reversing cardiac hypertrophy.[18–20]

Methods

Male Sprague-Dawley rats (Hilltop Laboratory) were used in all studies; they were housed 2 to 3 in a cage, fed a standard rat chow (Purina Chow), given water at will, and handled in the same way for weekly blood pressure determinations.

Coronary Blood Flow Measurements

LVCF was measured under resting conditions and after coronary dilation by carbochrome in conscious unrestrained rats using left atrial injection of radioactive microspheres, as

described in detail previously.[21] A left atrial catheter was positioned under adequate anesthesia at least 72 hours before measurement of CF. After this surgical procedure, the rats were placed in separate cages and allowed to recover for 3 to 6 days. During this period, they were trained to sit quietly on small boxes so that subsequent measurements were made in conscious unrestrained animals. Details of the procedure and the accuracy of CF determination by this method have been reported previously.[21]

Approximately 12 hours before CF determination, the right femoral artery was cannulated with the rat under ether anesthesia and the catheter was advanced about 3.5 cm into the aorta to below the level of the renal arteries. On the day of the measurement the rats were placed on top of their boxes, where they sat quietly, and the femoral catheter was connected to a Micron MP-15 transducer for blood pressure recording. The first injection of microspheres was given 45 to 60 minutes later, after both blood pressure and heart rate had stabilized.

Preparation and injection of microspheres: Radioactive microspheres (diameter 15 μm), labeled with either strontium-85 or cerium-141, were suspended in a 70% glucose solution (with 0.05% Tween® 80), whose specific gravity (1.3) was equal to that of the microspheres. This solution was shown in preliminary experiments to have no significant effects on either blood pressure or heart rate in conscious rats. After mechanical and ultrasonic agitation for 10 minutes, approximately 60,000 to 65,000 microspheres were withdrawn in PE-50 tubing; the tubing was then sealed and counted for 1 minute before being connected to the left atrial catheter.

Just before the injection, the femoral catheter was connected to a constant rate withdrawal pump. The microspheres were injected over a 10-second period and the tubing was flushed with 0.2 ml of saline solution in 15 seconds. Starting 10 seconds before the injection, blood was withdrawn for 70 to 75 seconds through the femoral catheter at a constant rate of 1.03 ml/min. After the first microsphere injection, coronary vasodilation was induced by 6 mg/kg of carbochrome[22] infused at a constant rate of 0.17 mg/min through the left atrial catheter. Forty minutes after the beginning of the infusion, a second set of microspheres with a different radioisotope label was injected in exactly the same way. Blood pressure and heart rate (from the pressure tracings) were recorded before and after each injection and just before and at the end of the carbochrome infusion.

At the end of the experiment, the rats were sacrificed with an overdose of pentobarbital sodium. The heart was removed rapidly and cleaned of fat and fibrous tissue. After the proper location of the left atrial catheter was confirmed in all cases, the right ventricular free wall was peeled away, leaving the LV free wall plus the septum as 1 piece which will subsequently be referred to as "left ventricle." This piece was placed in a separate plastic vial, weighed, and counted for 5 minutes in a gamma-well counter at the same time as the blood was withdrawn from the femoral catheter (reference sample).

Calculation of blood flow: Blood flows were computed from the radioactivity in each sample and in the reference sample, according to standard formulas.[23] CF was expressed in both absolute (ml/m) and relative terms (ml/min/100 g of wet tissue). Relative LV coronary vascular resistance was obtained by dividing the mean aortic pressure by LVCF, and expressed in millimeters of mercury per milliliter per minute per 100 grams. Total LV coronary resistance was similarly computed using total LVCF and results were normalized for body weight; this normalization had been proposed by O'Keefe et al,[4] and its value was confirmed by our own experience. In 56 rats with a wide spectrum of LV mass, we found a significant linear correlation between total heart conductance and body weight ($r = 0.59$, $p < 0.001$).

Experimental Protocols

Study 1: Development and reversal of LV hypertrophy: *Preparation of 2-kidney, 1-clip Goldblatt hypertensive and sham-operated rats:* two-kidney, 1-clip renal hypertension was induced in rats weighing 175 to 200 g by placing a silver clip (0.2 mm) on the left renal artery with the rat under ether anesthesia; the right kidney was left untouched. Blood pressure was measured at weekly intervals by an indirect tail cuff method. The pressure increased in approximately 60% of the clipped rats, but only rats with blood pressure consistently >170 mm Hg were used in this study. All sham-operated rats remained normotensive.

Treatment of hypertension and reversal of cardiac hypertrophy: Nine weeks after clipping, the renal hypertensive rats were divided at random into 2 groups. The first (RHR-C, n = 8) was given captopril in drinking water at an initial dose of 30 mg/kg/day. This dosage was gradually increased to 40 to 60 mg/kg/day to maintain blood pressure levels near normal (<140 mm Hg). The second group (RHR-N, n = 9) underwent left nephrectomy under ether anesthesia at the same time that captopril was begun in the first group (that is, after 9 weeks of hypertension). Both groups were followed up 15 weeks before determination of CF and LV mass (24 weeks after renal arterial clipping). Two other groups of hypertensive rats were left untreated and studied, 1 at 10 weeks (RHR_1, n = 17) and the other at 24 weeks after induction of hypertension (RHR_2, n = 9). Sham-operated untreated rats were followed up exactly the same way as the hypertensive rats and for the same period of time; 1 group was studied after 10 weeks of follow-up (Sh_1, n = 12, corresponding to RHR_1) and the other after 24 weeks (Sh_2, n = 11, corresponding to RHR_2 and to the 2 groups of treated rats, RHR-C and RHR-N).

Study 2: Dissociation of arterial pressure from changes in LV mass: Hypertensive and sham-operated rats were prepared and treated as previously described, but the duration of the therapeutic periods was modified in an attempt to alter the relation between arterial pressure and LV mass. A first group of RHR (group RHRA, n = 7) was given captopril (60 to 80 mg/kg/day) for only 1 week so that blood pressure was normalized but no time was given for reversal of LV hypertrophy. A second group of RHR (group RHRB, n = 5) was treated with captopril for 14 to 15 weeks to induce reversal of LV hypertrophy as previously demonstrated[24]; the drug was then discontinued 9 to 12 days before microsphere determination to allow the blood pressure to increase but again allowing little time for any significant increase in LV mass.

Statistical Analysis[25]

Values reported represent the mean ± 1 standard deviation. Analysis of variance was used for multiple group comparisons, followed by a Newmann-Keul multiple range test for comparisons between all pairs of means when an overall significant p value was obtained. Changes in mean arterial pressure and heart rate before and after each flow determination and before and after carbochrome administration were statistically analyzed for each group by a 2-way analysis of variance.

Results

Study 1

Development and reversal of LV hypertrophy: Both blood pressure and LV weight were markedly increased ($p < 0.01$) in untreated hypertensive rats 10 and 24 weeks after clipping (Table I). With prolonged treatment with captopril or after left nephrectomy, both arterial pressure and the LV mass/body weight ratio

Groups	Sham 1 (n = 12)	Sham 2 (n = 11)	RHR_1 (n = 17)	RHR_2 (n = 9)	RHR-C (n = 8)	RHR-N (n = 9)
MAP	110 ± 7	111 ± 6	177 ± 26*	164 ± 16*	121 ± 16	132 ± 16
LV/BW	1.9 ± 0.2	2.0 ± 0.1	3.0 ± 0.5*	3.0 ± 0.4*	2.3 ± 0.2	2.4 ± 0.3
BP/LV	58 ± 7	55 ± 5	59 ± 7	56 ± 7	53 ± 5	56 ± 4

* $p < 0.01$ (ANOVA); values for BP/LV were not significantly different among all groups.
Values reported are average ± 1 standard deviation. Groups are defined in study 1. (See text). BP/LV = blood pressure/left ventricular mass; LV/BW = left ventricular mass per gram of body weight; MAP = mean arterial pressure (mm Hg) before first coronary blood flow determination.

were significantly decreased ($p < 0.01$ versus hypertensive untreated rats) to values slightly higher than but not significantly different from those of sham-operated control animals (Table I). LV mass and arterial pressure correlated closely as demonstrated by the highly significant linear correlation found between the LV/body weight ratio and intraarterial pressure ($r = 0.88$, $p < 0.001$) (Fig. 1); the same correlation also was found whether the data from the treated groups (RHR-C + RHR-N) were analyzed separately ($n = 17$, $r = 0.71$, $p < 0.025$) or were included with the other groups. Consequently, the ratio of arterial pressure to LV mass normalized for both weight (blood pressure/LV mass ratio) was equivalent in all groups, treated or untreated (Table I).

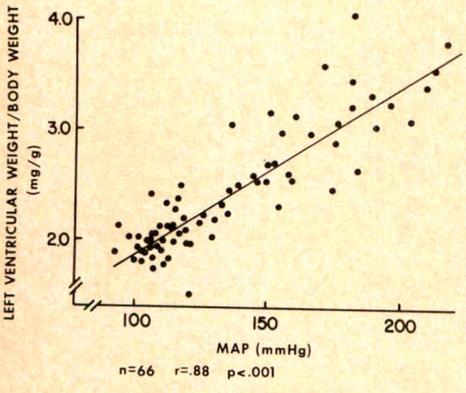

FIGURE 1. A close correlation was found between left ventricular weight (milligram per gram of body weight) and mean arterial pressure (MAP) in all rats (normotensive, hypertensive, and treated hypertensive).

Systemic hemodynamic data (Table II): Resting cardiac output did not differ among the various groups; accordingly, the high blood pressure in the untreated hypertensive rats (RHR_1 and RHR_2) was related to a significant increase in total peripheral resistance ($p < 0.01$ versus control animals). Nephrectomy as well as captopril therapy reduced blood pressure by decreasing resistance.

Carbochrome had no significant effect on arterial pressure, heart rate, or cardiac output; no significant change in any of these indexes was found between pre- and postcarbochrome hemodynamic determinations in any of the groups. The only exception was a modest reduction in blood pressure (−9 mm Hg, $p < 0.01$) in hypertensive rats treated by nephrectomy with no change in either heart rate or cardiac output (Table II).

Coronary hemodynamics: *At rest (Table III):* In the first group of untreated hypertensive rats (RHR_1), resting LVCF/100 g of tissue was higher by approximately 25% compared with its control (Sh_1) ($p < 0.05$). In contrast, resting LVCF was normal in the second group of hypertensive rats studied after 24 weeks of clipping. LV coronary resistance (per 100 g of tissue) was elevated in both hypertensive groups ($p < 0.01$ versus

* $p < 0.05$ versus sham 1 (ANOVA).
† $p < 0.01$ versus sham.
‡ $p < 0.05$ versus sham and RHR-N.
Values are means ± standard deviation.
All differences before and after carbochrome within each group were significant ($p < 0.01$); there was no statistically significant difference *among groups* with regard to left ventricular coronary flow (LVCF) after carbochrome or total LV coronary resistance.

sham); however, total LV coronary resistance (per kilogram of body weight) was not significantly different from that of the control group ($p = 0.34$). With reversal of LV hypertrophy, resting LVCF, LV coronary resistance/unit mass, and total LV coronary resistance were within normal values (Table III).

Coronary hemodynamic after carbochrome (Table III): Carbochrome led to significant increases in LVCF and decreases in LV coronary resistance in all groups ($p < 0.01$). The LVCF/unit mass after carbochrome was not significantly different by analysis of variance among all groups of rats ($p = 0.67$). Therefore, LV coronary resistance per unit mass remained elevated in the untreated hypertensive rats ($p < 0.05$). Most importantly, total LV coronary resistance was remarkably similar in all groups ($p = 0.47$) (Fig. 2).

Study 2 (Table IV)

Blood pressure levels were effectively dissociated from LV mass as planned. In group RHRA, the blood pressure/LV mass ratio was diminished because blood pressure had been reduced whereas LV weight was still increased. In group RHRB, exactly the opposite was achieved (Table IV). The ratio of mean arterial pressure to LV mass was averaged 41 ± 7 (standard deviation) in group RHRA versus 63 ± 4 in group RHRB ($p < 0.01$). Both these values were significantly different from each other ($p < 0.01$) and from those obtained in the control groups: Sham A (52 ± 7) and Sham B (53 ± 5) ($p < 0.05$).

Total LV coronary resistance was similar in all groups in this study and not significantly different from values obtained in study 1. However, LVCF/unit mass after carbochrome administration showed a significant reduction in group RHRA compared with group RHRB; more importantly, there was a significant positive correlation between CF after carbochrome administration and the blood pressure/LV mass ratio in these groups ($r = 0.76$, $n = 12$, $p < 0.01$). Thus, CF reserve seemed to diminish when blood pressure was decreased without a corresponding reduction in LV mass.

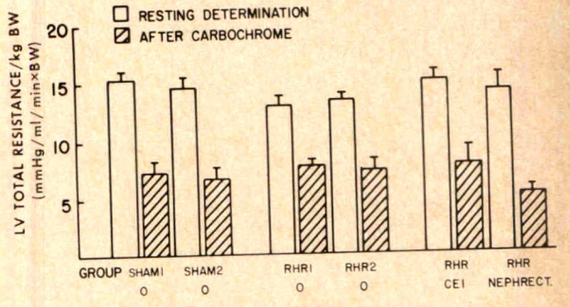

FIGURE 2. The resistance to coronary flow per ventricle (total LV resistance)[4] was not significantly different among any of the groups either at rest or after coronary dilation by carbochrome. BW = body weight; CEI = converting enzyme inhibition; NEPHRECT. = nephrectomy; RHR = renal hypertensive rats.

TABLE IV Dissociation Between Arterial Pressure and Left Ventricular Mass by Therapy in Renovascular Hypertensive Rats: Effect on Coronary Flow

Discussion

The results obtained in this study of renovascular hypertensive rats confirm those reported by Mueller et al[3] in renovascular hypertensive dogs and by Wangler et al[16] in spontaneously hypertensive rats. In all instances, and despite the fact that coronary vasodilation was obtained by adenosine in dogs, by dipyramidole in spontaneously hypertensive rats, and by carbochrome in RHR, LVCF reserve was not significantly altered in hypertensive LV hypertrophy. In all these studies, the minimal total LV coronary resistance remained unchanged despite the large spectrum of variations in LV mass. The present study extends these conclusions further to reversed LV hypertrophy. The absence of significant changes in minimal total LV coronary resistance among our 6 groups of hypertensive rats with various degrees of pressure elevation, alterations in ventricular weight, and therapeutic interventions was a striking observation (Fig. 2, Table III).

Whether the reduction in LV mass was obtained by surgical cure or by medical control of the hypertension, LVCF after maximal carbochrome-induced dilation remained within normal limits. Because it is flow that determines in large measure the oxygen supply to the heart under stress, the CF determined under these conditions was taken as an index of coronary reserve. This term has sometimes been used for the difference between CF at rest and "maximal" CF. However, the use of this definition could unduly subject "flow reserve" to values obtained at rest; if resting CF is increased, this increase would mathematically lead to a reduction in "reserve" despite an unchanged ability of the vessels to dilate.[26]

The maintenance in our experiments of normal CF reserve during the development and after the reversal of LV hypertrophy was tentatively attributed to the appropriate balance observed in this model of hypertension[24,27] between the alterations in arterial pressure and changes in LV mass (Table I, Fig. 2). We hypothesized that under these conditions there would be a near-normal CF reserve; this hypothesis was based on the assumption that under conditions of maximal or near maximal coronary vasodilation, flow becomes a direct dependent of the driving pressure. Because most studies,[3,4,6,16] including the present one, have demonstrated an unchanged minimal total LV coronary vascular resistance (per ventricle) in various models of LV hypertrophy, the ratio of coronary perfusion pressure to LV mass would then be an important determinant of myocardial perfusion. If mass is "appropriate" to the increase in pressure, then CF reserve would be within normal, but if LV mass was greater than expected for the perfusion pressure, maximal CF would be reduced.

This hypothesis was tested by the second protocol in which manipulations of therapy were used to alter the blood pressure/LV mass ratio. Reduction of arterial pressure for too brief a time to alter LV weight was associated with a diminished CF reserve. Reversal of LV hypertrophy was associated with normal CF reserve even when arterial pressure was allowed to increase. The same conclusions could also be deduced from the results reported by Murray and Vatner[28] in dogs with right ventricular hypertrophy secondary to banding of the pulmonary artery. Right ventricular CF reserve was significantly lower than that in control subjects because coronary perfusion pressure was not changed whereas right ventricular mass increased markedly.

Most studies of pressure-overload hypertrophy confirm the original suggestion by Marcus et al[6] that the functional cross-sectional area of the coronary circulation does not grow in parallel with ventricular mass. The reasons for the lack of growth of the coronary functional cross-sectional area with cardiac hypertrophy are not quite clear.[3] There may be little or no change in the coronary vasculature with the development[29,30] or reversal of cardiac hypertrophy. Alternatively, some neovascularization may occur, but the vasodilating capacity of the coronary vessels is impaired by functional factors or structural changes, or both.[3,4,31,32] With reversal of LV hypertrophy and control of blood pressure, these functional and structural factors would presumably be reversed, improving the vasodilatory capacity of each vessel.

Whatever the reasons for the constancy in the functional coronary cross-sectional area, its corollary is that CF reserve becomes dependent on the ratio of coronary perfusion pressure to LV mass, a concept supported by significant correlation found in this study between maximal coronary flow and the ratio of blood pressure to LV mass. If these results prove to be a feature of pressure-overload hypertrophy, this observation could have potentially important clinical implications. Antihypertensive drugs that induce a decrease in mass parallel to their reduction in blood pressure would be preferable, as regards CF reserve, to medications that can control arterial pressure without reducing LV mass.[18–20] Further studies are obviously needed to evaluate these hypotheses. In this context, a direct effect of captopril on the vasodilatory capacity of the coronary vessels is conceivable; however, we could not document any significant effect of captopril on minimal total LV coronary resistance in control rats (unpublished observations). Moreover, neither acute nor chronic converting enzyme inhibition with teprotide or captopril had any discernible effect on the coronary circulation in rats[33] or dogs[34] unless the latter were on a low sodium diet.

Advantages and limitations of this study: CF measurements were performed in conscious rats, and the left atrial injection allowed more precise CF measurements because of better mixing of the microspheres.[21] Carbochrome was used to induce coronary dilation, because it did not alter systemic hemodynamic indexes as adenosine or dipyramidole usually do. Dose-response studies showed that LVCF reached a plateau at doses of 9 and 12 mg/g in normal rats and at the slightly lower doses of 6 or 9 mg/kg in renal hypertensive rats (Table V). Convulsions in both groups of rats became a significant problem at the 9 mg/kg dose level; this problem did not occur with 6 mg/kg and this dose was therefore selected. The assumption that near-maximal coronary vasodilation was achieved at this dose level is based on the basic agreement of our results with regard to the unchanged minimal LV total

TABLE V Coronary Blood Flow After Carbochrome: Normal and Renal Hypertensive Rats (RHR)

Units/100 g LV	0.21 ± 0.08	0.18 ± 0.08	. . .

Values given are the average ± 1 standard deviation.
Within each group (normal or RHR) the values obtained at the 3 dose levels for either flow or resistance were not significantly different from each other.

coronary resistance in hypertension, with studies in which maximal coronary vasodilation was achieved.[3,4,28]

The distribution of CF between the endocardium and epicardium was not measured in this study. Therefore, our data do not exclude the possibility of diminished perfusion of the subendocardial layers even when total CF reserve is normal.[10,17,35]

End-Systolic Dimension-Wall Thickness Relations During Myocardial Ischemia in Conscious Dogs

A New Approach for Defining Regional Function

GENTA OSAKADA, MD, OTTO M. HESS, MD, KIM P. GALLAGHER, PhD, W. SCOTT KEMPER, MSEE, and JOHN ROSS, Jr., MD

Overall and regional left ventricular (LV) function was studied during progressive coronary stenosis in conscious dogs by determining the relations at end-systole between LV pressure, chamber dimensions, and regional LV wall thickness. An index of regional wall stress was also analyzed. Using ultrasonic dimension gauges, measurements were made of LV wall thickness in control and ischemic regions, and the external long- and short-axis LV diameters were determined; an implanted micromanometer measured LV pressure. Internal LV diameters were obtained from the external diameters by subtraction of wall thickness, and the index of regional wall stress employed a thick-walled ellipsoidal model. During regional ischemia, the LV long axis at end-systole did not change, whereas the short-axis diameter progressively increased (from 24 ± 7 mm [standard deviation] to 30 ± 9 mm, p <0.001, indicating a more spherical LV shape during ischemia). The end-systolic pressure did not change, and therefore the end-systolic pressure-diameter relation shifted progressively, suggesting a global decrease in LV contactility. The end-systolic points relating LV wall thickness in the ischemic region to the end-systolic LV pressure revealed the regional nature of the abnormality, showing a progressive displacement to the left, whereas there was no significant displacement of this relation in the control region. The application of this index over a range of loading conditions during partial vena caval occlusion was illustrated. Thus, the regional end-systolic wall thickness-pressure relation provides a new index for defining the regional contractile state of the LV myocardium which is potentially load-independent and offers the possibility for echocardiographic application.

End-systolic measures of left ventricular (LV) function using LV pressure and volume or diameter have recently been shown to provide a load-independent approach to assessing the contractility of the whole heart.[1–4] The end-systolic LV wall thickness-pressure or wall stress relation also can sensitively detect changes in myocardial contractility of the whole ventricle.[5] The regional nature of this measurement suggested that end-systolic indexes based on wall thickness might be useful for assessing overall and regional myocardial function during ischemia, and also might be used to develop an index of regional wall stress for understanding more completely the nature of regional loading conditions during coronary stenosis. Accordingly, the present study analyzes the effects of progressive coronary arterial narrowing on end-systolic LV pressure-dimensions and pressure-wall thickness relations during ischemia in the conscious dog.

Methods

Animal preparation: Eight mongrel dogs weighing 15 to 44 kg were anesthetized with sodium pentobarbital (25 to 30 mg/kg, intravenously). A thoracotomy was performed in the fifth intercostal space, and, using sterile technique, the animals were prepared for chronic studies. A high fidelity micromanometer (Konigsberg® P-7) and a small catheter were placed into the LV chamber through a stab wound near the apex.[6] The left circumflex coronary artery was dissected free near its origin and a hydraulic cuff was placed around the

vessel. For the continuous measurement of the external LV long axis, a pair of ultrasonic crystals was implanted at the base and apex, the base crystal being placed in the groove between the aortic root and the left atrium and the other crystal at the apical dimple.[7] A second pair of crystals was sutured to the epicardium of the anterior and posterior walls for the measurement of the external LV short axis. To obtain regional wall thickness, a third pair of miniature crystals was placed in the LV posterior wall in the center of the region perfused by the left circumflex coronary artery (designated as ischemic wall thickness), using a technique described previously.[8] One of the crystals was inserted tangentially through the myocardium into the subendocardium, and the other was sutured to the epicardial surface opposite the inner crystal at a site where the ultrasonic transit time was shortest between the 2 crystals. This technique allowed the placement of the crystals across the LV wall without damage to the intervening tissue and provided highly accurate wall thickness measurements which sensitively reflect various degrees of myocardial ischemia.[9,10] Another pair of crystals was placed in the anterior wall in the same manner and designated as control wall thickness. Both wall thickness pairs were positioned as close as possible to the crystals of the short axis. The position of the crystals used for diameter measurements and the wall thickness pairs was examined at necropsy and confirmed to be in proper alignment directly across the wall, with the inner crystal within 2 mm of the endocardial surface. The chest was then closed; all wires and tubes were passed subcutaneously to the back of the dog and brought through the skin between the scapulae.

Experimental protocol: Studies were performed 2 to 3 weeks after operation, when the dog was vigorous and healthy, and with the dog resting quietly on its right side on the floor. After control measurements were recorded in the resting state, a level of partial coronary stenosis was created with the hydraulic occluder placed on the left circumflex coronary artery using a screw-driven syringe. After stable hemodynamic and dimension conditions were attained for at least 2 minutes, measurements were obtained. The stenosis was released and the dog was then allowed to recover for at least 30 minutes. Several different levels of partial coronary stenosis were obtained in the same manner. Because it was difficult to create the same level of partial coronary stenosis in each dog, the degrees of coronary stenosis were categorized on the basis of the systolic wall thickening in the ischemic region. The levels of partial coronary stenosis were divided into 4 groups: (1) wall thickening reduced <60%, (2) wall thickening reduced 60 to 80%, (3) wall thickening reduced >80%, and (4) complete coronary occlusion (performed for 2 minutes).

Recordings were monitored continuously on a multichannel recorder and stored on magnetic tape for subsequent data analysis by computer. The dimension signals were calibrated by an electrical pulse of precisely known duration derived from a stable crystal controlled oscillator.[11] The micromanometer was calibrated by matching it to the pressure obtained through a fluid-filled catheter connected to the pressure gauge (Statham P-23Db) at the beginning and end of each study with frequent calibration checks throughout the study by known electrical voltages.

Data analysis: Analog signals played back from the magnetic tapes were digitized every 5 ms through an analog-to-digital converter and fed to a computer system with a microprocessor (DEC, LSI-11) and digital plotter (HP, 7221B). At least 10 beats were averaged, the reference signal being the first derivative of LV pressure (dP/dt), and beats with a duration >100 ms from the average were excluded from the averaging process.

The measured wall thicknesses of the ischemic region (IWTh) and of the control region (CWTh) were used to obtain the LV internal (int) long-axis diameter (LAD) and short-axis diameter (SAD) by subtraction from external (ext) diameters[7]: LADint = LADext − 1.1 × CWTh, and SADint = SADext − CWTh − IWTh. An index of regional wall stress (WSt) in both the control and ischemic regions was estimated from a thick-walled ellipsoidal model using the wall thickness in the control or the ischemic region: $WSt = p \times SADint \times 1 - 0.5 \times (SADint/LADint)^2/(2 \times WTh)$,[12] where P = LV pressure. As an index of global wall stress, the value was calculated using the same equation by employing the mean value of both wall thicknesses. The first derivative of wall stress (dWSt/dt) during ejection was computed at the time of maximal velocity of shortening of the internal short-axis diameter.

It is recognized that calculation of the true regional wall stress will require knowledge of local radii of curvature and that our approach represents only an estimate. Moreover, it is apparent that use of a single point in the ischemic region and another from the control wall to determine the LV short axis is subject to potential error. Thus, this approach assumes that an entire one half of the left ventricle is represented by the ischemic wall, whereas it is not likely that this was the case, particularly with less severe stenoses. The most powerful determinant of regional wall stress under these conditions, however, should be the regional wall thickness. Accordingly, the maximal error in end-systolic wall stress that could have been introduced by overestimation of the minor axis was determined by calculating end-systolic wall stress at the 4 levels of ischemia using the control (prestenosis) end-systolic ventricular diameter at each point together with the measured wall thickness during ischemia; these errors were 6.1 ± 3.1% (standard deviation [SD]) in mild stenosis, 10 ± 3.2% in moderate, 12 ± 4.5% in severe, and 15 ± 5.0% with complete coronary occlusion. Thus, despite this potential for modest overestimation of wall stress, the consistently large increases observed in the end-systolic wall stress index lend validity to the directional changes of wall stress in the ischemic region that we report.

To cancel out size dependencies of the left ventricle among the dogs, normalization of LV diameters was performed with respect to the LV muscle mass obtained at necropsy, the measured diameter being divided by the LV mass and multiplied by 100.[13] The wall thickness was normalized to a 10 mm initial thickness by dividing the measured thickness by the control resting end-diastolic thickness and multiplying by 10.[14] Velocities of a given parameter were normalized to the instantaneous value of the parameter and the peak value was used for analysis. End-diastole was identified at the point just before the onset of the positive dP/dt of the left ventricle, and end-systole at the point of maximal systolic excursion of the control wall thickness, occurring at or within 20 ms before peak negative dP/dt.[10,14]

Dynamic loops (X-Y plots) of various parameters during a cardiac cycle were generated by a computer-aided digital plotter from averaged beats.

Statistical analysis was done with an analysis of variance for repeated measures followed by the Bonferroni method of multiple comparisons, a p value <0.01 being considered significant.[15,16] All data are expressed as mean ± standard deviation unless otherwise stated.

Results

A typical example of original recordings from which the data were measured and computed is shown in Figure 1, illustrating the effect of various levels of re-

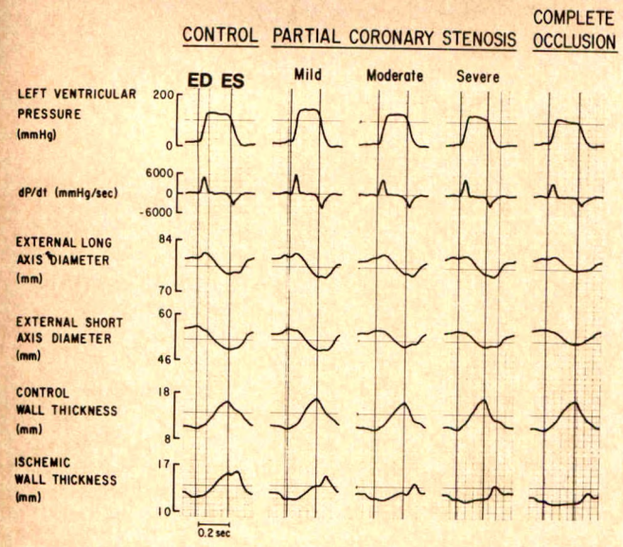

FIGURE 1. Representative original recording. The LV pressure, dP/dt, the external long- and short-axis diameters of the left ventricle, and the wall thickness in control and ischemic regions were simultaneously recorded in a conscious dog, and stored on magnetic tape for further processing by computer. After the control recording (**first panel**), stable conditions at various levels of myocardial ischemia were achieved by adjusting the hydraulic occluder on the left circumflex coronary artery (**3 middle panels**). Complete coronary occlusion was also performed (**last panel**). Note the progressive deterioration in systolic thickening of the ischemic wall and reduction of systolic shortening of the short-axis diameter during ischemia, with little change in control wall thickness and long-axis diameter. ED = end-diastole; ES = end-systole.

gional myocardial ischemia on the LV pressure, external long- and short-axis diameters, and wall thickness in the control and ischemic regions. The averaged LV hemodynamic and dimension data are summarized in Tables I and II and data on regional LV wall thickness and wall stress are shown in Table III.

Hemodynamic changes: During the 4 levels of myocardial ischemia, the peak and end-systolic LV pressure and its derivative were not significantly changed, and only during complete coronary occlusion was the end-diastolic pressure significantly elevated to 18 ± 6.2 mm Hg ($p < 0.001$) from control (9.9 ± 2.0, Table I). Heart rate increased with increasing severity of ischemia, being significantly elevated during severe stenosis and complete occlusion.

LV dimensions: The external and internal dimensions of the LV long axis were little affected by regional myocardial ischemia and only complete coronary occlusion induced significant decreases in systolic shortening extent and velocity of the long axis (Table I). The short axis showed progressive and significant increases in external and internal end-systolic diameters during ischemia, with significant deterioration of systolic shortening and peak systolic shortening velocity during the first level of coronary stenosis (Table I), while the end-diastolic diameters remained unchanged as the heart rate progressively increased. During myocardial ischemia, the ratio of the LV short-axis diameter to the long-axis diameter at end-systole was significantly increased while the ratio at end-diastole was not changed,

indicating that the left ventricle became more spherical during systole in the presence of ischemia compared with control (Table II).

Regional LV wall thickness: End-systolic wall thickness in the ischemic region was decreased to 12 ± 0.44 mm (p <0.001) during mild coronary stenosis from 13 ± 0.62 mm (control) and gradually decreased further with more severe ischemia; end-diastolic wall thickness was not significantly changed (Fig. 2, Table III). Wall thickening extent during systole was reduced by 52% in mild stenosis, 77% in moderate stenosis, and 96% in severe stenosis, and it was replaced by systolic thinning during complete coronary occlusion (Fig. 2). The peak wall thickening velocity during systole was also markedly decreased during myocardial ischemia (Fig. 2). Wall thickness in the control area, however, showed no significant changes in thickness at end-diastole and end-systole, or in systolic thickening extent and velocity (Fig. 2, Table III).

A representative example of the relations between ischemic wall thickness and LV pressure throughout the cardiac cycle is shown in the left panel of Figure 3 (end-systolic points are indicated by asterisks). During control, the loop rotated clockwise during ventricular systole. During partial coronary stenosis, the extent of systolic wall thickening decreased, producing a leftward shift of the loop, and the wall thinned and then thickened again late in systole as ventricular pressure decreased. During complete coronary occlusion, the loop area became nearly zero, suggesting passive deformation.

End-systolic relation: End-systolic LV pressure did not change significantly during progressive coronary stenosis while end-systolic internal short axis of the ventricle progressively increased (Table III), a finding which suggests that depression of global contractility is produced by ischemia since contractility changes are known to shift this relation. Assessment of the relations between regional wall thickness and LV pressure at end-systole in the ischemic zone showed a progressive shift to the left of this relation with increasing coronary stenosis (Fig. 4, top left), indicating progressive regional wall thinning at end-systole at a constant end-systolic pressure, whereas this relation remained unchanged in the control region (Fig. 4, bottom left, Table III).

Linear end-systolic relations between the LV pressure and wall thickness found previously under normal conditions[5] also are shown in Figure 4 (thick dotted line).

Regional wall stress index: The index of regional wall stress and the rate of wall stress change (dWSt/dt) during systole in the control region were not affected by myocardial ischemia (Fig. 5, Table III). The index of regional wall stress in the ischemic region showed a significant increase during ischemia, with the peak wall stress index significantly greater than control during severe coronary stenosis and during complete occlusion. The end-systolic wall stress index increased earlier and more markedly, being significantly increased during mild stenosis (160 ± 42 g/cm^2, compared with a control value of 134 ± 34 [p <0.01]); it increased substantially

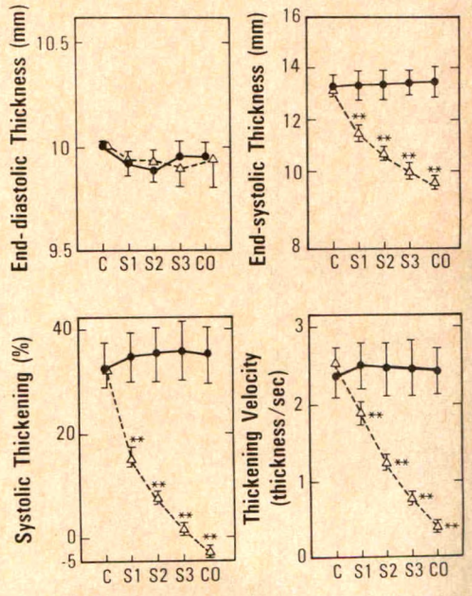

FIGURE 2. Mean values of regional wall thickness in the control (**closed circles**) (mean ± standard error of the mean) and ischemic regions (**open triangles**). End-diastolic wall thickness (**top left**) showed no significant changes during ischemia. End-systolic wall thickness (**top right**) in the ischemic region decreased significantly with progression of the severity of ischemia accompanied by the progressive deterioration in the systolic wall thickening (**bottom left**), as well as in systolic thickening velocity (**bottom right**). No changes were observed in these parameters in the control region. C = control; S1, S2, S3 = mild, moderate, and severe stenosis, respectively; CO = complete occlusion. * p <0.01, ** p <0.001, in comparison with control.

dWSt/dt = first derivative of wall stress at time of peak ventricular ejection (g/cm²/s); mean wall stress = estimated global wall stress using mean wall thickness (g/cm²). % thickening = percent wall thickening during systole; thickening velocity = peak normalized velocity of wall thickening during systole (thickness/s); wall stress index = an index of regional wall stress in each region (g/cm²). Wall thickness in millimeters. Other abbreviations as in Table I.

further with the progression of ischemia (Fig. 5). The dWst/dt in the ischemic area during ejection also decreased significantly during ischemia (Fig. 5).

The mean wall stress of the entire left ventricle showed little change during myocardial ischemia, and it increased significantly only during complete occlusion (Table III).

The relation between ischemic wall thickness and the index of wall stress in the ischemic region had a clockwise rotation, with wall stress decreasing during systole (Fig. 3, right). With progression of ischemia, the loops shifted upward and to the left, accompanied by increases in the peak and end-systolic wall stress indexes. These loops of regional wall thickness versus the index of regional wall stress (Fig. 3, right) provide some insight into the characteristics of regional loading conditions during progressive coronary stenosis. While systolic LV pressure during ejection tended to decrease in this example as ischemia developed (Fig. 3, left), there was an increase in the peak wall stress index and a more marked increase in the end-systolic wall stress index. Thus, the local contractile defect, by diminishing systolic wall thickening, leads to regional systolic loading during ejection, which could further impair the regional reduction in shortening produced by ischemia itself.

The relations at end-systole between the index of regional LV wall stress and the corresponding wall thickness in control and ischemic regions are summarized in the right panels of Figure 4 and in Table III. A significant leftward and upward shift of the relation occurred in the ischemic region, whereas no change was observed in the control region.

Discussion

The description and quantification of local changes in myocardial function appears essential to an understanding of the effect of various experimental and clinical therapeutic approaches designed to improve myocardial performance and reduce tissue damage during myocardial ischemia. The regional nature of myocardial dysfunction associated with ischemia due to coronary obstruction has been recognized since the original description of aneurysmal bulging in the area distal to an experimental coronary occlusion by Tennant and Wiggers.[17] Miniature ultrasonic crystals implanted in the LV subendocardium have been used to characterize regional contractile function and segment lengths in various regions of the left ventricle during acute coronary occlusion.[11,18,19] The ultrasonic dimension gauges have also proven to be highly suitable for the analysis of regional myocardial function using continuous measurements of regional wall thickness during myocardial ischemia[8,9,20]; echocardiography has also been used for this purpose.[21]

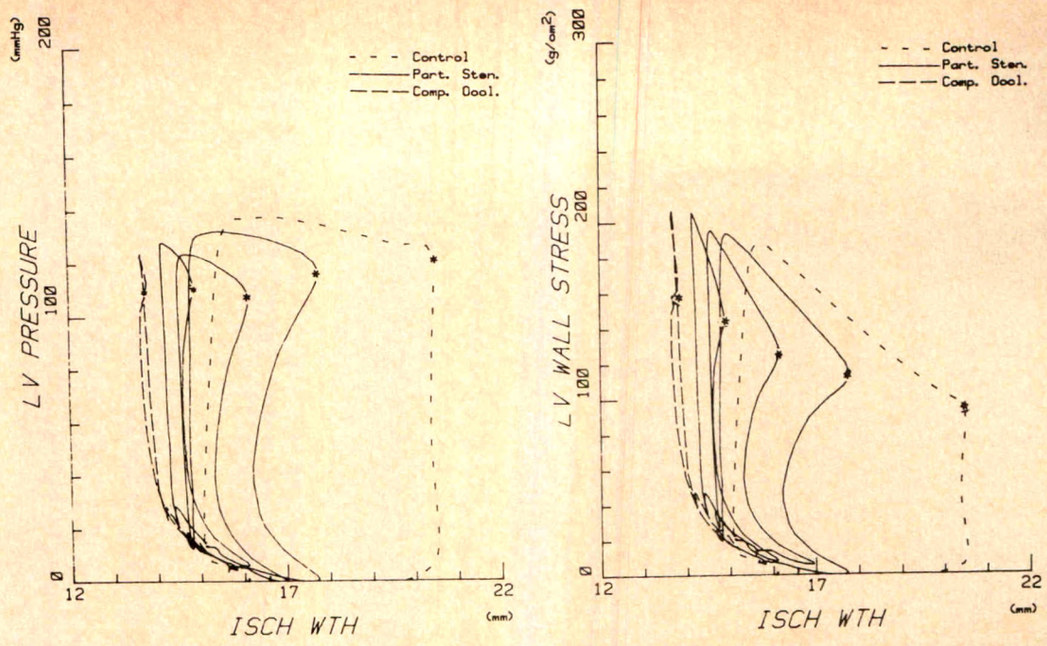

FIGURE 3. A typical computer plot of the relations between ischemic wall thickness (ISCH WTH) and left ventricular (LV) pressure (**left**) or wall stress index (**right**). **Short dashed lines,** control data; **solid lines,** partial stenosis (Part. Sten.); **long dashed lines,** complete occlusion (Comp. Occl.); **asterisks,** end-systole. During control, the normal loops rotate clockwise. During partial stenosis, reduced systolic wall thickening and marked thickening during isovolumic relaxation are apparent. During complete occlusion, systolic thickening was replaced by wall thinning and the area within the loop was near zero. While peak and end-systolic left ventricular pressure decreased a little during ischemia, end-systolic wall stress increased much more than the increase of peak stress. Thus, the loops of LV pressure-wall thickness shifted to the left of control during ischemia, while the loops of wall stress-wall thickness showed the end-systolic points to be displaced upward and to the left.

Recent studies comparing regional coronary blood flow distribution measured by the microspheres technique with regional systolic wall thickening show a close correlation between reductions in subendocardial blood flow and the degree of impairment of contractile function.[10] Although regional blood flow was not measured in the present study, the characteristics of regional wall thickness dynamics measured with the ultrasonic dimension gauges appear reliable for detecting changes in regional myocardial perfusion[10] and also were shown

Summary of end-systolic relations between the LV wall stress index (**right panels**) or LV pressure (**left panels**) versus wall thickness in the control (**bottom panels**) or ischemic regions (**top panels**). Notations as in Figure 2. **Thick dashed lines** at control in top panels show the average relations between the end-systolic LV pressure or wall stress and wall thickness obtained in our previous experiments (see text). With the progression of ischemia, the end-systolic points of wall stress index and wall thickness in the ischemic region were markedly shifted leftward and upward of control, and the points of LV pressure and wall thickness in the ischemic region were shifted to the left of control, while no significant displacement was observed in the control region, suggesting that the myocardial contractility was decreased in the ischemic region but not in the control region.

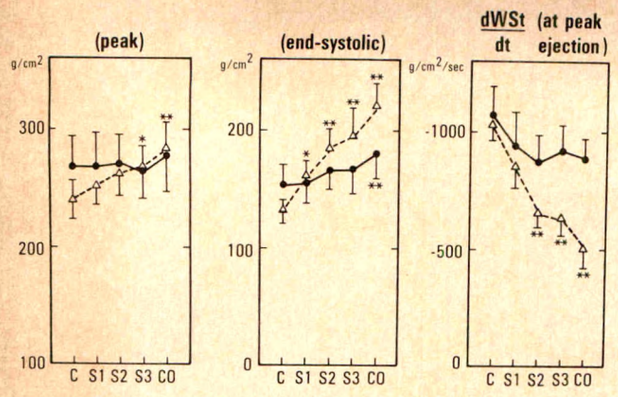

FIGURE 5. Summary of changes in the index of regional wall stress. Symbols and notations as in Figure 2. The end-systolic wall stress (**center**) in the ischemic region increased significantly during all levels of myocardial ischemia, while the peak wall stress (**left**) increased only in severe ischemia. The wall stress in the control region showed little change. The first derivative of wall stress in the ischemic region during peak systolic ejection (**right**) decreased significantly with the progression of ischemia.

to be more sensitive than surface electrocardiographic changes.[22] In the present study, we used regional wall thickening dynamics during systole together with data on overall LV dimensions to analyze global and regional myocardial function during ischemia within a framework of end-systolic pressure, dimensions, and an index of regional wall stress.

End-systolic measures of LV function have recently been investigated for assessing the contractility of the heart in both animal and human subjects.[1–4] In these reports, the end-systolic LV pressure or wall stress was found to be linearly related to the end-systolic LV volume or diameter, and the relations were shifted by changes in myocardial contractility. This type of approach was extended to the relations between the end-systolic LV pressure versus wall thickness, and end-systolic LV wall stress versus wall thickness in the conscious animal,[5] and it was concluded that the relative position of such relations was indicative of the level of inotropic state. Thus, the end-systolic pressure or wall stress versus wall thickness relation was shifted rightward by enhanced myocardial contractility and leftward by reduced contractility.[5] These findings offered the possibility of applying these local wall thickness relations for assessing global LV contractility, when localized regional contraction abnormalities were absent, without the need to determine chamber dimensions or volume. The regional nature of such measurements should also be useful in understanding the effects of myocardial ischemia on contractile function. In the present study, a shift of the LV end-systolic pressure–dimension relation suggested overall depression of contractility. As shown in Figure 4, the end-systolic wall thickness-pressure points in the ischemic region during various levels of coronary stenosis shifted to the left of the control point, indicating progressively decreasing myocardial contractility in that region, whereas little displacement of the end-systolic points in the control region indicated that regional contractility was not affected at that site.

To further illustrate the validity of this approach, in 3 dogs end-systolic relations were determined over a range of loading conditions, in addition to the single

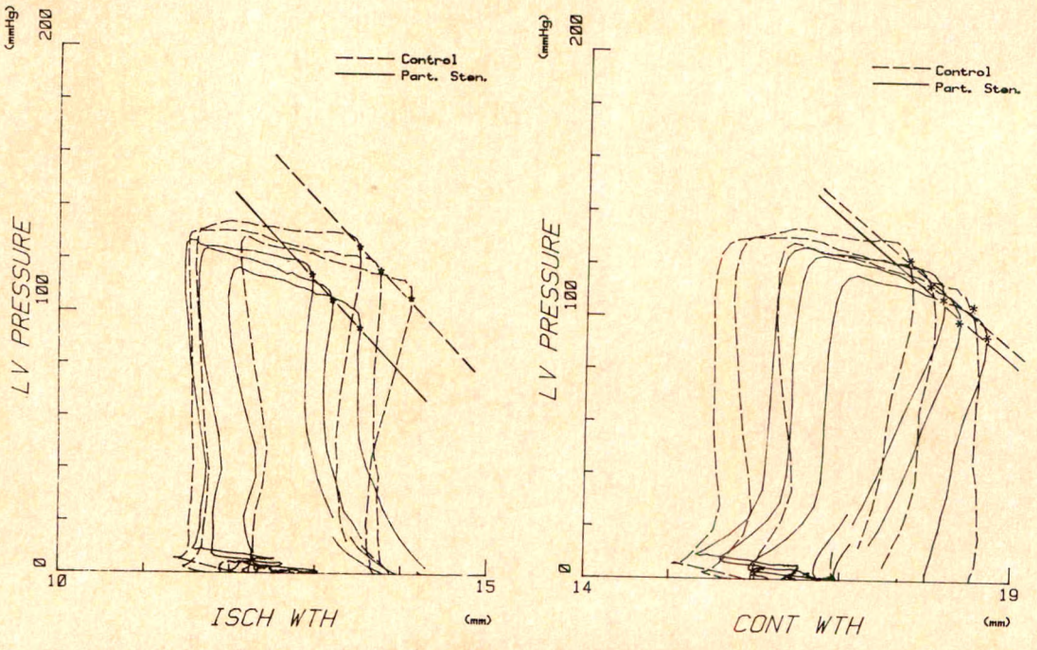

FIGURE 6. An example of computer plotted loops of wall thickness and left ventricular pressure in the control region (**right**) and in the ischemic region (**left**). During the control state (**dashed loops**), reduction in the afterload by vena caval obstruction yielded linear end-systolic relations (**dashed lines**). During partial coronary stenosis (**solid loops**), the linear relation in the ischemic region was shifted to the left of control in a parallel manner (**solid line**), while no change was observed in the control region. Abbreviations as in Figure 3.

point determinations, by producing partial occlusion of the inferior vena cava by means of a hydraulic cuff. This produced some reduction in preload and afterload during both the control state and partial coronary stenosis. A typical example of this procedure is shown in Figure 6. Several beats were sampled during the transient decrease of preload and afterload in the early phase of partial vena caval obstruction, before the occurrence of reflex tachycardia; such a short and transient change should induce little change in the level of ischemia.[18] Without coronary stenosis, the end-systolic points of the loops of wall thickness versus LV pressure in the region to be rendered ischemic showed a linear relation (Fig. 6, left, dashed line). During partial coronary stenosis, the linear end-systolic relation during caval occlusion was shifted downward and to the left of control in a parallel manner (Fig. 6, left, solid line). The end-systolic points in the control region showed a similar linear relation but were not shifted by ischemia (Fig. 6, right). Thus, the end-systolic regional wall thickness–pressure relation (or calculation of their ratio) can sensitively describe regional differences in myocardial contractility, regardless of loading conditions, supporting the usefulness of this relation as a load-independent index for assessing regional myocardial contractility.

Myocardial wall stress in an important determinant of the intrinsic function of myocardium,[23] and myocardial wall forces are a major determinant of energy utilization by the heart.[24] Various techniques have been used to calculate LV wall stress with geometric reference figures. These approaches have varied from the use of a thin-walled spheroid[25,26] or an ellipsoid of revolution[27,28] to treatment of the ventricle as a thick-walled passive elastic body.[29,30] More recently, such analyses have been extended to include consideration of fiber angle distribution within the LV wall.[31,32] The evaluation of myocardial wall stress in the intact ventricle is difficult, since the left ventricle is an irregularly shaped thick-walled structure composed of a continuum of fibers. In generating myocardial wall tension, these fibers undergo rearrangements and shear during the cardiac cycle.[9,33] Nevertheless, investigators have estimated myocardial wall stress by a variety of techniques. Most of them assume that the ventricle is a thick-walled ellipsoid of revolution and that it is composed of an isotropic homogeneous layer of muscle.[27,34] Although these applications of the basic Laplace relation to thick-walled structures can involve appreciable error,[27] the close agreement between measured wall stress and wall stress calculated from geometrical assumptions has been confirmed.[12] In the present study, an index of regional wall stress in both the control and ischemic regions was estimated with the thick-walled ellipsoidal equation using the wall thickness in either the control or the ischemic region. It is appreciated that this approach provides only an approximation, since local radius of curvature is unknown, but the estimated values show directionally appropriate changes during ischemia (see Methods section), and provide some insight into alterations in regional loading. With progressively more severe myocardial ischemia, although the global wall stress index was little changed, the index of wall stress in the ischemic region during systole was significantly increased; the end-systolic wall stress increased much more than the peak value, indicating that wall stress in the ischemic region was sustained at an elevated level throughout systole. This finding characterizes qualitatively for the first time a phenomenon in which regional loading is altered by the ischemic intervention, with systolic wall thinning leading to higher local afterload which must lead to further mechanical impairment of regional function by way of the force-velocity-length relation. Thus, the maintenance of normal systolic pressure by shortening in unaffected regions of the ventricle produced progressive regional systolic wall thinning in the involved zone, and thereby elevated the regional wall stress index. It is postulated that this load-dependent effect contributed to the striking decrease in the velocity and extent of wall thickening in the ischemic zone (Fig. 2).

In summary, end-systolic relations between wall thickness and LV pressure were progressively displaced in ischemic regions but not in control regions during increasing degrees of regional myocardial ischemia. This approach offers the possibility of a relatively load-independent measure of local myocardial contractility in various regions of the ventricle. It should be recognized, however, that if true regional wall stress could be calculated it would more accurately define the afterload. Clinical application of end-systolic measures using wall thickness should be feasible with techniques recently developed in echocardiography and 2-dimensional echocardiographic approaches coupled with systolic pressure measurements[4] also should make it feasible to evaluate regional myocardial function and contractility simultaneously in both impaired and normal myocardium during a variety of interventions.

MYTH: Fluid-filled catheters are an inexpensive and dependable means of measuring patient blood pressure.

FACT: When accurate patient diagnosis is at stake, "inexpensive" can be costly. Catheter-tip pressure transducers give substantially better accuracy and patient information at a *lower cost per use.*

There is a myth in the medical community that fluid-filled catheters are less expensive to use than catheter-tip pressure transducers.

But that myth is deceiving. The purchase price of a fluid-filled, disposable catheter can be one-seventh that of a reusable, catheter-tip pressure transducer.[1] But the catheter-tip pressure transducer can often give you twenty-five or more uses.[2] So, when the cost of use and not just the purchase price alone is examined, the "more expensive" catheter-tip pressure transducer is actually about half the cost per use of the fluid-filled catheter.

[1]Based on a Millar catheter-tip pressure transducer (Model PC-350).

[2]With the Millar MIKRO-TIP® pressure transducer with the new MT-10™ sensor, multiple usage is greatly increased. The new MT-10™ sensor sets the standard for ruggedness and durability in catheter-tip pressure transducers.

Accuracy and dependability bring the true cost of a catheter-tip pressure transducer even lower. With Millar MIKRO-TIP® catheter-tip transducers, you get an accurate reading the first time. Valuable man-hours are saved, and even more savings are available due to the increased number of measurements that can be performed.

With Millar MIKRO-TIP® catheter-tip transducers, you can forget:

- Time-consuming "debubbling"[3] of the measuring system before catheterization can begin
- Contending with a complicated, often messy, and usually inconvenient fluid-filled system
- Damping of the pressure signal due to changes of the fluid in the tubes, or air infiltration of the system
- Disturbance of the signal and, consequently, less accurate blood pressure measurements caused by the position of the transducer or movement of the patient

What you can depend on is easy-to-use, consistent, dependable, accurate readings of blood pressure — at the source — and at a cost per use much lower than you've been led to believe.

[3]i.e. debubbling tubing, stopcock connection, etc.

TRANSDERM NITRO 5

First-step anginal prophylaxis refined by advanced technology

Transderm®-Nitro

nitroglycerin

Nitroglycerin—for more than 100 years the classic therapy for angina—now becomes more convenient, more simple, more practical.

First-step anginal prophylaxis

Transderm®-Nitro

nitroglycerin

A step ahead of long-acting oral nitrates

"Transdermal delivery of nitroglycerin . . . overcomes the inherent problems of the oral dosage forms regarding . . . bioavailability, convenience and compliance."*

24-hour sustained therapeutic blood levels of nitroglycerin.
In contrast, so-called long-acting oral nitrates must be given in repeated doses throughout the day.

Eliminates the first-pass effect.
Unlike oral nitrates, which are predominantly inactivated in the liver, transdermal nitroglycerin bypasses the liver and enters directly into systemic circulation.

Only one simple application a day.
Avoids the inconvenience of multiple dosages.

Small, cosmetically acceptable and well tolerated.
Will not leak or stain clothing. May even be worn while bathing or swimming. Few reports of skin irritation.

Note: Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

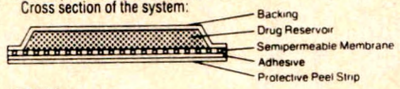
Transderm®-Nitro
(nitroglycerin)
Transdermal Therapeutic System

DESCRIPTION
Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semipermeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 cm^2 respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system: 0.5 mg nitroglycerin is delivered *in vivo* for every cm^2 of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface towards the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:



ACTIONS
When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

INDICATIONS AND USAGE
Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

HOW SUPPLIED

Transderm-Nitro System Rated Release *in vivo*	Total Nitroglycerin in System	System Size	Carton Size

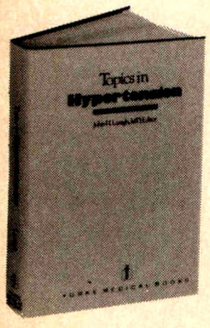
Laragh's eagerly awaited new book on the silent killer

TOPICS IN HYPERTENSION



Edited by

John H. Laragh, MD

Master Professor of Medicine
Director, The Cardiovascular Center Chief, Cardiology
Division The New York Hospital-Cornell Medical Center

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $55.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

PROGRAMALITH® AV

Programmable-Interrogatable™ Dual-chamber Pacing System-Model 223

(Except as noted, all data specified represent nominal values for a unit at standard values, measured at Beginning-of-Life, 100% pacing, 500 ohm load and 37° C.)

Nominal Pacing Rate	70 ± 1 ppm
Magnet Rate	90 ppm at Beginning-of-Life (BOL) 77 ppm at Recommended Replacement Time (RRT)
Interference Rate	Programmed Rate (70 ± 1 ppm)
Pulse Amplitude (leading edge)	5.3 V (BOL), 4.6 V (RRT)
Pulse Width	0.8 ms (BOL), 1.0 ms (RRT)
Inhibition Sensitivity to 50 Hz (20 ms) Haversine Signal	2.0 mV (positive or negative)
Refractory Period	325 ms
AV Interval (DVI Mode)	150 ms (105 ms with magnet applied)
Stimulating Energy	33 μjoules (BOL), 30 μjoules (RRT)

	VVI MODE	DVI MODE
Battery Current Drain:		
Inhibited	6 μAmps (16.8 μWatts)	6 μAmps (16.8 μWatts)
Pacing	23 μAmps (64.2 μWatts)	38 μAmps (106.9 μWatts)
Input Impedance	24 Kohms	

Programmable Parameters:	Rate, Pulse Amplitude, Pulse Width, Sensitivity, Refractory Period and Mode
Interrogation Functions:	
Programmed Parameter Status	All
With 398 Programmer:	
Vtr Lead Impedance	250-1990 ohms
Battery Impedance	1-50 Kohms
Battery Current Drain	5-100 μAmps
Measured Telemetry Values Retrieved Additionally with 398E Programmer:	Rate, Vtr. Pulse Current, Vtr. Pulse Voltage, Vtr. Pulse Energy, Vtr. Pulse Charge, Battery Voltage, A-V Delay
Programming Method	Pulsed Magnetic Energy in Conjunction with DC Magnetic Field. Unique "Error Screen" protects against phantom programming.
Print Mode	All Interrogatable Functions
Trace Mode	Step-by-Step Programming Procedure
Power Source:	
Chemistry	Lithium-Iodine
Capacity:	
Total	2.5 AH (7.00 WH)
Useful	1.93 AH (5.40 WH)
Voltage	2.8 V
Dimensions:	6.3 x 4.7 x 1.17 cm
Weight	68 gms
Volume	30 cc
Density	2.3 gm/cc (Approximately)
Hermetic Case	Titanium with Insulative Coating
Connector Material	Epoxy
Projected (theoretical) Life	9.6 years (VVI Mode)
Recommended Replacement Time:	
Magnet Rate Decrease	from 90 to 77 ppm
Pulse Width Increase	25%
Pacing Configuration:	223-dual unipolar

INDICATIONS The Pacesetter Model 223 Programalith® is a dual-chamber A-V sequential pacemaker specifically indicated for therapeutic control of conduction disorders requiring restoration of both rate and A-V synchrony. In the A-V sequential mode (DVI), the Model 223 has application for patients with extensive myocardial infarction with A-V block and sinus bradycardia. The Model 223 may also be programmed for single-chamber pacing in either ventricle or atrium.

CONTRAINDICATIONS Medical literature indicates no known contraindications to the use of pacemakers as a therapeutic means for heart-rate control. However, sequential atrial-ventricular pacing modes are contraindicated in the presence of atrial flutter and fibrillation.

WARNINGS Although special shielding and filters protect Pacesetter Pulse Generators against defibrillation pulses of up to 400 Watt seconds, defibrillator paddles should not be placed near the pulse generator and pacer function should be verified following defibrillatory charges. Caution should be exercised also with diathermy and electrosurgical units which produce high field strength signals, possibly resulting in suppression of the device's output, reversion to asynchronous mode and/or overheating of the metallic components. Pulse generators must not be sterilized by steam autoclaving or gamma radiation nor cleaned ultrasonically.

PRECAUTIONS Physicians should be aware that any pulse generator will ultimately cease to function from battery depletion and may fail at any time owing to random malfunction. Pacesetter Pulse Generators have been designed so that the average life of the circuitry will greatly exceed the expected life of the power source. As all critical circuitry and the battery are hermetically sealed, the package is virtually unaffected by the body environment; therefore, the longevity is determined almost entirely by the battery. Insufficient time has passed to completely determine various factors that may affect the life expectancy of the present battery configurations. Thus any estimates of pulse generator longevity must be based on theoretical projections of available date, principally accelerated test data, as well as expected pacing characteristics. Recommended replacement times, indications for end-of-life and longevity factors are discussed thoroughly in Pacesetter's appropriate physicians' manual for the unit to be implanted and should be consulted prior to implantation.

POTENTIAL COMPLICATIONS & SIDE EFFECTS Lead displacement/fracture, cardiac tamponade, muscle or nerve stimulation, embolism, infection, erosion of lead or pulse generator through skin and body rejection phenomena are possible.

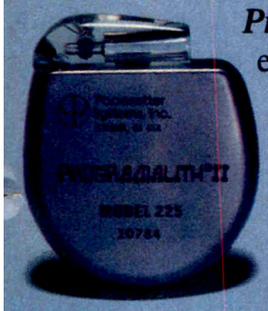
Pacesetter® Systems, Inc.

12884 Bradley Avenue, Sylmar, CA 91342 USA • (213) 362-6822 • Telex: 698415(Paceseter Sylm)

Another reason we're called PACE*SETTER*:

The dual-personality pacing therapy system.

Introducing a total pacing therapy system with *one* ultra-sophisticated programmer/telemetry unit compatible with both single-chamber and *dual*-chamber pacemakers.

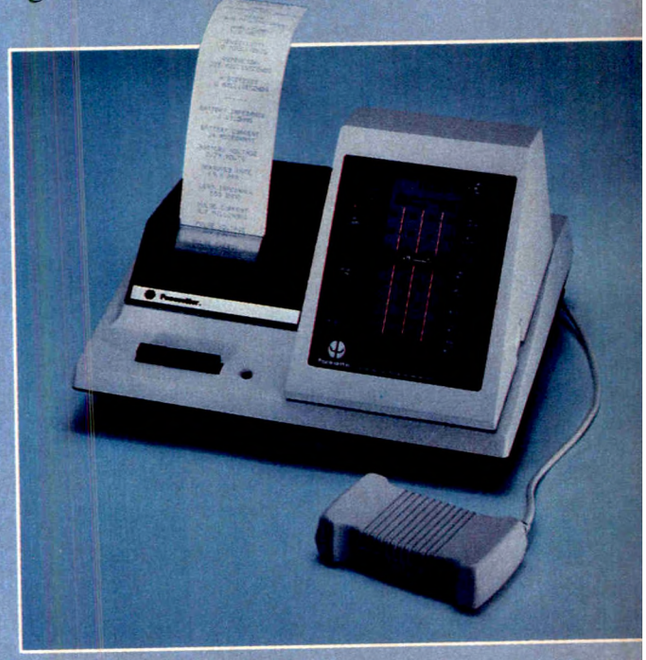


Programalith® II has established its own virtually unequalled cumulative survival record of 99.7% since January 1982. Its smaller, more physiologic configuration, thinness and theoretical longevity of greater than 8 years are combined with six-parameter multi-programmability and bi-directional telemetry features.

Programalith® A-V is a multi-modal, multi-programmable, dual-chamber A-V sequential pacemaker, incorporating extensive programmed and measured telemetry data.

It is presently the *only* dual-chamber pacemaker with vital measured telemetry, yet is small—11mm thin and 68 grams. This unique DVI pacer has established an industry standard cumulative survival figure of 99.7% since June 1981.

The Pacesetter® Model 398E Programming/Telemetry System.
Multi-programmability up to six parameters; extensive programmed and measured telemetry data capable of advising physicians both what the pacing system *should* be doing as well as what it is *actually* doing.



Printout indicates extensive telemetered information. Programmer face displays full menu of programmable parameters and values possible.

15 mg
30 mg
capsules

(temazepam)

A more appropriate half-life

One 30-mg capsule, h.s.—*usual adult dosage.*
One 15-mg capsule, h.s.—*recommended initial dosage for elderly and/or debilitated patients.*

INDICATIONS AND USAGE: Restoril® (temazepam) is indicated for the relief of insomnia associated with complaints of difficulty in falling asleep, frequent nocturnal awakenings, and/or early morning awakenings. Since insomnia is often transient and intermittent, the prolonged administration of Restoril is generally not necessary or recommended. Restoril has been employed for sleep maintenance for up to 35 consecutive nights of drug administration in sleep laboratory studies.

The possibility that the insomnia may be related to a condition for which there is more specific treatment should be considered.

CONTRAINDICATIONS: Benzodiazepines may cause fetal damage when administered during pregnancy. An increased risk of congenital malformations associated with the use of diazepam and chlordiazepoxide during the first trimester of pregnancy has been suggested in several studies. Also, ingestion of therapeutic doses of benzodiazepine hypnotics during the last weeks of pregnancy has resulted in neonatal CNS depression. Restoril is contraindicated in pregnant women. Consider a possibility of pregnancy when instituting therapy or whether patient intends to become pregnant.

WARNINGS: Patients receiving Restoril (temazepam) should be cautioned about possible combined effects with alcohol and other CNS depressants.

PRECAUTIONS: In elderly and/or debilitated patients, it is recommended that initial dosage be limited to 15 mg. The usual precautions are indicated for severely depressed patients or those in whom there is any evidence of latent depression; it should be recognized that suicidal tendencies may be present and protective measures may be necessary.

If Restoril is to be combined with other drugs having known hypnotic properties or CNS-depressant effects, due consideration should be given to potential additive effects.

Information for Patients: Patients receiving Restoril should be cautioned about possible combined effects with alcohol and other CNS depressants. Patients should be cautioned not to operate machinery or drive a motor vehicle. They should be advised of the possibility of disturbed nocturnal sleep for the first or second night after discontinuing the drug.

Laboratory Tesis: The usual precautions should be observed in patients with impaired renal or hepatic function. Abnormal liver function tests as well as blood dyscrasias have been reported with benzodiazepines.

Pregnancy: Pregnancy Category X. See Contraindications.

Pediatric Use: Safety and effectiveness in children below the age of 18 years have not been established.

ADVERSE REACTIONS: The most common adverse reactions were drowsiness, dizziness and lethargy. Other side effects include confusion, euphoria and relaxed feeling. Less commonly reported were weakness, anorexia and diarrhea. Rarely reported were tremor, ataxia, lack of concentration, loss of equilibrium, falling and palpitations. And rarely reported were hallucinations, horizontal nystagmus and paradoxical reactions, including excitement, stimulation and hyperactivity.

Restoril is a controlled substance in Schedule IV. Caution must be exercised in addiction-prone individuals or those who might increase dosage.

DOSAGE AND ADMINISTRATION: *Adults:* 30 mg usual dosage before retiring; 15 mg may suffice in some. *Elderly and/or debilitated:* 15 mg recommended initially until individual response is determined.

SUPPLIED: Restoril (temazepam) capsules—15 mg maroon and pink, imprinted "RESTORIL 15 mg"; 30 mg, maroon and blue, imprinted "RESTORIL 30 mg". Packages of 100, 500 and ControlPak® packages of 25 capsules (continuous reverse-numbered roll of sealed blisters). (RES-Z2 11/1/81)

First Ultra-Short–Acting Beta-Adrenergic Blocking Agent: Its Effect on Size and Segmental Wall Dynamics of Reperfused Myocardial Infarcts in Dogs

RÜDIGER LANGE, MD, ROBERT A. KLONER, MD, PhD, and EUGENE BRAUNWALD, MD

Beta-adrenergic blocking agents have an established role in the treatment of myocardial ischemia, but precipitation of cardiac failure or bronchospasm may restrict their use in some patients with acute myocardial infarction or in those undergoing coronary bypass surgery. ASL-8052 is a new cardioselective ultra-short–acting beta blocker which allows abolition of beta blockade within 16 minutes on termination of an intravenous infusion. An investigation was made of the effect of ASL-8052 on myocardial infarct size, regional myocardial wall function, and hemodynamic features during a 3-hour experimental occlusion of the left anterior descending coronary artery followed by 3 hours of reperfusion in dogs.

Twenty-two dogs (10 control, 12 treated) were instrumented for the measurement of left ventricular (LV) pressure, the first derivative of left ventricular pressure (LV dP/dt), systolic and diastolic aortic pressure, and heart rate. Two pairs of ultrasonic crystals were inserted into a nonischemic segment and an ischemic marginal zone segment to obtain percent segment shortening. The area of necrosis was determined by tetrazolium staining and expressed as a percentage of the in vivo area at risk obtained by autoradiography. Dogs in the control group received saline solution; in treated dogs, a continuous infusion of ASL-8052 was begun 15 minutes after occlusion with a dose "titrated" to reduce the heart rate by approximately 20% (100 to 150 μg/kg/min). After 3 hours of reperfusion, the amount of myocardial tissue necrosis, as a function of the in vivo area at risk, was significantly lower in ASL-8052–treated (48 $\pm$ 7%) than in control (73 $\pm$ 6%) dogs ($p < 0.025$). Upon reperfusion, segment shortening decreased in control dogs from $-3.3 \pm 1.1\%$ after 3 hours of occlusion to $-6.3 \pm 1.9\%$ ($p < 0.05$) 2 hours after reperfusion (that is, systolic bulging increased). This functional deterioration upon reperfusion did not occur in treated dogs. During the occlusion period, infusion of ASL-8052 caused a decrease in heart rate of 22 $\pm$ 3% ($p < 0.001$) and in LV dP/dt by 22 $\pm$ 4% ($p < 0.05$). Upon reperfusion, control dogs had an increase in heart rate of 26 $\pm$ 1% ($p < 0.05$). In treated dogs, heart rate did not change. Hence, infarct size, reperfusion tachycardia, and myocardial wall asynergy were reduced in ASL-8052–treated dogs. A potential advantage of this agent is that its short duration of action would allow rapid reversal of beta blockade if adverse effects developed.

Beta-blocking agents have an established place in the treatment of myocardial ischemia; in some studies they have been shown to reduce the size of an experimentally induced myocardial infarct (MI)[1,2] and to reduce long-term mortality in patients with acute MI.[3] However, fear of adverse effects, particularly precipitation of cardiac failure, bronchospasm, bradycardia, and atrioventricular block, has restricted the use of beta blockers in patients with acute MI or in those undergoing cardiac surgery who have a history of left ventricular dysfunction, pulmonary disease, or atrioventricular conduction delay. The relatively long duration of action of available beta blockers restricts the flexibility of their use in such patients. ASL-8052 is a new cardioselective beta-adrenergic antagonist without intrinsic sympathomimetic activity, which has an extremely brief duration of action believed to be due to rapid metabolic degradation by serum and tissue esterases[4] (Fig. 1). ASL-8052 is administered by continuous infusion and the dose is "titrated" in order to achieve any desired level of blockade. The potential advantage of this drug over available beta blockers is that, should adverse effects ensue from its administration, beta blockade can be rapidly terminated upon discontinuation of the infusion.

From the Department of Medicine, Harvard Medical School, and Brigham and Women's Hospital, Boston, Massachusetts. This study was supported in part by Grants HL 23140 and SCOR 26215 from the National Heart, Lung, and Blood Institute, the National Institutes of Health, Bethesda, Maryland; by a grant from the American Critical Care Corporation, McGaw Park, Illinois; and by funds contributed in part by the Massachusetts Heart Association, Boston, Massachusetts. Manuscript received November 29, 1982; revised manuscript received March 9, 1983, accepted March 12, 1983.

Address for reprints: Robert A. Kloner, MD, PhD, Harvard Medical School, 180 Longwood Avenue, Room 235, Boston, Massachusetts 02115.

In patients, early coronary revascularization can seldom be initiated before 3 to 4 hours after the onset of chest pain. Since there is evidence that beta blockade can delay cell death before reperfusion,[2] it was of interest whether this mode of treatment, in conjunction with reperfusion, could reduce ultimate infarct size.

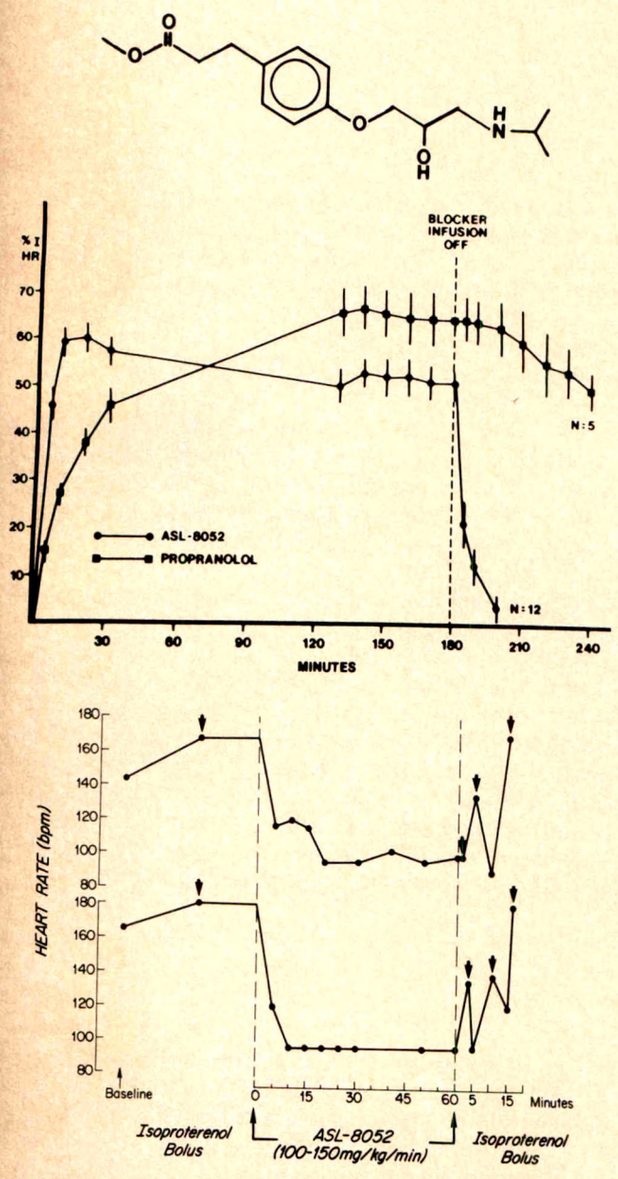

FIGURE 1. Top, molecular structure of ASL-8052. **Middle,** time course of beta blockade during and after constant infusion of ASL-8052 (50 μg/kg/min) and propranolol (1.13 μg/kg/min) in dogs. Graph shows percent inhibition (%I) of heart rate (HR) response to isoproterenol boluses (0.5 μg/kg) on the ordinate over time on the abscissa. Isoproterenol bolus doses were administered at 10-minute intervals before, during, and after a 3-hour intravenous infusion of ASL-8052. The time required for 80% recovery from beta blockade was only 12 ± 3 minutes in the group receiving ASL-8052. (Reprinted with permission from Zaroslinski et al, Life Sciences 1982; 31(9):899–907). **Bottom,** heart rate response to bolus doses of isoproterenol in 2 dogs that we subjected to a 60-minute continuous ASL-8052 infusion. Sixteen minutes after the termination of the infusion the HR response to bolus doses of isoproterenol was 100% of the preinfusion response and hence beta blockade was considered to be reversed.

However, under these circumstances the depression of function of nonischemic myocardium by the persistent action of conventional beta blockers could be potentially undesirable. The specific objective of the present study was to determine the effects of a continuous infusion of ASL-8052 on myocardial infarct size, regional myocardial wall function, and hemodynamic function during a temporary 3-hour coronary artery occlusion followed by reperfusion.

Methods

Preparation: Twenty-nine mongrel dogs of either sex weighing 11 to 23 kg were anesthetized with sodium thiamylal (30 mg/kg), intubated, and placed on a Harvard respirator. All dogs received an intravenous bolus dose of succinylcholine (40 mg/kg). The right femoral vessels were dissected free and catheters inserted. A thoracotomy was performed in the fifth left intercostal space, the heart was suspended in a pericardial cradle, and a small segment of the left anterior descending coronary artery was isolated. A micromanometer-tipped pressure transducer (Millar Instruments, Houston, Texas) was inserted into the left ventricle through a stab wound in the apex, and a polyethylene catheter was placed into the left atrium.

Regional function: Two pairs of miniaturized piezoelectric crystals (Dimonics, Boston, Massachusetts) (1.5 to 2 mm) functioning as emitters and receivers were implanted 10 to 20 mm apart into the epicardium through a small incision. One pair of crystals was placed in the upper part of the left anterior ventricular wall to measure nonischemic regional function. The other pair was placed toward a marginal border zone assessed by visual cyanosis, during a 5- to 10-second occlusion of the left anterior descending coronary artery as has been described previously by Theroux et al.[5] Both pairs were positioned perpendicularly to the major axis of the left ventricle. The epicardial location of the crystals was chosen to assess specifically the function of the myocardium presumed to have the best chance of being salvaged by reperfusion, that is, the epicardium at the edge of the ischemic zone. The position of the crystals was confirmed at necropsy. The dynamics of segment length changes were recorded on line by continuous measurement of ultrasonic transit time between the crystals. The measured transit time was calibrated in steps of 1 μs generated by a crystal controlled pulse generator.

In vivo area at risk and infarct size. The in vivo area at risk (AR) and the area of necrosis (AN) were determined by a method described previously.[6] Six hundred thousand human albumin microspheres labeled with technetium-99m (diameter 20 μm) (3M, Eagen, Minnesota) were injected into the left atrium 15 minutes after coronary occlusion. At the end of the experiment, the heart was excised and the left ventricle was sectioned into 4 mm thick slices. The slices were then incubated for 15 minutes in triphenyltetrazolium chloride at 37°C. Triphenyltetrazolium chloride stains normal tissue containing dehydrogenase enzymes brick red whereas infarcted tissue, depleted of these enzymes, remains pale yellow.[7] The slices were then exposed for 18 hours on an 8 × 10 in sheet of high speed x-ray film, and developed in an X-Omat (Kodak Medical Products, Rochester, New York) automatic processor. Normally perfused tissue appears as an area of high radiographic density on the final autoradiogram, whereas ischemic tissue appears as an area of low or absent radioactivity. This "in vivo" AR technique was chosen to reflect the physiologic conditions during coronary artery occlusion by taking into account collateral blood flow distribution as 1 major determinant of infarct size.

All slices were weighed and the inner and outer margins were traced on a clear acetate overlay. By superimposing the same tracing over the autoradiogram, the boundary of the ischemic area (in vivo AR) was drawn at the edge of the zone of decreased radiographic density by eye. The AN was traced on an acetate overlay. AN and AR were planimetered, expressed as a percentage of the total slice area, and calculated for weight in grams. By adding the weights for all slices, the total size of the infarct and the risk region were obtained as absolute weight and as percentage of total left ventricle. The AN as a percentage of the AR was calculated by: AN/AR × 100.

Regional myocardial blood flow: To assess regional myocardial blood flow, approximately 2.0×10^6 radioactive microspheres labeled with either scandium-46, tin-113, or cerium-141 were injected into the left atrium and a reference blood sample was drawn from the femoral artery over a 90-second period at 15.3 ml/min. For tissue counting, sections from 4 different zones were cut from 2 representative heart slices; these were divided into epicardial and endocardial halves: zone 1, the central ischemic zone; zone 2, the zone within the lateral portion of the AR cut according to the acetate overlay tracing; zone 3, the zone approximately 5 mm outside the AR; and zone 4, the zone remote from the AR in normally perfused tissue.

Dissected pieces were weighed and blood flows were calculated as previously described.[8]

Experimental Measurements and Protocol

Left ventricular systolic pressure was recorded from the micromanometer tipped pressure transducer which had been calibrated before the experiment. Aortic pressure and left atrial pressure were obtained through fluid-filled catheters connected to a Statham P23Db pressure transducer. LV dP/dt was obtained by electronic differentiation. Lead aVF of the electrocardiogram was monitored and was used to calculate heart rate. From the recorded signals of the ultrasonic dimension gauges, the end-diastolic length (EDL) and end-systolic length (ESL) were identified by the beginning of the rapid increase in left ventricular pressure just before the isovolumetric contraction and the peak negative first derivative of left ventricular pressure respectively. Percent segment shortening (% SS) was calculated from the following formula: % SS = (EDL − ESL)/EDL ×100.

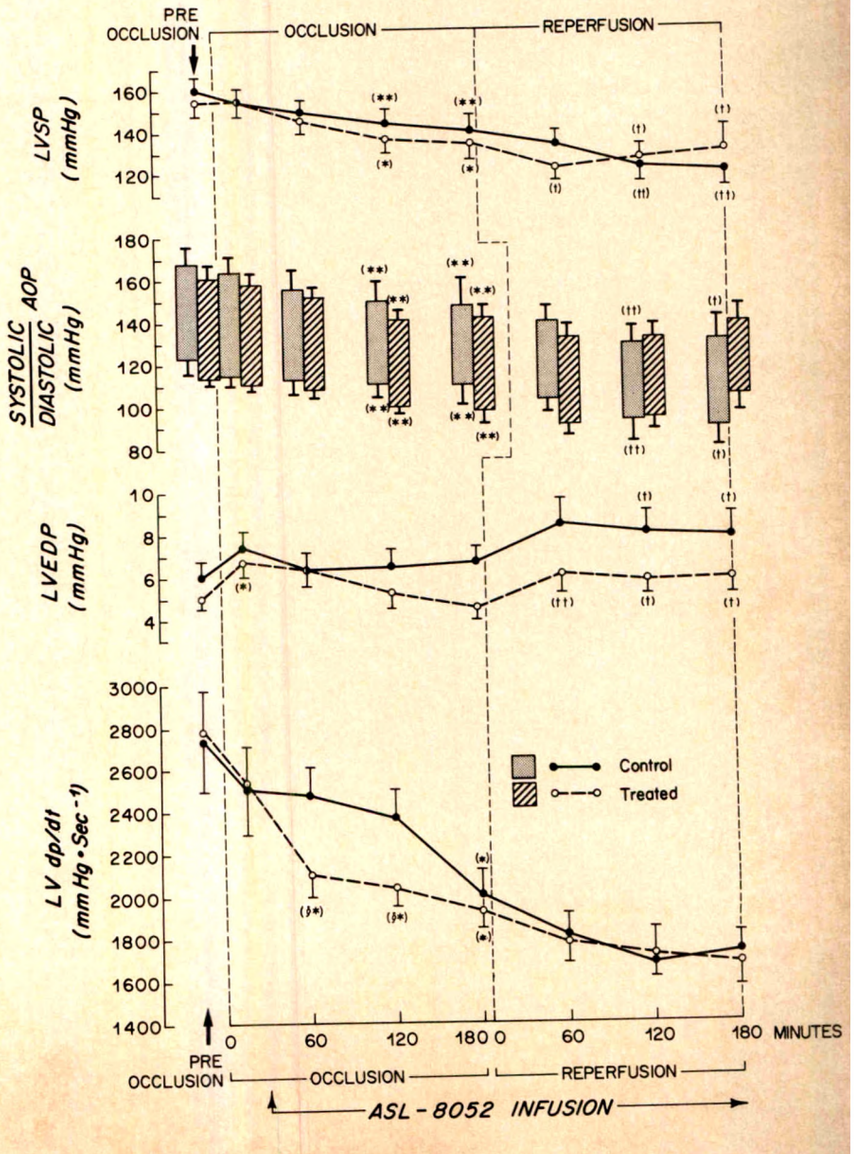

FIGURE 2. Top, left ventricular systolic pressure (LVSP), systolic and diastolic aortic pressure (AoP), and left ventricular end-diastolic pressure (LVEDP) in control and treated dogs. **Bottom,** rate of increase of left ventricular pressure (LV dP/dt). ASL-8052–treated dogs show significantly lower LV dP/dt values during the occlusion period. * $p < 0.025$ compared with preocclusion value; ** $p < 0.001$; † $p < 0.05$ compared with 180 minutes after occlusion value; ‡ $p < 0.025$; § $p < 0.05$ compared with corresponding value in control group.

All animals received an intravenous bolus dose of 1.5 mg/kg of lidocaine immediately after left anterior descending coronary artery occlusion. At 10, 60, and 240 minutes after occlusion, microsphere injections into the left atrium were performed for determination of regional myocardial blood flow. Albumin microspheres for autoradiography were injected into the left atrium 15 minutes after coronary occlusion. Immediately thereafter a continuous infusion of either saline solution (10 dogs) or of the ultra-short-acting beta blocker ASL-8052 (12 dogs) was started and continued until the termination of the experiment. The dose of ASL-8052 ranged from 100 to 150 μg/kg/min and was adjusted in order to reduce heart rate by approximately 20% of the preocclusion value. The infusion rate of ASL-8052 was then held constant. The coronary occlusion was released after a 3-hour period of ischemia which was followed by 3 hours of reperfusion. These time periods were chosen because of their relevance to patients undergoing early fibrinolytic or surgical revascularization.

Results

A total of 29 dogs were studied. In 2 dogs, the pharmacologic properties of ASL-8052 were investigated without coronary artery occlusion. Five dogs were excluded from the study, 4 because of ventricular fibrillation during the first 15 minutes after coronary artery occlusion and 1 because of the high coronary collateral flow which prevented the development of sufficient ischemia to produce epicardial cyanosis. Of the 22 remaining dogs, 10 were assigned to the control and 12 to the treated group.

Beta blockade by ASL-8052: Preliminary experiments were designed to confirm previous reports about the short duration of action of ASL-8052[4] (Fig. 1 middle). Two dogs were instrumented as described above but coronary artery occlusion was not carried out. An intravenous bolus dose of isoproterenol (0.5 μg/kg) resulted in an increase in heart rate of 10 to 15%. After the heart rate had returned to baseline, ASL-8052 was infused for 60 minutes at a dosage of 100 to 150 μg/kg/min. Five minutes after the initiation of the ASL-8052 infusion, the heart rate was about 20% below the preinfusion value; it remained there during the infusion period. After discontinuation of the infusion, the attenuation of the ASL-8052 pharmacologic action was determined by examining the response to bolus doses of isoproterenol (0.5 μg/kg). Sixteen minutes after discontinuation of the infusion, the heart rate response was 100% and the LV dP/dt response was 92% of the preinfusion response to isoproterenol; hence, beta blockade was considered reversed (Fig. 1 bottom).

Hemodynamic changes (Fig. 2): Hemodynamic changes immediately upon occlusion were not significantly different from preocclusion value in either group. At 120 minutes and 180 minutes after occlusion left ventricular systolic pressure, as well as aortic systolic and diastolic pressures, were significantly lower than preocclusion values in both the control (saline solution-treated) and ASL-8052–treated group ($p < 0.05$). Sixty minutes after occlusion, or 45 minutes after the

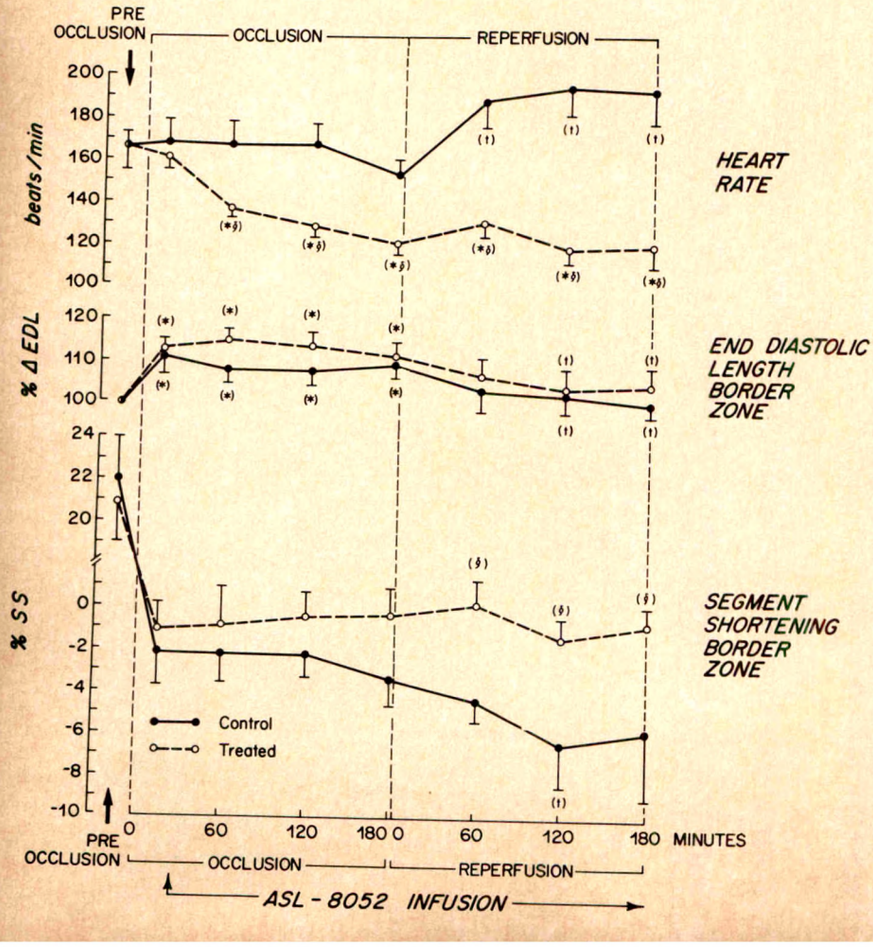

FIGURE 3. Top, heart rate in ASL-8052–treated and control dogs. Values are mean ± standard error.
* Significantly ($p < 0.05$) different compared with preocclusion value (§ $p < 0.001$).
† Significantly different compared with 180 minute value ($p < 0.05$).
‡ Significantly different compared with value at comparable time in control group ($p < 0.05$) (‖ $p < 0.025$).

initiation of either ASL-8052 or saline solution infusion, LV dP/dt in the treated group had decreased to 78 ± 4% of the preocclusion value ($p < 0.05$ compared with preocclusion baseline). In contrast, in the saline solution-treated controls, LV dP/dt did not decrease within the first 2 hours of coronary artery occlusion and was significantly ($p < 0.05$) higher than in the beta-blocked group. During the third hour after occlusion, LV dP/dt values also decreased in the control group and approached those observed in the treated group. Adjusting the beta-blocking agent according to heart rate resulted in an 18 ± 3% decrease in this parameter below preocclusion values ($p < 0.001$) 60 minutes after occlusion (Fig. 3). The infusion rate of the beta blocker was then held constant. Heart rate showed no change in the saline solution-treated controls during the 3 hours of occlusion, and was hence significantly ($p < 0.025$) lower in the ASL-8052–treated animals.

On reperfusion, LV systolic pressure as well as aortic systolic and diastolic pressures and LV dP/dt decreased. Left ventricular end-diastolic pressure increased both in control and treated animals (Fig. 2). Saline solution-treated dogs showed a significant increase in heart rate, from 153 ± 8 at the end of the occlusion period to 189 ± 12 after 60 minutes of reperfusion ($p < 0.05$) (Fig. 3). This reflected the occurrence of reperfusion arrhythmias, which included sinus tachycardia, ventricular tachyarrhythmias, and multifocal premature ventricular contractions. In 2 control dogs, however, sinus rhythm was maintained during the entire reperfusion period, suggesting that arrhythmias are frequently but not invariably associated with reperfusion. Heart rate in treated dogs during reperfusion was significantly lower than in control dogs ($p < 0.025$) (Fig. 3).

In summary, in contrast to control dogs, treated animals had a decrease of approximately 20% in heart rate and in LV dP/dt upon ASL-8052 infusion. During reperfusion, the 2 groups exhibited important differences in heart rate, which increased 25% above the occlusion level in saline solution-treated animals and did not change significantly in treated dogs.

TABLE II Values for Area at Risk and Area of Necrosis as Percentage of Total Left Ventricle and Area of Necrosis as Percentage of the Area at Risk

	Control (n = 10)	Treated (n = 12)	p
Area at risk (%LV)	23 ± 2	23 ± 2	NS
Areas of necrosis (%LV)	18 ± 3	11 ± 2	NS
Areas of necrosis/ area at risk ×100	73 ± 6	48 ± 7	$p < 0.025$

Values are mean ± standard error.
NS = not significant.

Regional function (Table I): In the nonischemic zone, end-diastolic segment length increased after occlusion, by 7% in both groups ($p < 0.05$ compared with preocclusion baseline). In the border zone segments, end-diastolic length increased by 12 ± 3% in the control group ($p < 0.01$ compared with preocclusion) and 13 ± 2% ($p < 0.05$) in the treated group. During the 3-hour occlusion period, the end-diastolic length in both the nonischemic and border zone segments remained elevated but returned to preocclusion levels upon reperfusion in both groups (Fig. 3). Segment shortening in the nonischemic segments was elevated in all animals during occlusion, indicating compensatory hyperkinesia. The initial response to coronary artery occlusion in the ischemic border zone was a change from active shortening to passive systolic lengthening in most dogs. Two control and 3 treated animals retained residual shortening of 3 to 6% and 1 dog in each group had an akinetic border zone segment. Since systolic bulging was predominant in both groups, the mean values for segment shortening at 15 minutes after occlusion, that is, just before treatment, were negative (Fig. 3).

During reperfusion the border zone segments of the saline solution-treated animals exhibited marked de-

terioration so that the mean segment shortening decreased from −3.3 ± 1.1% 180 minutes after occlusion to −6.3 ± 1.9% after 120 minutes or reperfusion ($p < 0.05$). In treated animals, this functional deterioration did not occur; 2 of the 12 treated dogs even demonstrated minimal systolic shortening presumably due to hyperemia during the early reperfusion period. Thus, reperfusion caused a significant increase in paradoxical systolic bulging in the border zone of the saline solution-treated animals, which was not observed in the dogs treated with the beta blocker (Fig. 4). The differences in segment shortening between the 2 groups were significant at 60 ($p < 0.01$), 120 ($p < 0.025$), and 180 ($p < 0.05$) minutes after the onset of reperfusion.

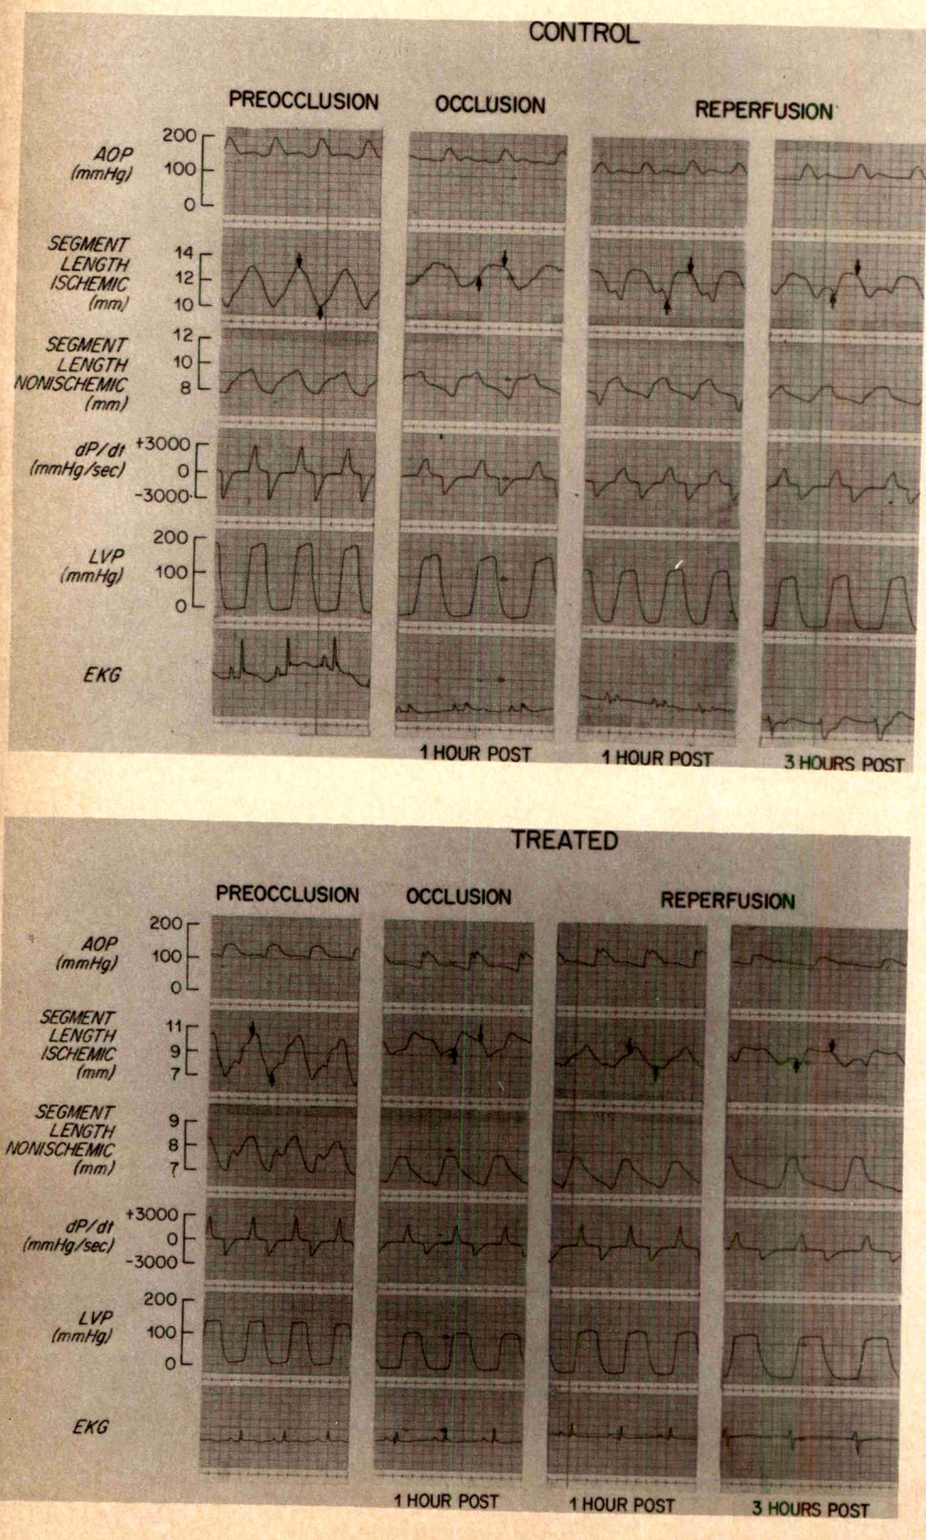

FIGURE 4. Tracings of ischemic ("border zone") and nonischemic segment length, aortic pressure (AoP), dP/dt, left ventricular pressure (LVP), and electrocardiogram (EKG). The control animal shows increased systolic paradoxical bulging (**arrows**) 1 and 3 hours after reperfusion (**top**). The ASL-8052–treated dog shows some contraction (**arrows**) 1 hour after occlusion which is however not maintained throughout the reperfusion period (**bottom**).

Values are mean ± standard error.

Infarct size (Table II): The AR defined by autoradiography was similar in both groups. In control animals, 73 ± 6% of the ischemic AR became necrotic while only 48 ± 7% became necrotic in treated animals ($p < 0.025$) (Fig. 5). Examination of the autoradiograms and the triphenyltetrazolium chloride-stained slices of the left ventricle revealed that in control dogs the salvaged myocardium, that is, the tissue that was ischemic but did not progress to necrosis, was generally subepicardial in location.

There was an inverse correlation between the quantity of myocardial necrosis, expressed as a percentage of the AR, and subepicardial regional myocardial blood flow within this area ($r = -0.60$ control; $r = -0.90$ treated) (Fig. 6). The regression line for the treated group is significantly ($p < 0.01$) displaced downwards compared with that of the control dogs, suggesting that there was less necrosis per given blood flow.

Regional myocardial blood flow (Table III): Ten minutes after occlusion, blood flow in the central ischemic zone was 10 to 15% of that in the normal zone with a generally greater reduction of flow in the subendocardium. In both groups there was a tendency to blood flow redistribution with time, with flow increasing in the subepicardium at the expense of that in the subendocardium. Throughout the study flows in treated animals were not different from control dogs.

Discussion

The present investigation yielded 2 major results. First, after a 3-hour occlusion of the left anterior descending coronary artery followed by 3 hours of reperfusion, myocardial tissue necrosis expressed as a function of the in vivo AR was significantly lower in dogs treated with an ultra-short–acting beta blocker than in saline solution-treated control dogs. Second, in comparison with saline solution-treated controls, in dogs treated with this agent, the extent of paradoxical systolic expansion of the border zone segment did not increase upon reperfusion. Also during reperfusion, dogs treated with the beta blocker did not develop the ventricular tachyarrhythmia observed in control dogs.

The potential of beta-blocking agents to reduce infarct size both in experimental animals and in patients has been studied extensively; although a number of investigators have reported favorable effects,[1,2,9,10] the

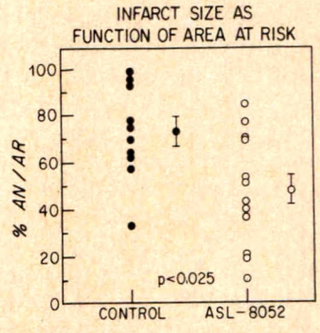

FIGURE 5. Area of necrosis (AN) by tetrazolium staining as a function of the "in vivo" area at risk (AR) by autoradiography.

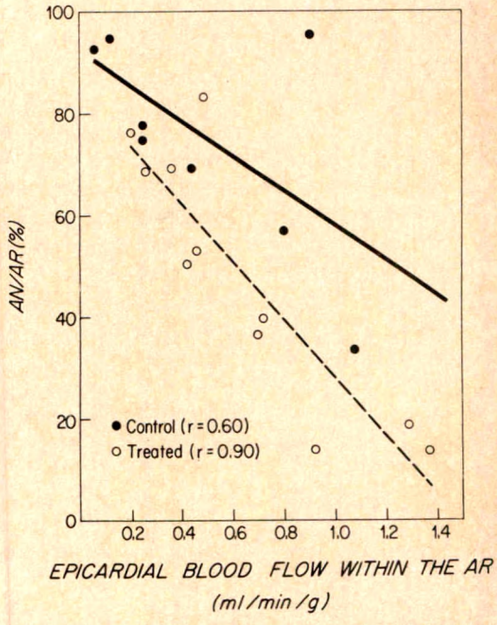

FIGURE 6. Regression lines correlating infarct size (AN/AR [%]) with subepicardial blood flow ($r = -0.60$ control; $r = -0.90$ treated). Comparison of the 2 lines indicates that infarct size is lower in the treated group than in the control group for any given blood flow. The 2 lines are $y = 91.78 - 33.63x$ (control) and $y = 85.77 - 57.45x$ (treated). The *t* test for equal slopes is not significant ($t = 1.26$, $df = 15$, not significant). Assuming that the lines are parallel, the regression lines are $y = 98.69 - 47.73x$ (control) and $y = 79.45 - 47.73x$ (treated). The test for equal intercept is $t = 2.64$ ($p < 0.01$).

results have not been uniform and a substantial number of studies have in fact shown no beneficial results.[11–13] A recent study by Reynolds et al[2] suggested that beta blockers may only be capable of delaying necrosis, and hence are only beneficial in a reperfusion model.

Several modes of action could be responsible for the reduction in infarct size by ASL-8052 in the present study. There is general agreement that infarct size is determined by the quantity of coronary collateral blood flow,[14] the size of the occluded coronary vascular bed,[11] myocardial oxygen consumption,[15] and the duration of coronary artery occlusion.[16] Since the quantity of coronary collateral flow as assessed by microspheres, the risk region as assessed by autoradiography, and the duration of occlusion were the same in control and ASL-8052–treated dogs, it appears likely that the reduction of myocardial oxygen requirements by beta blockade[13,15] was responsible for the reduction of infarct size. ASL-8052 caused a significant reduction in heart rate and LV dP/dt, both of which are important determinants of myocardial oxygen consumption.[15]

Regional function: Before occlusion the values for segment shortening were slightly lower in the nonischemic segments than in the border zone segments in both groups, because the nonischemic segments were located closer to the heart bases and therefore contracted less than the border zone segments which were in a more contractile mid-ventricular area. Both saline solution- and ASL-8052–treated dogs showed comparable levels of compensatory hyperfunction of nonischemic segments during the occlusion period. In contrast, Vatner,[17] Theroux,[5] and their co-workers reported that propranolol depressed regional contractility assessed by ultrasonic crystals in the nonischemic zone in closed-chest conscious dogs subjected to coronary artery occlusion. However, Theroux[18] did not find depression of nonischemic segments of myocardium by propranolol in anesthetized open-chest dogs, which is consistent with our results. Hence, the dose of the ultra-short–acting beta blocker which achieved salutory results in terms of infarct size reduction and performance of ischemic myocardium did not depress the performance of the nonischemic myocardium.

A surprising finding was the deterioration of function as expressed as increased systolic bulging of the border zone segment during reperfusion in the control group (Fig. 3 and 4). Delayed recovery of myocardial wall function after institution of reperfusion assessed by strain gauges[19] and ultrasonic crystals[20] has been reported after coronary artery occlusion. In the present study, systolic bulging, expressed as a percentage of end-diastolic length, increased in control dogs. Presumably, the myocardium at the edge of the ischemic zone, in which the crystals were placed, consists of cells with varying degrees of ischemic damage. In the untreated group these cells may have been further damaged and their residual contraction may have ceased during reperfusion, perhaps as a consequence of calcium influx and resultant mitochondrial damage and ischemic contracture. In the treated group this reperfusion injury might have been prevented because the cells were less damaged at the time reperfusion was begun.

Clinical implications: The results of this study suggest that ASL-8052 may be a potentially useful agent in the early treatment of patients with acute MI who are to undergo early revascularization, either thrombolytic or surgical. Rapid degradation of ASL-8052 by tissue and serum esterases permits cessation of beta blockade within minutes of discontinuation of a continuous infusion or a reduction in blockade with a lowering of the dose. This offers a potential clinical advantage over standard beta blockers, which have a much longer duration of action, since it is not possible to "back off" when the dose is too high and the natural temptation of the clinician is to err on the side of administering a safe, but possibly ineffective dose.

In view of the brief duration of action of ASL-8052, this drug could be used in clinical practice to reduce myocardial oxygen consumption maximally; the hazard of serious depression of cardiac function which accompanies persistent beta blockade is reduced since the drug can be discontinued or its dose reduced and adverse effects can be expected to disappear promptly. It is now common practice to continue beta blocker administration through the entire perioperative period in patients undergoing coronary bypass surgery,[21] because abrupt cessation has been associated with severe adverse effects.[22] However, some patients receiving beta blockers require inotropic support to be weaned off bypass and have poor hemodynamic performance in the early postoperative period. Using a continuous infusion of ASL-8052, beta blockade could be maintained until just before the thoracotomy, then discontinued during the perioperative period, and reinstituted just as soon as hemodynamic stability has returned postoperatively. The frequently observed increased postoperative sympathetic tone with resultant tachycardia and hypertension could thus be treated safely with ASL-8052.

Acknowledgment: We acknowledge the secretarial assistance of Laura Ducey and Nancy Watterson. We thank the American Critical Care Corporation for supplying ASL-8052, and for support and advice concerning this study. Animals used in this study were maintained in accordance with the guidelines of the Committee on Animals of the Harvard Medical School and those prepared by the Committee on Care and Use of Laboratory Animals of the Institute of Laboratory Animals Resources, National Research Council (DHEW publication (NIH) 78-23, revised 1978).

Sympathetic Denervation Limited to a Region of Acutely Ischemic Canine Myocardium Increases Excitability Threshold and Duration of Bipolar Electrograms

JAMES B. MARTINS, MD, THOMAS M. MUELLER, MD, and DOUGLAS P. ZIPES, MD

This study determines the direct effects of sympathetic denervation on excitability threshold and bipolar electrograms in acutely ischemic myocardium. Regional denervation was performed by application of phenol to the epicardium surrounding the ischemic zone in order to eliminate the possible hemodynamic effects that global cardiac denervation may exert on the ischemic zone. Data were obtained during serial occlusions (≤6 minutes in duration) of left anterior coronary artery in open-chest dogs with sympathetic denervation performed before the last occlusion. Late diastolic threshold was measured every 5 seconds by a constant voltage pacemaker which automatically registered threshold in stimulus duration. During ischemia, regional denervation (n = 9) increased peak excitability threshold from 240 ± 51 (standard error of the mean) to 552 ± 182 μs ($p < 0.05$) and prolonged electrographic duration in epicardium from 19 ± 3 to 25 ± 4 ms ($p < 0.025$) and in endocardium from 20 ± 3 to 25 ± 4 ms ($p < 0.01$). Phenol application did not alter aortic pressure, ischemic wall motion (sonomicrometer technique), or ischemic zone blood flow (microsphere technique). Thus, acute sympathetic denervation when limited to ischemic myocardium increases the peak excitability threshold and concomitantly prolongs duration of bipolar electrograms.

Sympathetic neural input to the heart importantly affects the electrophysiologic properties of ventricular myocardium. In normal myocardium, sympathetic nerve activity influences duration of the refractory period,[1,2] but not late diastolic excitability threshold or conduction velocity.[3–7] Sympathetic neural influences may also affect electrophysiologic characteristics of ischemic myocardium since stellate ganglionectomy or stimulation may affect the tendency to ventricular fibrillation during myocardial ischemia.[8–13] Recent work has suggested that acute surgical interruption of the stellate ganglia reduced the extent of epicardial electrographic alterations produced by ischemia.[14] The present study examines the direct effects of sympathetic denervation on excitability and conduction by producing denervation limited to the ischemic zone. By this means, we can avoid the global cardiac and systemic effects of stellate ganglia interruption which may indirectly influence electrophysiologic properties of the ischemic zone.

Methods

General: Healthy mongrel dogs weighing 14 to 25 kg were given morphine sulfate (2.3 mg/kg) intramuscularly and alpha chloralose (80 mg/kg) intravenously. We also constantly infused chloralose (16 mg/kg/h) to maintain anesthesia. The chloralose was prepared in a 2% solution dissolved in 40% polyethylene glycol (average molecular weight 200). The dogs

were mechanically ventilated. Arterial pH and partial pressures of carbon dioxide and oxygen were monitored and maintained in the normal range throughout the experiment. Sodium bicarbonate (10 mEq) was infused each hour to reverse the metabolic acidosis produced by intravenous chloralose.[15]

The sternum was split and the parietal pericardium was incised and sutured to wound edges to support the heart. The right femoral artery was cannulated with a 40 cm fluid-filled catheter which was advanced to the aortic arch and connected to a Staham P23 dB transducer to monitor pressure. To maintain normal body temperature, the animal was placed on a heating pad. In addition, the sternal incision was covered with a plastic sheet, and the operating table lamp was focused on the cardiac surface.

The left anterior descending artery was mobilized before its last large diagonal branch. In dogs with large anterior descending coronary vessels extending over the apex (carrying blood to posterior myocardium), the origins of 2 or 3 diagonal branches of the anterior descending coronary artery were dissected instead. An umbilical tape was passed beneath the vessel or vessels which were occluded with a bulldog clamp. Occlusions were 3 to 6 minutes in duration with at least 25 minutes allowed between repeat occlusions; occlusion was maintained for 6 minutes unless failure to capture or premature depolarizations prevented data collection. Duration of all the occlusions and periods between occlusions for any 1 dog were the same. Occlusions lasting <6 minutes generate reproducible changes[14] and do not produce irreversible damage.

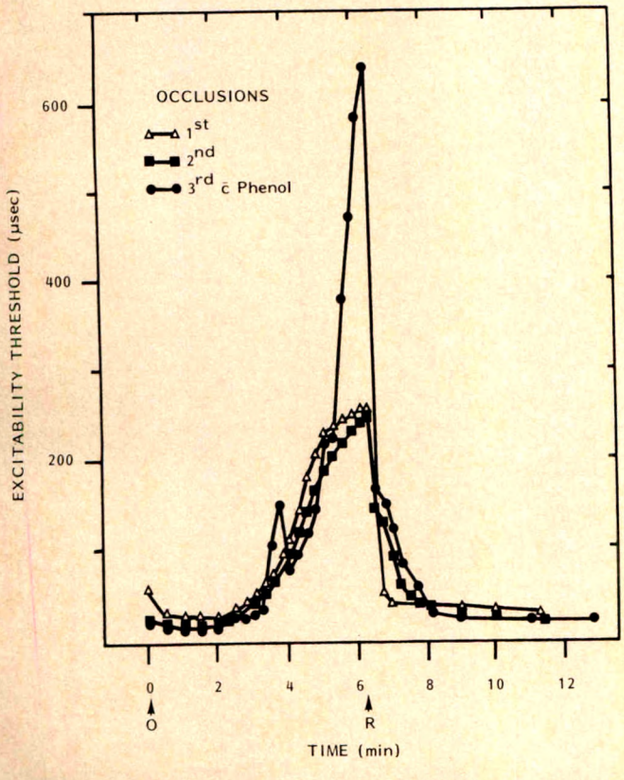

FIGURE 1. Graph showing serial excitability threshold measurements in microseconds during 3 coronary occlusions of 6.25 minutes' duration in 1 dog. Changes in excitability threshold for the first and second control occlusions are almost identical. The third occlusion after phenol encircling of the ischemic area results in a 2.5-fold increase in peak excitability threshold. 0 = occlusion; R = reperfusion.

All animals received 5,000 units of heparin before the first coronary artery occlusion.

Excitability measurement: The region of the sinus node was crushed to slow the spontaneous heart rate. The center of the left ventricular ischemic zone, identified by transient occlusion of the anterior coronary vessel(s), was paced with a unipolar cathodal stimulus at a basic cycle length of 360 to 410 ms. The cycle length was fixed in any 1 dog throughout the experiment. The anode was a 3.5 cm diameter electrode located in the subcutaneous tissue of the abdomen. The electrode delivering ventricular stimuli was either an epicardial or endocardial Teflon® coated stainless steel wire electrode (0.107 mm diameter bare only at the tip) or an acrylic plaque electrode (1 mm diameter stainless steel embedded in 1 cm diameter acrylic) sutured to the epicardial surface. Similar results occurred with both electrodes, and therefore the data were combined.

Excitability was measured by 2 methods. In the first method, stimuli were delivered to the ischemic zone electrode by an automatic threshold following pacemaker (Fig. 1).[16,17] At constant voltage (usually 2 V), the pacemaker decreased the duration of the stimulus in 2 μs steps until failure to capture occurred. The latter was determined with a separate sensing electrode; if no ventricular response was registered, the pacemaker recorded the duration of the stimulus that produced capture immediately before the subthreshold stimulus. The next stimulus duration was increased by 20 μs and was placed just 60 ms after the subthreshold stimulus; thus, the pacing cycle length stayed uniform except for 1 cycle 60 ms longer than the rest occurring at least every 5 seconds. Measurement of diastolic excitability threshold in this fashion is accurate to 1.5 μs.[17]

In the second method, constant current stimuli were delivered to the ischemic zone electrode. This method was used to exclude the possibility that changes in tissue impedance influenced the experimental results. A pacemaker set at a basic cycle length of 370 ms drove a constant current source at initially 2 times diastolic threshold. The dial regulating the current source was gradually turned to a lower intensity until ventricular capture failed, determined by visual evaluation of a cathode ray oscilloscope recording the electrographic responses of each stimulus. When failure to capture occurred, the current was read off the dial and recorded by an assistant. The dial was then turned to a higher current intensity until capture occurred. This sequence was repeated every 15 seconds.

Electrographic recording: Bipolar electrograms were monitored constantly with pairs of Teflon-coated stainless steel wires (1 to 2 mm interelectrode distance) placed in the endocardium and epicardium of the ischemic zone ≤1 cm from the pacing electrode and in the mid-wall of the posterior left ventricle. These sites were verified at the end of the experiment. The signals were amplified, filtered between 1.2 and 500 Hz, displayed on a storage oscilloscope, and recorded simultaneously on a stripchart recorder at 400 mm/s. Measurements were performed on the recordings obtained just before the delivery of the subthreshold pacing stimulus. These measurements were performed only on electrograms from recording sites which maintained the same basic contour and activation sequence (compared with other electrograms) during coronary occlusions (Fig. 2), suggesting that activation of the muscle was similar with each occlusion. Electrographic duration was measured from the first to the last definable rapid deflection from the isoelectric line (Fig. 2). Amplitude was the vertical distance between the largest positive-going wave to the largest negative-going wave of the electrogram. Measurements performed in this manner on 2 sequential electrograms did not differ.

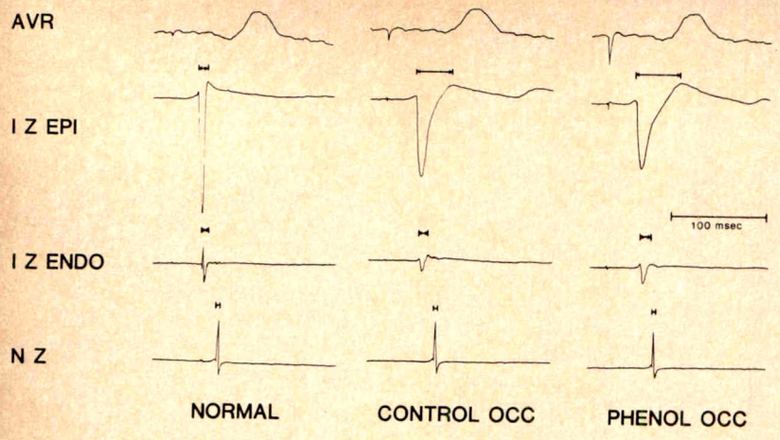

FIGURE 2. Left, "normal" indicates recordings before coronary occlusion. **Middle,** "control occlusion" indicates recordings during the sixth minute of occlusion showing a larger pacing spike in AVR (indicating a higher pacing threshold) and prolongation of electrogram duration (indicated by the distance between **vertical bars**) in ischemic zone epicardial and endocardial leads compared with the same leads before coronary occlusion and to the normal zone lead. Although not shown here, after reperfusion, all recordings return to normal. **Right,** "phenol occlusion" refers to recordings during the sixth minute of occlusion after phenol treatment. Note the still larger pacing spike and further prolongations of electrogram duration in IZ epicardial and IZ endocardial compared to control occlusion. AVR = surface electrographic lead; IZ EPI and IZ ENDO = ischemic zone epicardial and endocardial electrograms; NZ = normal zone electrogram; OCC = occlusion.

Microsphere blood flow measurements: Regional left ventricular blood flow was measured using microspheres of 7 to 10 μm diameter labeled with scandium-45, niobium-95, tin-113, ruthenium-103, and chromium-51. The spheres were suspended in dextran and vigorously agitated mechanically for 5 minutes. Blood was withdrawn from 2 large arteries at 2.06 ml/min, starting 1 minute before and continuing 3 minutes after injection. For each measurement, approximately 2×10^6 microspheres were injected over a 10-second period into a cannula placed in the left atrial appendage. Three to 4 g samples from normal zones were taken from the anterior base, posterior base, and posterior apex of the heart. These positions were chosen since they were sites in which recording electrodes were placed. Samples of similar mass from the center of the ischemic zone were taken from myocardium in which electrograms were recorded and in which pacing stimuli were administered. All samples were divided into endocardial, mid-wall, and epicardial thirds. They were weighed to the nearest milligram and placed in plastic tubes for counting in a well scintillation counter. The reference blood samples were counted similarly.

Myocardial blood flow was calculated as follows: Blood flow (in milliliters per minute × 100 g) = counts per gram of tissue × 100 × blood withdrawal rate (from reference arteries) ÷ total counts in the reference blood samples (averaged from femoral and brachial arteries). The calculations were performed for each sample with a computer. Since the endocardial, mid-wall, and epicardial blood flows changed similarly with each occlusion, the ischemic zone samples were pooled.

Sonomicrometer measurements: To evaluate the effect of sympathetic denervation on wall motion, sonomicrometer measurements of myocardial segment length in the ischemic region were studied.[18,19] A pair of 1.5 mm diameter 5 mHz piezoelectric crystals was implanted in the left ventricular myocardium in the center of the ischemic zone surrounding the pacing electrode. Analog signals were recorded simultaneously with electrograms and arterial pressure. End-diastolic segment length (EDL) was measured (in millimeters) at the onset of the endocardial electrogram (recorded from an adjacent electrode). End-systolic length (ESL) was measured at the dicrotic notch of a simultaneously recorded aortic pressure tracing.[18]

Protocols: Measurements of diastolic excitability threshold were obtained continuously. Electrogram recordings were made every minute after coronary occlusion up to 6 minutes. In preliminary experiments, it was noted that the first coronary occlusion of a series usually resulted in greater peak excitability threshold increases and greater maximal electrogram durations than subsequent coronary occlusions. Thereafter, serial occlusions were reproducible (see Group 1 data). Therefore, in this report (except for Figure 1), control data refer to the second occlusion.

Initially, animals were divided randomly into 2 groups. In the control Group I (n = 8), the third occlusion was performed without sympathetic denervation. In the phenol Group II (n = 9), 25 minutes before the third occlusion, animals underwent regional sympathetic denervation by application of a thin circle (3 cm diameter) of 88% phenol (carbolic acid) surrounding the ventricular epicardium of the area to be made ischemic. Such a procedure interrupts sympathetic innervation to the encircled epicardium and underlying endocardium.[20–22] In these groups blood flow was measured during each episode of ischemia 1 minute before release of the oc-

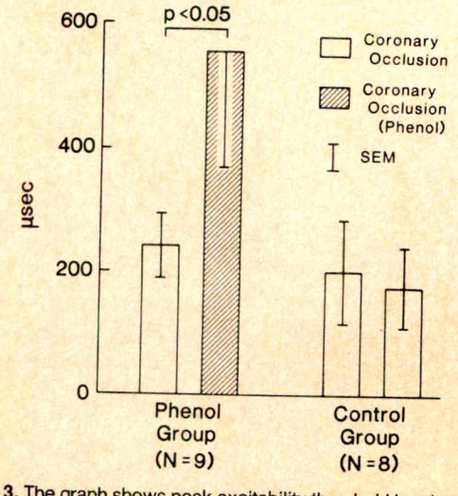

FIGURE 3. The graph shows peak excitability threshold in microseconds during sequential coronary occlusions in the phenol group (which had phenol applied to the epicardium surrounding the ischemic zone) and the control group (which had no intervention between occlusions). Note the further increase in peak excitability occurring only after the phenol application. SEM = standard error of the mean.

TABLE I Wall Motion Data (mm)

	Preocclusion	Occlusion	Intervention	Postintervention Preocclusion	Postintervention Occlusion
Group III (n = 6)					
EDL	10.9 ± 0.6	11.9 ± 0.6	None	10.9 ± 0.6	12.2 ± 0.6
ESL	10.8 ± 0.6	13.2 ± 0.7		11.0 ± 0.7	13.4 ± 0.8
Group IV (n = 9)					
EDL	9.3 ± 0.6	10.5 ± 0.6	Phenol	9.5 ± 0.8	10.6 ± 0.7
ESL	8.5 ± 0.6	11.0 ± 0.7		9.2 ± 0.8	11.2 ± 2.3

EDL = end-diastolic length of segments before and during ischemia; ESL = end-systolic length of segments before and during ischemia.

clusion and during at least one control period 25 minutes after the preceding occlusion.

To evaluate the possibility that changes in ischemic wall motion resulted from the the sympathetic interventions, we repeated the above protocols in separate experiments while recording segment length in the ischemic muscle from which electrophysiologic measurements were also recorded. Again, animals were assigned randomly to 2 groups. In Group III (n = 6), the third coronary occlusion was performed without sympathetic intervention. In Group IV (n = 9), phenol treatment was performed at least 25 minutes before occlusion 3.

Finally, a group of 3 dogs was studied employing constant-current stimulation to evaluate the possibility that changes in tissue impedance could account for the results. In 1 of these, reserpine (0.25 mg/kg) was given intraperitonally for 2 days before study to determine whether phenol application produced electrophysiologic effects separate from sympathetic denervation.

Effective refractory period testing and sympathetic nerve stimulation: To demonstrate whether phenol or ischemia alone produced regional sympathetic denervation, we measured the response of effective refractory period in various ventricular sites during electrical stimulation of sympathetic nerves at the end of each experiment as previously described.[22] After reperfusion after the final coronary artery occlusion, the central connections of both stellate ganglia were cut and prepared for stimulation. Endocardial and epicardial test sites in the anterior wall (from which electrogram changes were recorded during ischemia) and electrode sites from the posterior apex and anterior base (normal perfused zones) underwent refractory period testing. Testing was performed before and during continuous sympathetic nerve stimulation in each site.

Statistical methods: The data are expressed as mean ± standard error. Comparisons within the groups were performed by 2-way analysis of variance employing Duncan's multiple range test for comparisons.[23] Statistical significance was ascribed to p values <0.05.

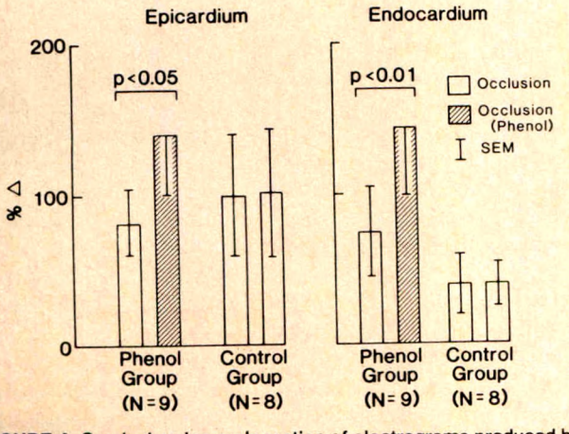

FIGURE 4. Graph showing prolongation of electrograms produced by ischemia expressed as percent change from before each occlusion in epicardium (**left**) and endocardium (**right**). The phenol group had phenol applied to the epicardium surrounding the ischemic zone between occlusion while the control group had no intervention between occlusion. Note that the electrographic duration was further prolonged by phenol in both epicardium and endocardium. SEM = standard error of the mean.

Results

Excitability data (Fig. 1 and 3): During coronary occlusion, the excitability threshold decreased in the first few minutes of occlusion and then gradually increased to a value which was maximal or peak immediately before reperfusion (Fig. 1). After reperfusion of the coronary artery, the excitability threshold returned to control levels. Peak excitability threshold significantly increased during coronary occlusion only in Group II after phenol (Fig. 3).

In 2 dogs with constant-current measurements, excitability peak threshold during ischemia increased from 44 to 200 μA and from 430 to 1200 μA after phenol application. In the animal pretreated with reserpine, there was no change in excitability threshold after phenol nor was any detectable norepinephrine found in the ventricular tissue (measured by a modification of the Anton and Sayer alumina-trihydroxyindole procedure[24]).

Electrographic data (Fig. 2 and 4): Before coronary occlusion, the electrographic duration averaged 11 ms and ranged from 7 to 15. Ischemic zone electrograms prolonged during each occlusion while normal zone electrograms did not change. The amount of prolongation in electrographic duration from the ischemic zone was progressive with each minute of coronary occlusion. However, there were no differences in electrogram duration comparing similar time after onset of coronary occlusion in Group I at all or in Group II until just before reperfusion. In the latter, there was a significant increase in electrogram duration from both ischemic epicardium (from 19 ± 3 to 25 ± 4 ms, p <0.025) and endocardium (from 20 ± 3 to 25 ± 4 ms, p <0.01) which occurred during the occlusion after phenol (Fig. 4).

Electrographic amplitude decreased with each coronary occlusion. However, no significant differences ($p > 0.25$) in electrographic amplitude were recorded in ischemic areas in either group.

Hemodynamic data (Fig. 5, Table I): In Groups I (control) and II (phenol), no significant aortic pressure differences occurred with coronary occlusion or between occlusions. In neither group were there significant differences ($p > 0.25$) in blood flow in normal (Group I, 80 ± 12 to 81 ± 5 ml/100 g/min; or Group II, 84 ± 15 to 73 ± 17 ml/100 g/min) or ischemic zones (Fig. 5) produced between occlusions. Blood flow returned toward normal levels on reperfusion.

The 2 groups reported in Table I yielded similar results in peak excitability threshold and electrogram duration as in corresponding Groups I and II. Just before reperfusion, when peak excitability threshold was highest, there were no significant differences in EDL or ESL ($p > 0.1$) when either no intervention or phenol was applied between occlusions (Groups III and IV).

Effective refractory period data: In dogs without phenol treatment, stimulation of the ansa subclavia shortened effective refractory period in 6 normal sites from 182 ± 25 to 163 ± 19 ms ($p < 0.01$) and in 8 previously ischemic sites from 198 ± 18 to 182 ± 14 ms ($p < 0.01$); the percent change in the former (9.6 ± 1.8) was not different ($p > 0.1$) from the latter (7.7 ± 1.6). By contrast, phenol-treated areas demonstrated no change in refractory period in endocardium (159 ± 7 versus 159 ± 7 ms, $p > 0.1$) or in epicardium (164 ± 6 versus 165 ± 6 ms, $p > 0.1$), while untreated sites in the anterior base (from 161 ± 11 to 150 ± 11 ms, $p < 0.01$) and in the posterior apex (from 164 ± 7 to 146 ± 6 ms, $p < 0.01$) shortened during sympathetic nerve stimulation. Thus, in these experiments phenol treatment but not serial coronary occlusion prevented refractory period responses to sympathetic nerve stimulation.

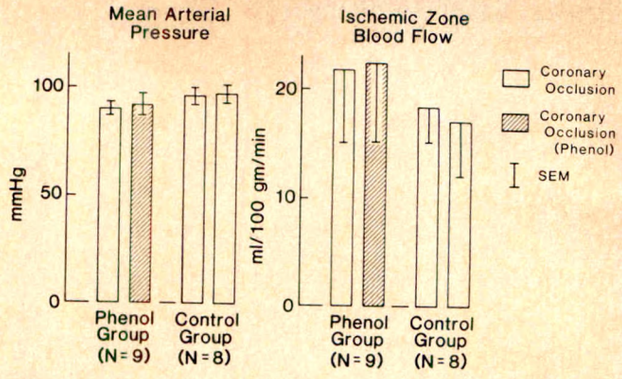

FIGURE 5. Graph showing mean arterial pressure (**left**) and absolute ischemic zone blood flow measured by radiolabeled microspheres (**right**). Sequential coronary occlusions were associated with no change in mean arterial pressures and ischemic zone blood flows in both the phenol and control groups.

Discussion

There are 2 new observations in this study. Acute sympathetic denervation when limited to ischemic myocardium increases peak excitability threshold and comcomitantly prolongs duration of electrograms in epicardium and endocardium. These electrophysiologic effects of regional denervation are not associated with changes in aortic pressure, ischemic wall motion, or ischemic zone blood flow, suggesting that they were due to the direct effects of withdrawal of sympathetic nerve influence in the ischemic zone.

Effects of regional sympathetic denervation: Previous studies have demonstrated that phenol application to the surface of the canine heart causes local denervation[20–22] by producing necrosis of epicardial sympathetic nerves which travel in the superficial 0.25 mm. The encircled tissue, being 2 to 3 cm away from the necrotizing effects of phenol, responds normally to cathecholamine[22] and after reserpine pretreatment shows no effect of phenol whatsoever. In the present study, we proved that the phenol treatment produced sympathetic denervation since it prevented refractory period responses to sympathetic nerve stimulation in the ischemic zone after reperfusion. In addition, we showed that previous transient ischemia alone does not impair refractory period responses to sympathetic nerve stimulation.

The acute application of phenol significantly increased peak excitability threshold compared with that produced by ischemia alone.[16] We considered several possibilities to explain these results. First, aortic pressure did not change with phenol denervation. Second, myocardial segment lengths in the ischemic zone were unchanged with phenol denervation. Third, ischemic zone blood flow did not change with phenol denervation. Taken together, these data suggest that the degree of ischemia present in the center of the regionally denervated zone was unchanged.

Therefore, we believe that elevation of peak excitability threshold by phenol denervation was due to withdrawal of direct effects of sympathetic neural influence on ischemic myocardium. A mechanism for this effect is suggested by previous in vitro studies. Acute ischemia produces depolarization of Purkinje fibers and ventricular muscle studied in vitro[25] and increased excitability threshold of subepicardial ventricular muscle studied in vivo.[26] Catecholamines may reduce the change in excitability threshold by minimizing the extent of cellular depolarization.[27] Our data may be an in vivo demonstration of the withdrawal of these electrophysiologic effects of sympathetic influences on depolarized and relatively inexcitable ischemic myocardial cells.

Because excitability is a major determinant of conduction velocity in Purkinje fibers,[28] we expected and found that electrographic duration increased along with peak excitability threshold when both measurements were performed in closely adjacent ischemic areas subjected to sympathetic denervation. These data appear compatible with effects of sympathetic influences on dV/dt and conduction velocity of depolarized Purkinje fibers in vitro.[29]

Our electrographic duration data appear contrary to that of Ruffy et al.[14] They showed that the epicardial electrographic duration shortened (toward normal) after stellate ganglionectomy. In other experiments not herein reported, we performed stellate ganglionectomy employing the methods of the present study. Similar to the present data, we found that stellate ganglionectomy increased excitability threshold but, in contrast, stellate ganglionectomy did not prolong ischemic zone electrograms as the regional denervation did. It is possible that phenol treatment may have affected ischemic zone blood flow differently than stellate ganglionectomy; however, data in chronically denervated animals studied by Barber et al[30] suggest that blood flow to ischemic zones is also unchanged with a global cardiac denervation. It is more likely that decreases in mean arterial pressure similar to those reported by Ruffy et al and a prolongation of ischemic zone segment length after stellate ganglionectomy could have resulted in decreased oxygen demand and a lessening of ischemic injury which may reverse the prolongation of ischemic zone electrogram.[31] Thus, we believe that the data of Ruffy et al reflect the electrophysiologic effects of both direct sympathetic influence on the ischemic zone and indirect effects of global hemodynamic changes which may decrease the degree of ischemia. Our results may be interpreted as reflecting electrophysiologic changes resulting from regional denervation alone.

Consideration of the model: In assessing the results of this study, several points should be emphasized.

First, all experimental variables were measured during constant pacing of the ischemic area since continuous excitability threshold was evaluated. Dyssynergy was therefore produced,[32] which may have influenced the results. For example, regional sympathetic denervation with phenol may not have produced further ischemic segment lengthening because of this dyssynergy. In addition, it is possible that phenol, by decreasing sympathetic influences to the ischemic tissue, might decrease the size of the ischemic zone. Our data do not allow us to judge the effect of phenol on ischemic zone size; however, the fact that blood flow to and wall motion of the tissue where electrical testing was performed did not change suggests that hemodynamic factors were an unlikely explanation for the electrophysiologic results.

Second, the present studies were performed in anesthetized open-chest dogs, which are likely to be under high baseline sympathetic influence. However, increased sympathetic influences are commonly found in patients with arrhythmias in acute myocardial infarction.[33] Therefore, the present observation may be relevant to the properties of ischemic myocardium responsible for arrhythmias.

A final limitation of the present study concerns the fact that only short-term occlusion of ≤6 minutes in duration were studied. It is possible that different results might pertain at a later time in the course of acute coronary occlusion. However, this early period after occlusion is a time at which a greater propensity to the development of spontaneous ventricular arrhythmias occurs[34]; therefore, our attention to this time frame may be important.

Possible significance for development of arrhythmias: Previous studies have suggested that *acute* interruption of sympathetic neural influence prevents ventricular fibrillation in dogs undergoing coronary artery occlusion.[8,9,11] These results have been challenged by Ebert et al,[10] who maintained that chronic denervation with depletion of catecholamine stores is necessary to produce protection from arrhythmias. The results of the present study and that of Ruffy et al[14] suggest electrophysiologic mechanisms which could prevent ventricular fibrillation, since acute sympathetic denervation can influence excitability and conduction in ischemic myocardium during the first 6 minutes of coronary occlusion. We speculate that sympathetic denervation might further increase excitability threshold or render certain areas inexcitable in the ischemic zone and thus eliminate potential pathways for arrhythmogenesis. Other mechanisms produced by the multiple effects of stellate ganglionectomy, such as decreased dispersion of refractoriness[35] or decreased degree of ischemia, may also be operative.

Transvenous Ablation of the Atrioventricular Conduction System in Dogs: Electrophysiologic and Histologic Observations

GUST H. BARDY, MD, RAYMOND E. IDEKER, MD, PhD, JACK KASELL, SETH J. WORLEY, MD, WILLIAM M. SMITH, PhD, LAWRENCE D. GERMAN, MD, and JOHN J. GALLAGHER, MD

The correlation of histologic and electrophysiologic findings in dogs undergoing transvenous ablation of atrioventricular (AV) conduction has not been described. The creation of complete AV block in 10 dogs was attempted by delivering a direct-current shock transvenously through a standard tripolar electrode catheter. The catheter was positioned to record the largest unipolar atrial and His bundle electrograms. A 280 J shock was delivered to the recording electrode by a standard cardioversion unit. After 1 shock, all dogs were in complete AV block refractory to isoproterenol (1 to 4 μg/min) and atropine (0.5 to 2.0 mg). Four weeks later, 5 dogs remained in complete AV block, 1 had first-degree block, and 4 had resumed normal AV conduction. Each dog with complete heart block had histologic evidence of severe damage to the AV node, His bundle, or both. On gross examination, these dogs were found to have discrete scars at the base of the septal leaflet of the tricuspid valve. Of the 5 dogs that had resumption of AV conduction, only 1 had histologic evidence of significant damage to the AV conduction system. That animal manifested a marked increase in the P-R interval (100 to 210 ms). Although temporary heart block occurred in each animal, chronic interruption of AV conduction was more difficult. Catheter location, atrial and His bundle electrogram relations, and the electrode used for delivery of energy were factors determining the effectiveness of this technique.

Intentional interruption of normal atrioventricular (AV) conduction by destruction of the AV node is possible with a variety of techniques in the animal laboratory.[1–9] Similarly, there are several methods for therapeutic ablation of the AV conduction system in patients with medically refractory supraventricular tachycardias.[10–22] Until recently, methods for interruption of AV conduction in man and in laboratory animals have required an open-chest procedure. Several current studies suggest that closed-chest ablation of atrioventricular conduction is feasible and effective with a variety of techniques.[23–31] One method of particular interest is that performed by delivery of a direct-current shock through a standard His bundle catheter.[30] The equipment required is that found in any laboratory capable of recording His bundle electrograms and providing direct-current cardioversion. The effective technique can be readily mastered and avoids the risks attendant to thoracotomy. Although this technique is easily applied and appears relatively safe, the degree of tissue destruction resulting from this method is unknown. This study was therefore undertaken to correlate the electrophysiologic consequences of such a direct-current shock with histologic changes in the AV conduction system.

Methods

Ten dogs weighing 15 to 20 kg were studied. After induction of anesthesia with 30 mg/kg of pentobarbitol, each dog was intubated and ventilated. Using sterile technique, a standard 6 Fr tripolar intracardiac recording catheter (United States Catheter Instrument) with 1 cm interelectrode distances was inserted through the femoral vein and positioned in the region

of the His bundle. Two unipolar electrograms (1 from the distal pole and 1 from the middle pole) were filtered to pass 5 to 1,000 Hz and were displayed by way of a switch box (Fig. 1) on a Hewlett-Packard oscilloscope and chart recorder. A bipolar signal, recorded from the distal and middle poles of the catheter, was filtered to pass 50 to 1,000 Hz and was displayed with the unipolar signals. The proximal pole was not utilized. A back paddle was positioned between the spine and left scapula and was connected to the anodal output (sink) of the cardioversion unit. The switch box (Fig. 1) allowed the catheter electrodes to be utilized first for recording purposes, and subsequently, as a vehicle for current delivery. When the electrode showing the largest unipolar His deflection was identified, the defibrillator was charged. With a large, stable, unipolar His deflection still evident, the defibrillator was discharged synchronously with the QRS complex by way of the switch box through the electrode recording the largest His electrogram. Each dog received a single direct-current shock (280 J delivered, not stored) resulting in complete heart block. After induction of complete heart block, atropine (0.5 to 2.0 mg) and isoproterenol (1 to 4 μg/min) were used in an attempt to improve atrioventricular conduction. When heart block proved refractory to pharmacologic manipulation, the animals were allowed to recover from anesthesia.

All dogs were monitored for a 2-hour interval immediately after the shock. This was repeated 1 week and 4 weeks later to observe the occurrence of spontaneous arrhythmias. After 4 weeks, intracardiac recordings were obtained (Fig. 2) in addition to surface electrograms. During each observation period any sign of tricuspid insufficiency was looked for (for example, holosystolic murmur, neck vein distention, or ascites). Four weeks after shock, the animals were killed for gross and microscopic examination. Each heart was examined for a flail or torn tricuspid leaflet, right atrial dilatation, or right ventricular dilatation—findings consistent with tricuspid insufficiency. (Three representative gross specimens are illustrated in Figure 3.) After visual inspection for structural damage, the entire section of the AV node and His bundle were embedded as 1 block. This included the lower atrial septum and the upper ventricular septum. The block was sectioned serially, perpendicular to the interventricular septum, and slides were made at each millimeter. An average of 25 sections was obtained from each dog. Each section was stained with hematoxylin and eosin and was studied for damage to the AV conduction system and adjacent myocardium. A von Kossa stain was used to identify microscopic calcium deposits. The amount of damage to the approaches to the AV node, the AV node proper, the penetrating portion of the bundle of His, the branching portion of the bundle of His, and the proximal right bundle branch was determined from the histologic sections. The amount of destruction of each of these regions was estimated from the amount of tissue necrosis and from the amount of connective tissue deposited.

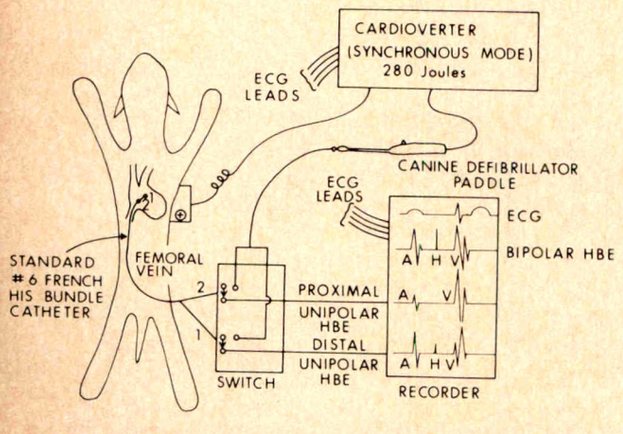

FIGURE 1. Schema for transvenous ablation of the atrioventricular conduction system using a standard cardioversion unit and recording catheter. After a large, stable His bundle deflection is identified, a direct-current discharge (280 J) is delivered by way of a switch box to the recording electrode. A back paddle serves as a sink, completing the circuit. ECG = electrocardiogram; HBE = His bundle electrogram.

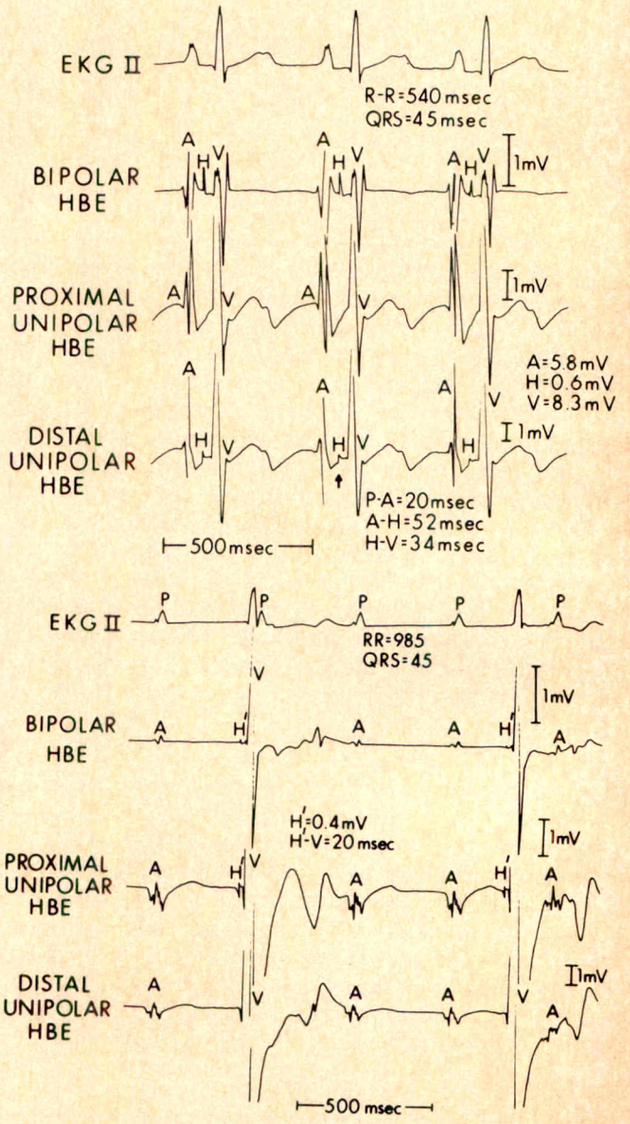

FIGURE 2. Intracardiac recordings immediately before (**top**) and 4 weeks after (**bottom**) atrioventricular interruption. These electrograms were obtained from the same animal whose gross specimen is shown in Figure 3A. The **top panel** demonstrates sinus rhythm with the His deflection (H) identified on the bipolar and distal unipolar electrograms. Four weeks after the shock, complete heart block is evident in the **bottom panel.** The earliest recorded deflection from specialized conduction tissue (H′) is now of smaller amplitude (0.3 mV) than the His deflection seen before ablation (0.5 mV). This suggests the ventricular escape rhythm arises in the distal segment of the His bundle or proximal right bundle branch. Note that the QRS morphology is unchanged after the shock. ECG = electrocardiogram; HBE = His bundle electrogram.

Damage was estimated using a scale of 0 to 3+ with 0 corresponding to no damage, 1+ representing destruction of less than one third of the structure, 2+ representing destruction of one third to two thirds of the structure, and 3+ representing destruction of more than two thirds of the structure (Tables I and II). The volume of damaged ventricular myocardium was estimated by projecting serial histologic sections onto a display screen from a modified slide projector and then planimetering the area of damaged ventricular myocardium for each section.

Results

Immediately after a single direct-current 280 J shock, all 10 dogs had complete heart block refractory to isoproterenol and atropine. Recovery from the procedure was without incident. Upon initial follow-up evaluation 1 week after shock, only 5 dogs remained in complete heart block while 5 resumed conduction through the AV node-His bundle. Those 5 dogs that were in complete heart block 1 week after the shock remained so for the 4-week observation period. No dog had spontaneous arrhythmias, sudden death, or signs of hemodynamic compromise.

Of the dogs with complete heart block 4 weeks after the shock, 4 had an escape rhythm QRS duration that was unchanged from the preshock QRS duration (Table III). Only 1 dog had a prolonged QRS duration after shock (from 43 to 65 ms). This was because of damage to the right bundle branch. Before heart block, the interval from the His bundle deflection to the onset of ventricular depolarization (H-V) ranged from 28 to 44 ms in the 5 dogs. After shock, the interval from the onset of the earliest recorded deflection from specialized conduction tissue to the onset of ventricular depolarization (H′-V) was less than the respective preshock H-V in all dogs in which H′ could be found (Table III). No His deflections were observed to follow the atrial electrogram.

Histologic examination of the dogs with chronic complete heart block demonstrated that each dog had severe damage to the approach to the AV node, to the

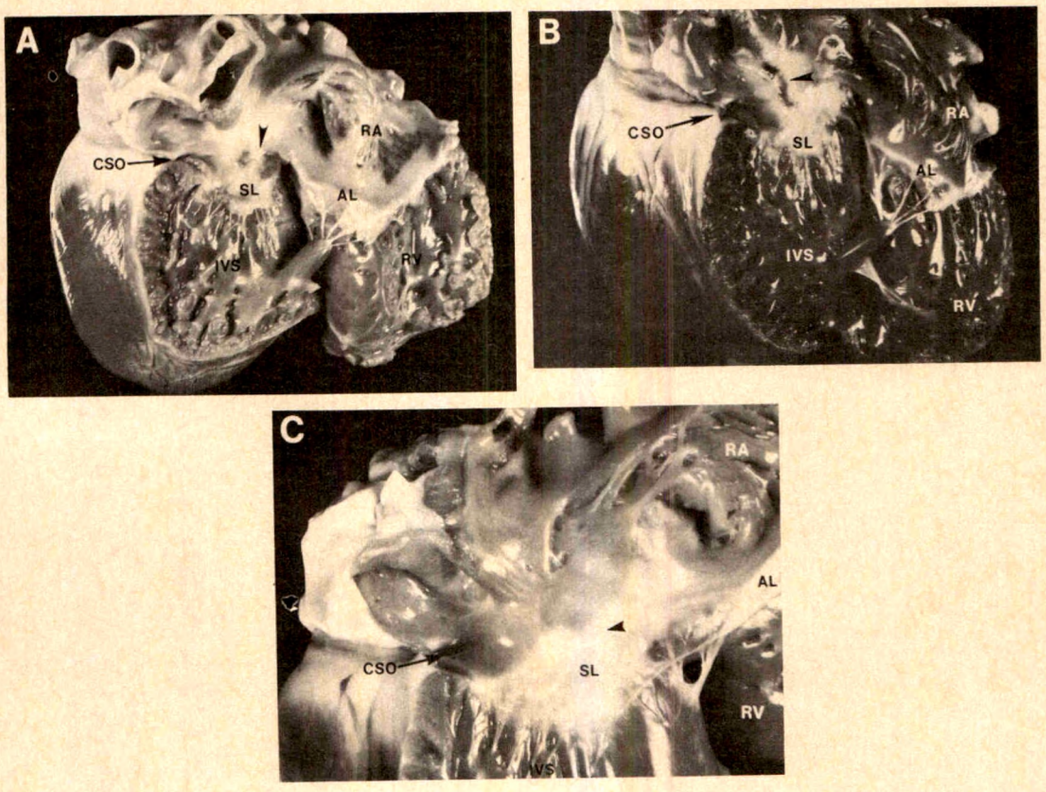

FIGURE 3. Gross specimens demonstrating location and character of injury in 3 dogs. In all 3 specimens the anterior free wall of the right ventricle (RV) has been dissected back to expose the interventricular septum (IVS) and the septal leaflet of the tricuspid valve (SL). The coronary sinus orifice (CSO) is a slitlike structure in these views. The anterior leaflet (AL) of the tricuspid valve is on the inner surface of the free right ventricular wall which is partially dissected back. The **arrowhead** designates the injured tissue. Note the absence of septal perforation or flail tricuspid leaflets in all 3 hearts. **A,** the effect of the shock resulting in the largest amount of injury to the tricuspid valve. This shock was delivered to the middle pole of the His bundle catheter and is just "distal" to the ideal location, which would be centered at the base of the septal leaflet of the tricuspid valve. This shock involved more of the interventricular septum than did shocks delivered through more proximally situated catheters and therefore resulted in right bundle branch block. In addition, the base of the septal leaflet of the tricuspid valve is fibrosed and partially adherent to the interventricular septum. Clinical tricuspid insufficiency was not observed however. **B,** demonstration of a lesion delivered through the distal catheter electrode just superior to the base of the septal leaflet of the tricuspid valve. This was the largest lesion seen after direct-current shock with the majority of injury confined to atrial tissue. Little ventricular tissue was involved. This shock damaged only the proximal atrioventricular conduction system resulting in a narrow escape rhythm. **C,** a well-placed shock delivered through the distal electrode. This lesion is less well seen grossly than the other 2, but in general is more characteristic. The pale white scar in this specimen is not well differentiated from normal tissue. Nevertheless, this adequately destroyed the approaches to the AV node, the AV node, and proximal penetrating bundle resulting in a narrow escape rhythm. This lesion actually resulted in the greatest amount of ventricular damage. The histologic findings from this specimen are shown in Figure 4.

TABLE I Heart Rhythm and Histologic Findings 4 Weeks After Direct-Current Shock

Dog	Rhythm	Tissue Injury (0 to 3+)				
		AV Node Approach	AV Node	Penetrating His	Branching His	Right Bundle

CHB = complete heart block.

TABLE II Electrocardiographic Changes Before and After Shock in Dogs With Resumption of AV Conduction

Dog	QRS Duration (ms)		P-R Interval (ms)		Damage to AV Conduction System (0–3+)
	Before	After	Before	After	
1	41	40	107	135	1+
2	47	47	82	155	0
3	41	75 (RBBB)	100	130	1+
4	48	79 (RBBB)	100	210	3+
5	60	62	72	73	0

AV = atrioventricular; RBBB = right bundle branch block.

TABLE III Correlation of Conduction System Damage With Changes in the QRS Duration and H-V Interval in Dogs With Chronic Complete Heart Block

Dog	QRS Duration (ms)		H-V Before (ms)	H′-V After (ms)	Regions With Severe Damage to AV Conduction System
	Before	After			
1	45	45	34	20	Penetrating His bundle
2	46	48	44	39	AV node approach and AV node
3	46	42	31	26	AV node approach
4	43	65 (RBBB)	30	18	AV node approach, AV node, branching His bundle and RBB
5	42	44	28	...	Branching His bundle

AV = atrioventricular; H-V = His-ventricular interval; H′-V = earliest specialized conduction tissue-ventricular interval; RBB = right bundle branch; RBBB = right bundle branch block.

AV node, to the penetrating His bundle, to the branching His bundle or to some combination of these (Table I). One dog with QRS prolongation and right bundle branch block after shock (dog 4, Tables I and III) had severe damage to the proximal right bundle branch as well as to the AV node and His bundle. In all dogs with complete heart block, areas of injury were characterized by dense, fibrous tissue. In some injured areas, calcium deposits were surrounded by granulomatous inflammation with giant cell formation. One dog (dog 2, Tables I and III) had vasculitis of the AV nodal artery in addition to conduction tissue injury.

Although each dog with chronic complete heart block had severe damage to some segment of the AV conduction tissue, none had perforation of the interatrial or interventricular septum. In addition, there was no thinning of the interventricular septum. All of the dogs with chronic complete heart block had a mild fibrous reaction at the base of the septal tricuspid leaflet at the point where it originates in the lower atrium at the tricuspid anulus. One dog (Fig. 3C) had an inflammatory reaction between the basal portion of the tricuspid septal leaflet and the septal right ventricular endocardium. Histologic evaluation of the AV conduction system from this dog is illustrated in Figure 4. Sections through the upper AV node, lower AV node, and penetrating portion of the His bundle are shown. This particular animal had the largest degree of ventricular damage despite a rather unimpressive appearance on gross examination.

When the mass of damaged ventricular myocardium was estimated by planimetry of serial sections, no dog proved to have ventricular tissue loss exceeding 65 mm^3 or 0.068 g. This compared favorably with ventricular

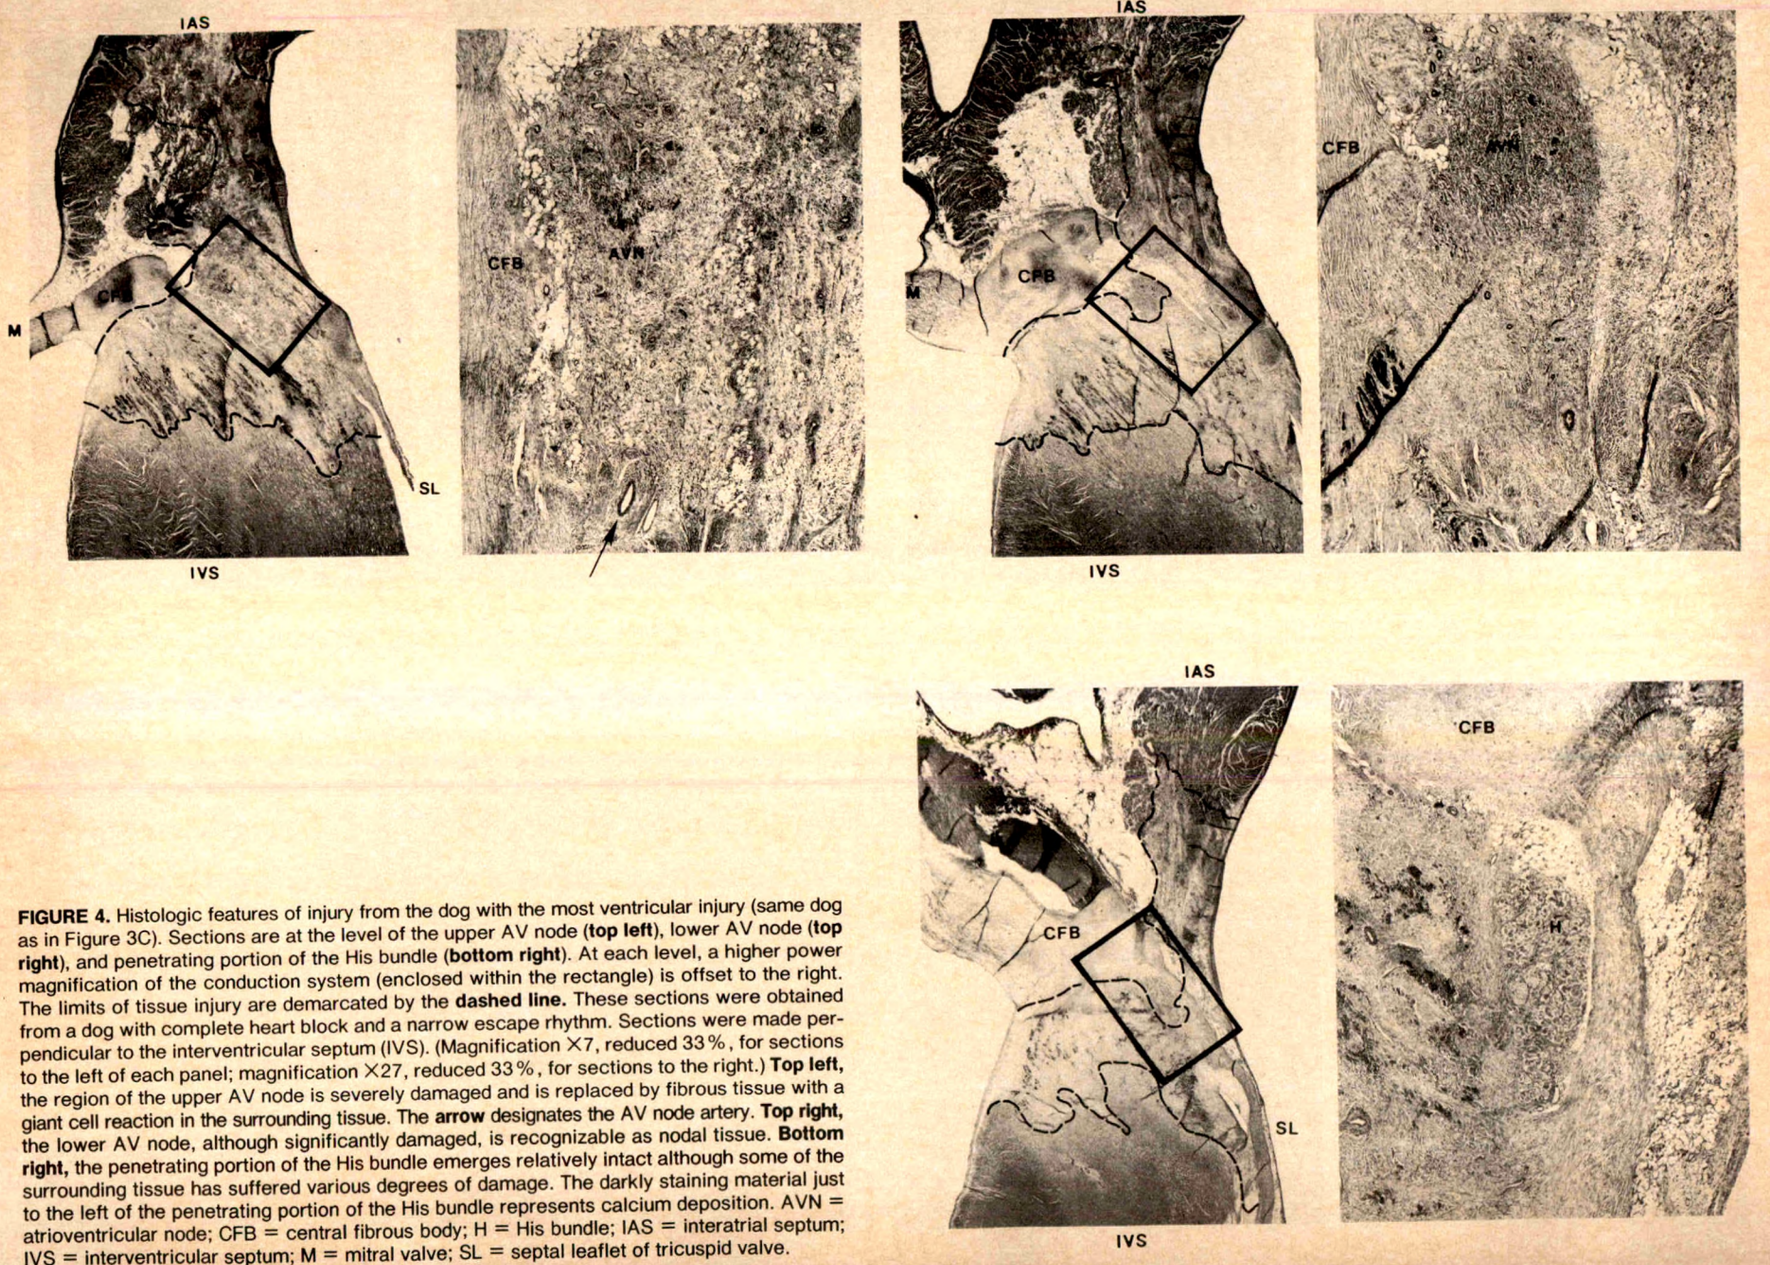

FIGURE 4. Histologic features of injury from the dog with the most ventricular injury (same dog as in Figure 3C). Sections are at the level of the upper AV node (**top left**), lower AV node (**top right**), and penetrating portion of the His bundle (**bottom right**). At each level, a higher power magnification of the conduction system (enclosed within the rectangle) is offset to the right. The limits of tissue injury are demarcated by the **dashed line.** These sections were obtained from a dog with complete heart block and a narrow escape rhythm. Sections were made perpendicular to the interventricular septum (IVS). (Magnification ×7, reduced 33%, for sections to the left of each panel; magnification ×27, reduced 33%, for sections to the right.) **Top left,** the region of the upper AV node is severely damaged and is replaced by fibrous tissue with a giant cell reaction in the surrounding tissue. The **arrow** designates the AV node artery. **Top right,** the lower AV node, although significantly damaged, is recognizable as nodal tissue. **Bottom right,** the penetrating portion of the His bundle emerges relatively intact although some of the surrounding tissue has suffered various degrees of damage. The darkly staining material just to the left of the penetrating portion of the His bundle represents calcium deposition. AVN = atrioventricular node; CFB = central fibrous body; H = His bundle; IAS = interatrial septum; IVS = interventricular septum; M = mitral valve; SL = septal leaflet of tricuspid valve.

tissue damaged by cryoablation of the AV conduction tissue, which can be greater than 2,000 mm^3 or 2.1 g for a lesion with a 25 mm diameter on the ventricular endocardial surface extending 6 mm into the myocardium.[32,33]

Five dogs that initially had complete heart block resumed AV conduction, probably after resolution of edema. Return of AV conduction in these 5 animals occurred sometime before the first postshock electrocardiogram (1 week later). In these 5 animals, AV conduction remained intact through the fourth week of observation. Gross and histologic examination revealed that only 1 of these dogs had evidence of significant damage to the approaches to the AV node, to the AV node, to the penetrating His bundle, or to the branching His bundle. The dog that did have severe damage to the approaches to the AV node and to the AV node (dog 4, Table II) had marked prolongation of the P-R interval (from 100 to 210 ms) as well as the A-H (from 66 to 130 ms) and the H-V (from 34 to 53 ms) intervals. In addition, this dog had prolongation of the QRS duration from 48 ms before shock to 79 ms after shock, with the QRS demonstrating right bundle branch block morphology as a result of severe damage to the proximal right bundle branch. Of the remaining 4 dogs that resumed AV conduction, 1 had mild damage to the branching His (dog 1, Table II), 1 had mild damage to the branching His and severe damage to the right bundle branch (dog 3, Table II), and 2 had no histologic evidence of injury to the AV conduction system whatsoever (dogs 2 and 5, Table II). Even though these 4 dogs had minimal damage to the AV conduction system, only 1 (dog 5, Table II) had no change in the P-R interval after compared with before shock. This dog was 1 of 2 that had no evidence of conduction system damage on histologic examination. The other dog (dog 2, Table II) did have prolongation of the P-R interval from 82 ms before shock to 155 ms after shock. One dog (dog 3, Table II) had right bundle branch block as a result of a shock applied too distal to the AV conduction system, injuring the right bundle branch with only mild damage to the His bundle.

Six animals received the shock through the distal electrode and 4 had the shock delivered through the middle electrode. Severe damage to the approach to the AV node, penetrating His bundle, or branching His bundle occurred with shocks delivered through the distal electrode in 5 dogs and through the proximal electrode in 1. The ratio of the atrial electrogram amplitude to the His deflection amplitude for those dogs incurring severe AV conduction system injury ranged from 4 to 10 (mean 7.6 ± 2.0). The ratio of the atrial electrogram amplitude to the His deflection amplitude in those dogs without severe conduction system injury was <4 or >10 in all but 1 animal.

Discussion

Interruption of AV conduction for refractory supraventricular tachycardia has been performed with a variety of methods.[10–22] Of these methods, cryoablation has probably offered the best control over damage to the AV node.[9,21,22] It is effective and preserves collagen fibers while leaving a well-circumscribed fibrous lesion.[9,21,22,32,33] Unfortunately, a median sternotomy is necessary for its application.

Closed-chest induction of complete heart block, on the other hand, has the obvious advantage over cryoablation and several other methods used for interruption of AV conduction because thoracotomy is not necessary. Percutaneous transvenous ablation of AV conduction as described in this report is applicable with relative ease, using a standard cardioversion unit and a standard intracardiac recording catheter. Other methods have been described for closed-chest interruption of AV conduction. These have required specially designed instruments and may yield less than optimal results. The closed-chest technique for ablation of AV conduction proposed by Beazell[26,27] involves electrocautery through a sheathed transseptal needle positioned fluoroscopically in the interatrial septum in the region of the AV node. Although successful in the short-term preparation, effective long-term interruption of AV conduction was not shown. Furthermore, 3 dogs had massive hemorrhage, perforation of the heart, or both. Gonzalez et al[29] have reported another technique requiring a specially modified quadripolar catheter. In their study, 5 of 10 dogs had complete heart block with a single 35 J shock. Four others received as many as 4 shocks to create complete heart block. In 1 dog, ventricular fibrillation developed during the shock. This method generated broad QRS complexes after shock in all animals studied, possibly reflecting characteristics of the catheter or the technique. The inability to localize a His deflection after shock may indicate a distally applied shock. Nevertheless, the escape rhythms in these animals were apparently satisfactory. Detailed histologic studies to determine whether broad QRS escape rhythms were a result of large tissue damage or of distally applied shocks were not described. These results were similar in patients who had larger energies (500 J) delivered with the same technique.[31]

Our work as well as others' suggest that the location and extent of tissue damage with the transvenous technique is probably very protocol-dependent and may prove to be more sensitively related to 1 factor over another. The findings in this study suggest that the success of our technique is dependent upon several factors. Of prime importance is catheter position. If the catheter is distal to the His bundle, right bundle branch damage is possible. Furthermore, heart block from a lesion created in a relatively distal segment of the His-Purkinje system may have a poor escape rhythm. On the other hand, a too proximal discharge may miss the AV conduction system altogether. Therefore, in addition to fluoroscopic guidance, one can properly position the catheter by observing the electrogram characteristics. Specifically, locating a relatively large atrial deflection with respect to the His deflection indicates good catheter position. In dogs, an atrial deflection-to-His deflection ratio of 4 to 10 appears to be a useful guide for proper catheter positioning over the proximal AV conduction system. A second consideration for effective energy delivery is catheter contact with the endocardial surface. The topography of the endocardial surface

overlying the AV node and His bundle is such that a catheter can firmly contact the endocardium of this region only over a small area. Considering the anatomy, the distal electrode of the catheter is more likely to securely contact the endocardium than a more proximal electrode would be. In those dogs with no damage or minimal damage to the AV conduction system, catheter contact with the endocardium may have been less than optimal, allowing much of the delivered energy to be dissipated in the blood. This may explain, in part, the greater effectiveness of using the distal electrode than the proximal one. Another factor that may be pertinent to tissue damage is current density or current flux. Current flow from the cylindrical, middle electrode with both ends adjacent to insulation differs from current passing from the cylindrical, distal electrode with a rounded free end.[34] Under similar conditions, current flux is higher from the rounded free end of a distal electrode. This theoretical consideration may further explain why shocks from distal electrodes tended to be more effective. Finally, another factor possibly related to effective ablation of the AV conduction system is the characteristic of the direct-current pulse. Since these experiments began, variability has been shown to occur in current flow, voltage, and resistance over the time during which the shock is delivered. These are dependent upon circuit characteristics and energy delivered as well as characteristics of the electrode-tissue interface. With further study, particulars of the direct-current pulse may prove important for effective ablation of AV conduction.

The anatomic findings in dogs with chronic complete heart block after application of direct-current shock suggest that tissue destruction is not extensive. The lack of atrial or ventricular septal perforation reflects the smallness of the injury (Fig. 3 and 4). Typical cardiac mass for a 20 kg dog is approximately 200 g. The fact that no dog had a ventricular volume of injury >65 mm^3 or a mass >0.068 g (<1% of myocardial mass) emphasizes how little ventricular tissue was affected. Qualitative changes, however, were significant and resembled those observed during transthoracic and directly applied paddle countershock.[35,36] Dahl et al,[35] in an experiment designed to evaluate optimal paddle size and time intervals between transthoracic discharges, found that transthoracic direct-current countershock could result in necrosis of myocardial fibers. Furthermore, in nonnecrotic myocardial fibers that retained cross striations, calcium deposition was frequent and was shown by electron microscopy to be deposited in the mitochondria. A mononuclear cell reaction was also present. Similar findings were observed by Doherty et al[36] who studied the effects of direct-current countershock delivered by paddle electrodes applied directly to the heart. Their study demonstrated increased technetium 99m-pyrophosphate uptake with repetitive shocks administered at short-time intervals compared with the same shocks delivered over longer periods. These findings were presumably a consequence of cumulative thermogenic injury, because tissue injury could be minimized by increasing the time between shocks. The cellular damage consisted of granulation of cytoplasm, nuclear pyknosis, and myocyte contraction bands. Tissue damage extended into the deeper layers with higher energy levels and with similar electrode size. The greater the shock, the more likely the tissue would develop gross patches of calcification. As demonstrated by Dahl, Doherty, and ourselves, the principle histologic changes produced by direct-current shocks are myocyte degeneration, calcium deposition, and mononuclear infiltrates. The additional finding of giant cell formation in our study probably reflects a late tissue response to calcium deposits.

The use of transvenous direct-current shock through a standard intracardiac recording catheter proved to be a safe technique for closed-chest interruption of the AV conduction tissue. Complete heart block could be consistently induced with a single shock in the acute preparation and with moderate success in the chronic situation. Successful transvenous ablation of the AV conduction system appeared to be facilitated by proximal catheter position, as judged by the relation of the atrial and His electrograms, and by use of the distal electrode. Alterations in cardiac conduction appeared to be a direct consequence of the location and degree of injury produced by the shock. Even with the largest lesion created by this technique, a small fraction of ventricular myocardium was destroyed with minimal damage to the base of the tricuspid septal leaflet and with no evidence of cardiac perforation. Several other factors attested to the technique's safety. No dog had arrhythmia during any of the postshock observation periods and no dog had sudden cardiac death. Furthermore, the integrity of the tricuspid valve remained intact as witnessed by the absence of clinical findings of tricuspid regurgitation and by the absence of an enlarged right heart at postmortem examination. This technique, therefore, promises to facilitate safe, effective induction of AV block experimentally and clinically.

Premature Ventricular Contraction Or Ventricular Extrasystole?

LEO SCHAMROTH, MD, DSc

Electrocardiology is an exact scientific discipline. Yet it is, on occasion, punctuated with terms that are vague and nondefinitive. One such term is *premature ventricular contraction*, which is a nonspecific degeneration from the original term *ventricular extrasystole.* A scientific term or definition should ideally be sufficiently precise so as to be applicable to 1 circumstance only. *Premature ventricular contraction*, however, is nonspecific. The only meaning conveyed is: a ventricular contraction that is premature. Nothing else is embodied in the term. Premature ventricular beat and premature ventricular depolarization are equally vague. There are indeed many mechanisms that result in premature ventricular contractions or beats, and to which the term could be readily applied.

All of the following result in premature ventricular contractions: (1) a ventricular extrasystole (see later); (2) a manifest ventricular parasystolic discharge; (3) a ventricular capture beat; (4) a reciprocal beat of ventricular or atrioventricular junctional origin; (5) a conducted atrial or atrioventricular junctional extrasystole; and (6) a relatively early beat during atrial fibrillation. In this context, Scherf (1953)[1] specifically comments: "As far as extrasystoles in auricular fibrillation are concerned the term 'premature beats' would be altogether unacceptable."

The question may also be posed as to whether a primary electrical event should be described by the hemodynamic term *contraction* which, when it occurs, is the secondary result of the primary electrical event. Furthermore, concealed ventricular extrasystoles have been described which do not give rise to contractions at all.[2,3] It would be patently absurd to refer to these as concealed premature ventricular contractions. Confusion becomes more confounded by the term *premature junctional contraction.*[4] If *premature ventricular contraction* refers to a ventricular contraction resulting from an impulse arising in the ventricles, and *premature atrial contraction* refers to an atrial contraction resulting from an impulse arising in the atria, does a *premature junctional contraction* refer to a junctional contraction resulting from an impulse arising in the junction? Does the atrioventricular junction itself contract, and in isolation? Would a concealed atrioventricular junctional extrasystole[5,6] (due to concomitant retrograde and anterograde atrioventricular block) which does not result in a contraction anywhere in the heart still be referred to as a *premature junctional contraction?*

The term *extrasystole* was first used by Engelmann in 1896,[7] in his studies of artificial electrical stimuli applied to the heart. The use of this term was continued by other authorities of the day: Pan (1903),[8] MacKenzie (1907),[9] Rihl (1912),[10] Wenckebach (1914),[11] and Lewis (1920).[12] Very early on, the extrasystole came to be associated with a very specific property, namely, a fixed coupling of the premature beat to the preceding (usually) sinus beat: a property, moreover, that is not possessed by any of the other causes of premature ventricular contraction.

Thus, Lewis (1920),[12] for example, states: ". . . isolated extrasystoles and the first beat of a paroxysm *have the same degree of prematurity"* (italics mine). And Scherf and Schott (1953)[1] clearly state that the extrasystole is ". . . accurately coupled to the preceding beat." This is the essential feature of the ventricular extrasystole,[11–14] which should, in the context of modern electrocardiography, be defined as an impulse that arises prematurely in an ectopic ventricular focus and is fixedly coupled to the preceding beat. The term *impulse* is used for the extrasystole, not *beat* or *contraction*, because it is primarily an electrical event; *beat* is justified in the context of *preceding beat* because a complete ventricular activation resulting in a beat is necessary to precipitate or force the ensuing extrasystole. Such a definition is specific and could only be applied to a ventricular extrasystole; it excludes all other causes of premature ventricular contraction.

In this context, the Criteria Committee of the New York Heart Association[4] applies the term *premature ventricular contractions* not only to beats with fixed coupling, but also to beats with variable coupling, namely, parasystolic beats. This interchangeable application to different electrocardiographic mechanisms further emphasizes how ambiguous and vague the term really is.

From the Department of Medicine, Baragwanath Hospital, and the University of the Witwatersrand, Johannesburg, South Africa. Manuscript received November 2, 1982; revised manuscript received and accepted December 9, 1982.

Nevertheless, the *systole* part of *extrasystole* could also be semantically challenged, because it derives from the Greek meaning "to draw together": in other words, a contraction. Yet, the term has increasingly come to have an electrical connotation. Butterworth's Medical Dictionary (1978),[15] for example, refers to *electrical systole:* "The period during which there is electrical activity relating to the stimulation and recovery of the myocardium." The concept of *electrical systole* is also becoming embodied in modern texts of electrocardiology.[16,17]

The prefix *extra* of the *extrasystole* has long been a source of unnecessary confusion. It was, for example, defined by Katz and Pick (1956)[18] as an additional beat, and hence would only apply to an interpolated ventricular extrasystole. This was neither justified by the preceding use of the word, nor supported by the succeeding voluminous electrocardiographic literature. The prefix *extra* in the context of extrasystole does not mean addition, but rather outside the normal, as in extracurricular or extraordinary.

Thus, historically, and by long-established application to a specific electrocardiographic mechanism, *ventricular extrasystole* has come to have 3 well-defined properties: (1) ectopic ventricular origin of an electrical impulse; (2) prematurity of the electrical impulse; and (3) fixed coupling of this electrical impulse to the preceding event.

The term *ventricular extrasystole* thus defines a primary electrical event, and, although open to semantic challenge (the purist would have to coin an entirely new word), is far more satisfactory than *premature ventricular contraction*, which is nonspecific, reflects a secondary hemodynamic event, and may result from several different mechanisms. Linguistically, *premature ventricular contraction* is more cumbersome, and its use, therefore, cannot even be justified or condoned on the basis of facility or economy of language. Thus, it does not simplify, it does not clarify, and it confuses.

Identity and the Electrocardiogram, With A Note on Twins and Altered Identities

M. IRENÉ FERRER, MD

The reproducibility, or identical characteristics, of the 12-lead electrocardiogram (ECG) in any 1 individual is so well-known a feature of electrocardiography that the clinical electrocardiographer seldom verbalizes or emphasizes this point. Indeed, it is accepted as routine that an electrocardiographic reader clearly appraises the identity of the tracings in a series of ECGs and determines that they are all from the same person. When an error of identification is made, that is, a record carries the wrong name, and appears in a series of ECGs, it is usual for the electrocardiographer to pick up this error. The record's origin is checked by comparison with previous tracings which all have more or less the same characteristics. Substitution of another's ECG for one's own is a well known attempted ploy when falsification of preinsurance information is perpetrated. This fraudulent situation can also be recognized if previous or repeated and current ECGs are available to the insurance examiner.

From the Department of Medicine, College of Physicians and Surgeons, Columbia University, The Presbyterian Hospital and the Electrocardiographic Department of the Columbia-Presbyterian Medical Center, New York, New York. Manuscript received August 25, 1982; revised manuscript received January 18, 1983, accepted January 21, 1983.

Address for reprints: M. Irené Ferrer, MD, 962 Park Avenue, New York, New York 10028.

There is a long and reliable clinical experience on the uniqueness of each person's ECG. The identity of one's ECG is relatively well preserved through life, and some stable features persist even when cardiac disease or drug effects alter certain parts of the tracing. The most stable features include the form and duration of the P wave (during sinus rhythm) and the duration and notching of the QRS. These waves result from depolarization of atrial and ventricular myocardium. The reproducibility or stability of these waves was very satisfactory, with only a ±15- to 30-ms variation in durations and identical numbers and locations of notchings as measured by computerized analysis of 2 to 6 records for the same normal adults. This study was part of an evaluation of a computer analysis comparison program written by myself and my colleagues.[1] In this same study the frontal plane axis of the P and QRS complexes was also constant, with a variation that seldom exceeded ±10° to 15° unless body shape or diaphragm level altered markedly.[1] S-T and T waves are less stable, being susceptible to many extracardiac influences. The P-R and Q-T intervals are relatively stable, but the P-R varies with heart rate, vagal tone, and drug effects and the Q-T with heart rate and drug effect.

When one considers the reliance placed on exactly matching electrocardiographic records arising from each individual in clinical electrocardiography, 2 related concepts are of interest: the ECG of twins and the use of the ECG to positively identify an individual.

The ECG of Twins

The incidence of twins in the United States is 1 in 86 pregnancies, with identical twins constituting 25 to 33%.[2] The ECG in normal twins (that is, those with no abnormalities) has been studied infrequently. The early report of Wise et al[3] in 1939 compared only the QRS in a study of 32 pairs of indentical twins (presumably monozygotic) and 18 pairs of nonidentical twins (dizygotic). Although more identical twins showed close similarity of tracings than did nonidentical twins (50% versus 22%), they did not find absolute correspondence in all identical twins as might have been expected. Mathers et al[4] and Preis and Srubarova[5] also found dissimilar ECGs more often in dizygotic than in monozygotic twins. Havlik et al[6] carried out a very limited study in 355 sets of middle-aged male monozygotic and dizygotic twins, examining only heart rate, P-R, QRS, and Q-T durations. They opined that there was genetically determined variability in ventricular rate and P-R interval. A case report in 1978[7] described a pair of identical twins, both having the Lown-Ganong-Levine form of preexcitation (short P-R interval and normal QRS complex) who had identical 12-lead ECGs. A careful and thorough study of ECGs in twins finally appeared in 1978.[8] There were 72 pairs of twins, 59 of which were monozygotic and 13 dizygotic. The investigators gave clear criteria for calling the tracings identical or different. The record of 1 twin was considered identical to that of the other twin when the frontal plane axis did not vary more than 10°, there was no more than 20% variation in duration of P, P-R, QRS, Q-T, and heart rate, there was no difference in polarity of S-T and T waves, and the same cardiac rhythm was present in both records. In the group of monozygotic twins, similar ECGs were found in 52% and dissimilar tracings in 48%. In the dizygotic twins 42% had similar tracings and in 58% the ECGs were different. Therefore, identical tracings are seen in both identical and nonidentical twins. This finding deserves considerable genetic investigation now that refined techniques can be applied to chromosomal and other features of twins. It is well known that exact zygosity is determined by careful examination of the placenta at birth or subsequently through comparison of physical characteristics, detailed blood typing, or possibly trial of tissue transplant from twin to twin.[1] Perhaps some twins in these various studies did not receive a full evaluation of zygosity. The subsets of twins with identical ECGs deserve full evaluation genetically.

Identification by ECG

There are times when identification of an individual must be done without the cooperation of or information from this person. An unconscious patient, a person unable to communicate because of loss of speech or a language barrier, and finally someone who has tried to hide his or her true identity by assuming a different personality and even different external physical characteristics—in all of these cases (and only if a previous ECG is available for comparison)—exact identification can be made by looking at the current and previous ECG. Fingerprints can be altered by a person wishing to hide his or her identity, but no one can alter the ECG. Thus, in crucial cases requiring exact identification of a person, the ECG offers primary information. Because it is becoming quite common to secure an ECG as part of many asymptomatic work-ups (preoperative, insurance, epidemiologic studies of communities and groups, and annual checkups), the likelihood of an individual having a tracing in his or her records is growing yearly.

In summary, one's ECG remains closely linked to, or even specific to, the individual. Identical twins, as presently defined, can have different ECGs. Furthermore, nonidentical twins, as presently defined, may have identical ECGs. We must determine if the criteria for identity in twins are correct. These electrocardiographic findings challenge the criteria used to determine whether a person is homozygous or heterozygous. Finally, the ECG perhaps can be considered a very stable identity marker of an individual.

New Choices for the Initial Drug Therapy of Hypertension

NORMAN M. KAPLAN, MD

After their introduction in 1958, thiazide diuretics were soon found to be effective antihypertensive agents. As they were more widely used, they quickly became the initial drug chosen by most practitioners. Their place as the initial drug in a sequential, stepped-care approach was formalized in 1977 and reaffirmed in 1980 by the reports of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure.[1]

The diuretic-first, stepped-care approach has been defended as both effective and safe. It has been used in all of the large-scale trials of the therapy of systemic hypertension, starting with the *VA Cooperative Study* in the 1960s[2] and proceeding to the *Hypertension Detection and Follow-Up Program* (HDFP) reported in 1979,[3] the *Australian trial* in 1980,[4] and the *Multiple Risk Factor Intervention Trial* (MRFIT) in 1982.[5]

The latter 3 trials involved mainly patients with "mild" hypertension, with diastolic blood pressure (BP) >90 mm Hg in MRFIT, from 90 to 104 in the HDFP, and from 95 to 109 in the Australian trial. These massive trials were needed for 2 reasons: first, patients with diastolic BP in the 90 to 104 mm Hg range comprise about 75% of the hypertensive population, perhaps 30 million Americans, so there is a great need to know if therapy is of value. Second, their rate of developing cardiovascular complications is relatively low so that many "patient-years" of observation were required to document the value of reduction of their BP. For various reasons, the results of these trials have not answered 1 of the critical questions: Does reduction of the BP prevent coronary heart disease, the major complication among hypertensive patients and the leading cause of death in the United States and other industrialized countries?

Let us examine the design and results of these 3 trials to better understand their implications for the therapy of patients with mild hypertension.

The 3 Trials

Hypertension Detection and Follow-Up Program: This trial proved that large numbers of hypertensive patients could be effectively managed to achieve a goal of diastolic BP <90 mm Hg. The study was designed to compare the effects on mortality rates of more intensive stepped-care drug therapy, provided in special clinics using various techniques to improve adherence, with the less intensive referred-care therapy, provided by community physicians using traditional practices. At the end of the 5-year study, those receiving more intensive care, the stepped-care group, had 26% fewer cardiovascular deaths and 13% fewer noncardiovascular deaths than did the less intensively treated referred-care group. As important as this study was in demonstrating the ability to manage large populations of mild hypertensive patients effectively, it was not designed as a straightforward trial of the efficacy of antihypertensive therapy.

Of those with mild hypertension who entered the trial with no antihypertensive medication and with no evidence of target organ damage, a 29% reduction in mortality rate was observed.[6] But that 29% figure should not be taken to indicate that 29% of the patients were saved. It represents a decrease in the 5-year mortality rate from 5.6% in the referred care group to 4% in the stepped care group. Thus, 5 years of more intensive drug therapy protected <2% of this population from death, a significant number but hardly 29% as some might infer.

Australian Trial: This trial was designed to test antihypertensive drug efficacy. Within 3 years of its start, those who received antihypertensive drugs (half of the sample) had 30% fewer cardiovascular complications (total endpoints) than those who received a placebo. The benefit was limited to patients whose diastolic BP remained >95 mm Hg during the study. Though the incidence of strokes, heart failure, and other cardiovascular complications was reduced, the number of heart attacks was not significantly reduced among the half that was treated with drugs.

Multiple Risk Factor Intervention Trial: This study enrolled men with high levels of overall risk: 62% were hypertensive, 64% were cigarette smokers, and their mean blood cholesterol level was 253 mg/dl. As in the HDFP trial, the enrollers were randomly divided into a more intensive, broad-based program to reduce the level of all 3 risks—the special intervention group and a usual care group followed by community physicians. Unfortunately for the trial, but fortunately for the patients, the usual care group received so much care that they had a much lower death rate than expected, a rate almost as low as the special intervention group.

Of those hypertensive patients who started with a diastolic BP >100 mm Hg, those more intensively treated had a lower rate of coronary and overall mortality; however, such protection was not provided in those who started with a diastolic BP from 90 to 94 mm Hg or in those with an abnormal resting electrocardiogram (Table I).

A possible explanation for the results: The results of these 3 trials, then, do not provide the hoped for ev-

From the University of Texas Health Science Center at Dallas, Dallas, Texas. Manuscript received January 1, 1983; revised manuscript received February 16, 1983, accepted February 16, 1983.

idence that more effective reduction of BP would reduce the incidence of coronary heart disease. One possible reason for this lesser effect may be the manner in which antihypertensive therapy was given, namely the diuretic-first, stepped-care approach. This cannot, however, be asserted with any degree of certainty. Because all 3 trials used a diuretic first in almost all treated patients, no comparison can be made of the effect of different drugs. Two trials comparing diuretics with beta-blockers are now in progress—1 in England and 1 in Sweden. Such evidence will be forthcoming, but not for some time.

The potential hazards of diuretics: In all 3 trials, about one third of the patients required a diuretic only to achieve the goal of therapy, and almost half received a diuretic plus a second-step drug. The possibility that the widespread use of a diuretic as first and often sole therapy could have decreased the protection from coronary events that was anticipated from lowering of BP is based on this premise: diuretics are now known to cause biochemical disturbances that increase cardiovascular risk, which could reduce the protection offered by the lower BP.[7]

These well-documented disturbances include an average decrease in serum potassium levels of 0.6 mmol/liter, an occasional worsening of glucose tolerance, and a 10 to 20 mg/100 ml increase in serum cholesterol levels. Other potential problems include an increase in plasma renin levels (related to a shrinkage of blood volume), increased blood viscosity, and an increase in plasma uric acid.

Of these changes, the ones that seem most likely to increase cardiovascular risks are the decrease in serum potassium levels and the increase in serum cholesterol levels. Hypokalemia may increase myocardial irritability, as was demonstrated in a study upon a group of hypertensive patients reported by Holland et al.[8] The patients were hypertensive with prior diuretic-induced hypokalemia. Their diuretics were stopped, and they were given enough potassium supplements to bring their serum potassium levels back to normal. At that time, they had no excess ventricular ectopic activity on 24-hour electrocardiographic monitoring. Diuretics were restarted, the serum potassium levels decreased again, and after 4 weeks another 24-hour monitor study was performed. Of the first 21 patients, 7 had significant increases in the frequency and severity of ventricular ectopic activity.

Although none of these patients had clinical manifestations of myocardial dysfunction, higher frequencies of life-threatening ventricular fibrillation in hypokalemic patients after acute myocardial infarction have been observed by others.[9,10] Thus, it may take an acute ischemic episode to uncover the potential hazard of hypokalemia upon myocardial irritability, possibly by a catecholamine surge which transfers potassium out of the plasma into cells, further reducing the plasma potassium level.[11] Patients who start with an abnormal electrocardiogram may be particularly susceptible to diuretic-induced hypokalemia. Recall the findings of the MRFIT study,[5] in which coronary deaths were higher in those hypertensive patients with abnormal electrocardiograms who were more intensively treated (Table I). Their therapy almost certainly included diuretics, but no specific information is now available about which drugs the individual patients were taking or the frequency of diuretic-induced hypokalemia among them.

TABLE I MRFIT: Mortality Rates in Hypertensive Patients Given Therapy

Initial BP (mm Hg)	Number		Coronary Deaths Per 1,000		Total Deaths Per 1,000	
	SI	UC	SI	UC	SI	UC
90–94	1,157	1,181	15	10	41	26
95–99	830	846	23	22	52	46
≥100	771	739	21	30	32	61
Normal ECG	2,785	2,808	16	21	36	43
Abnormal ECG	1,322	1,185	29	18	60	40

Synthesized from report of the Multiple Risk Factor Intervention Trial Research Group.[5]

BP = blood pressure; ECG = electrocardiogram; SI = Special Intervention; UC = Usual Care.

The potential risks of diuretic-induced increases of serum cholesterol levels are less acute and dramatic than those of hypokalemia. Not all have noted a significant increase after diuretic use and others have noted the increase to be only transient; however, many have documented a 10 to 20 mg/dl increase in serum cholesterol levels after weeks to years of diuretic therapy. It is likely to take many years for such an elevated cholesterol level to increase the degree of atherosclerosis, but the therapy of hypertension is obviously a prolonged process. By using the data from the Framingham study published in the American Heart Association's Coronary Risk Handbook, a persistent 10 to 20 mg/dl increase in serum cholesterol level will largely overcome the protection from coronary disease offered by a 10 to 15 mm Hg decrease in the BP. If such an increase in serum cholesterol level occurs with long-term diuretic therapy, lesser protection against coronary artery disease might be observed than would be predicted from the lowered BP.

Alternatives to diuretic-first stepped care: The evidence incriminating diuretics is largely circumstantial and should not be overdramatized. Millions of patients have taken diuretics for many years with no obvious trouble, and the resultant lowering of their BP has likely protected them from strokes, heart failure, progressive renal damage, and other hypertensive complications. More recently, hydrochlorothiazide was found to provide a greater antihypertensive effect than propranolol in black hypertensive patients, whereas the 2 drugs were comparable in whites.[12] But the potential atherogenic and arrhythmogenic hazards from diuretics should not be disregarded, particularly in view of the lesser protection shown against coronary artery disease in the trials that have used diuretics as initial and often sole therapy.

The use of diuretics as the first choice of therapy arose empirically: they were found to be effective and generally well tolerated. Moreover, when other nondi-

uretic drugs were used as initial therapy, fluid retention occasionally developed, causing their antihypertensive effectiveness to be largely lost. Such "pseudotolerance" due to fluid retention only served to strengthen the practice of using a diuretic first or in combination with the second-step drugs then available.

In the last few years, additional drugs have been introduced that cause less fluid retention and may therefore maintain their antihypertensive effectiveness without concomitant diuretic therapy. The *beta-blockers* were the first to be shown to work as monotherapy, except in the 20 to 30% of the hypertensive population who started off with low levels of plasma renin activity. Such patients were susceptible to fluid retention and some of them actually had paradoxical increases in BP when given beta-blockers alone.[13] There are, of course, adverse effects from beta-blockers that preclude their use in perhaps 25% of all hypertensive patients. In addition, a tendency for them to increase serum triglyceride levels and to lower the levels of the cardioprotective HDL-cholesterol has been recognized.[14]

Central alpha-agonists, including clonidine and guanabenz, are effective antihypertensives and may cause less fluid retention. The *peripheral alpha-antagonist* prazosin is a particularly attractive alternative; it usually does not cause the sedation so often seen with the centrally acting drugs, it can be used in those who are susceptible to problems from beta-blockade, and, unlike the beta-blockers, its use has not been accompanied by adverse effects on lipid levels.[15] Moreover, it lowers peripheral resistance—which is the hemodynamic fault in hypertension—unlike the beta-blockers which may increase peripheral resistance. Though tolerance has been observed with its use as an unloader in the treatment of heart failure, it has been shown to maintain its antihypertensive effect over 4 to 7 years.[16]

As we treat more and more mild hypertensive patients, who have relatively less risk from elevated BP itself, we need to be more cautious about potentially deleterious adverse effects from the therapies themselves. In view of the potential problems from diuretics, 1 or another of the currently available nondiuretic drugs may serve better as initial therapy. Although all of them may cause some problems, they should be considered as logical alternatives to the routine use of a diuretic as initial therapy. If they are used, even closer attention should be given to moderate sodium restriction, so as to reduce any tendency to fluid retention. Even so, if they fail to decrease the BP or if their effect is lost, fluid retention may be responsible, so that diuretics may then be needed. In addition, we should remember that many mild hypertensive patients can have the BP brought to safe levels by the judicious and enthusiastic use of nondrug therapies, including *weight reduction* for the obese and a moderate *restriction of dietary sodium intake* for all.

CAROLE A. WARNES, MB, BS, MRCP and WILLIAM C. ROBERTS, MD

Radioactive Iodine for Angina Pectoris (Robert L. Segal, Solomon Silver, Stephen B. Yohalem, and Robert A. Newburger)

The concept of treating intractable angina pectoris by inducing hypothyroidism was first proposed in 1933 by Blumgart, Levine, and Berlin (*Arch Intern Med* 1933;51:866). The paper by Segal et al described 65 adults with angina pectoris "refractory to standard therapeutic measures." Each was given radioactive iodine (I^{131}) in doses sufficient to produce thyroid ablation and myxedema. After the development of hypothyroidism, 8 patients died within 3 months and the other 57 were followed 6 to 60 months. Of the 57 survivors, 15 became "essentially free of angina" ("excellent result"), 23 had "a significant reduction in frequency and severity of angina" ("good result"), 19 had some lessening of pain, remained unchanged, or had worsening of angina ("fair" or "poor" response).

Viewing the I^{131} treatment of angina from the current perspective shows that these reported studies were nonrandomized, nonblinded, and noncontrolled. Diagnosis before therapy and evaluation after therapy was entirely historical. The criterion for I^{131} treatment was that angina was "intractable" to medical therapy, which, of course, meant nitroglycerin. Whether some of those patients would have remained intractable had beta-blockers and calcium-channel blockers been available is unknown. Although I^{131} therapy of angina was based on the supposition that the hypothyroidism produced would diminish myocardial oxygen requirements, this hypothesis was never proven. Furthermore, although this therapy often decreased the severity and frequency of angina pectoris, at the same time it increased the serum cholesterol level, and thus probably accelerated the underlying atherosclerotic process. The benefit, therefore, was only short-term.

Treatment of Congenital Endocardial Fibroelastosis by Operative Poudrage (Raphael N. Paul and S. Gwin Robbins)

This report concerned 9 patients with primary endocardial fibroelastosis and 1 patient with anomalous origin of the left coronary artery from the pulmonary trunk. All 10, aged 4 to 24 months, were treated surgically by instilling sterile talc powder into the pericardial sac, the aim being to "stimulate the growth of new blood vessels." Preoperative diagnosis was based on the angiographic demonstration of a large, thick-walled, hypokinetic left ventricle and electrocardiographic and radiographic evidence of left ventricular hypertrophy. Four died early postoperatively, and the 6 survivors, followed for up to 3 years, were "clinically well" and had slight increases in weight curves.

Thus, this operation, which had only a theoretical basis, was performed in 10 children without objective follow-up criteria to determine success or failure. As with the I^{131} treatment for "intractable" angina, the operative treatment for presumed congenital endocardial fibroelastosis was both nonrandomized and noncontrolled, and its evaluation was nonobjective.

Acute Myocardial Infarction in a City Hospital in a 1-Year Period (264 Cases) (Monte Malach and Benjamin A. Rosenberg)

This report described 264 cases of acute myocardial infarction (AMI) seen at King's County Hospital, Brooklyn, New York, during a 1-year period (Table I). The duration of hospitalization varied from <1 hour to 80 days (mean 15 days); mortality was 47%! The criteria

TABLE I Clinical Features of Patients With AMI

Before AMI		
Age (yr)	32–97	(mean 68)
Male:female	162 (61%):102	(39%)
Smoking	56/96	(58%)
Angina pectoris	148/244	(61%)
Previous AMI	61	(23%)
Previous congestive heart failure	113/255	(44%)
Systemic hypertension	86/232	(37%)
Previous cerebrovascular accident	22	(8%)
Diabetes mellitus	69	(27%)
Digitalis treatment before AMI	57/246	(23%)
After AMI		
Rectal temperature >100°F	218	(82%)
Tachycardia (>100 beats/min)	74	(28%)
Enlarged heart by X-ray	61/138	(44%)
Congestive heart failure	137	(52%)

for inclusion included one of the following: (1) demonstration at autopsy of an AMI; (2) electrocardiographic demonstration (usually in a 12-lead tracing) of serial changes compatible with AMI; (3) a history suggestive of AMI without diagnostic or electrocardiographic changes, with a history of coronary artery disease followed by a temperature >100°F rectally or by leukocytosis >10,000 mm^3 or by elevation of the erythrocyte sedimentation rate, "not explainable by any other recognized disease."

These diagnostic criteria are obviously untenable in the light of current knowledge. The mortality of 47% appears alarmingly high, but this did not surprise the authors because of their patients' relatively older age, the high frequency of congestive heart failure, and the long delay before hospitalization. A significantly greater survival rate, however, was observed in those patients who received 50 mg daily of vitamin C—a study "randomized" by prescribing the vitamin to patients in alternate wards.

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Prescribing Information

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors of malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications**, **Warnings**, and **Precautions**.

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings**.

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

Writing with care for CHF:

Avoid any change in the classic digitalis-Lasix® regimen.

BRAND OF (furosemide)

9 out of 10 cardiologists specify LASIX® (furosemide) by brand name.* And 2 out of 3 take the extra step to prevent substitution.*

7 out of 10 cardiologists also specify the leading brand of digoxin.* Both are part of the classic LASIX®-digitalis regimen.

In the same survey,* LASIX® and the leading brand of digoxin were named more often than any other agent, in any therapeutic class, as drugs for which these cardiologists would *never* allow generic substitution. Both were prescribed by brand name more often than any other drug.

LASIX®—specified for good reason.

Especially in CHF, precision is crucial. Any therapeutic variable could easily upset the sensitive digitalis/diuretic/electrolyte balance and precipitate digitalis toxicity.

LASIX®, the most thoroughly documented drug in its class, offers quality so consistent that almost 8 billion tablets have been manufactured without a single product recall. In more dosage strengths and forms than any other diuretic. Good reason for the cardiologists surveyed to say they prescribe LASIX® more frequently than all other diuretic agents they named.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

*National survey of 2960 physicians, including 1502 cardiologists and other physicians subspecializing in cardiology, conducted by Hoechst-Roussel Pharmaceuticals Incorporated, Somerville, New Jersey. August, 1982.

The diuretic of choice in CHF.

Do Not Substitute

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

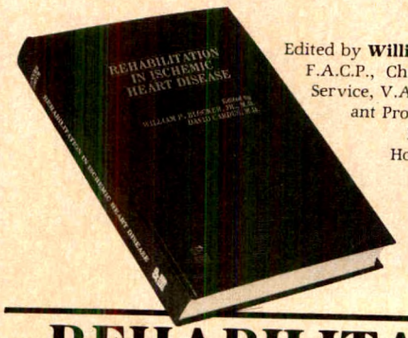
This book contains the most complete list of cardiac risk factors to be found in any text . . .



Edited by **William P. Blocker, Jr., M.D.**, F.A.C.P., Chief, Rehabilitation Medicine Service, V.A. Hospital, Houston, Assistant Professor of Physical Medicine, Baylor College of Medicine, Houston, and **David Cardus**, M.D., F.A.C.C., Professor of Physiology and Rehabilitation, Baylor College of Medicine, Houston, Texas.

REHABILITATION IN ISCHEMIC HEART DISEASE

Heavily illustrated, this volume presents 60 self-contained chapters dealing with *all* aspects of rehabilitation of the patient with ischemic heart disease. The 45 noted contributors discuss topics such as: designing a cardiac rehabilitation center; methods of rehabilitation for the stroke patient, amputee, spinal cord injury patient who has had a heart attack; equipment needs for a cardiac rehabilitation center; and legal responsibilities of the physicians and therapists.

All major aspects, from epidemiology and pathogenesis through prevention and education are covered, including ambulatory monitoring of electrocardiogram and blood pressure; evaluation of degree of disability; and pathogenesis of atherosclerosis. This book contains the *most complete* list of cardiac risk factors to be found in any text. This encyclopedic guide to the total care and rehabilitation of cardiac patients is written for *every* member of the cardiac rehabilitation team.

Update your echo lab with Cardiac Doppler.

Sonacolor® CD

CARDIAC DOPPLER

The Cardiac Doppler system expands conventional echocardiography by providing noninvasive assessment of flow velocities through all four heart valves. It is all you need to confirm stenotic or regurgitant valvular disease.

- Color spectral patterns grade the degree of valve stenosis and turbulence.
- Valve cross-sectional areas can be derived from pressure gradient half-times.
- Color spectral patterns grade the degree of regurgitation. Valve prolapse is identified through the presence and timing of regurgitation.
- Detects the high velocity jets of flow through prosthetic valves. Detects prosthetic valve leakage. Monitors valve function over time.
- Color spectral patterns locate and grade shunts.
- Displays ECG trace for time reference. Phono trace for correlation of heart sounds with Doppler flow velocity patterns.
- Computes cardiac output approximation, stroke volume and average flow.

Call 1-800-334-4531 to place your order, for in-depth information or an on-site demonstration.

Now for angina pectoris

ISOPTIN® TABLETS (verapamil HCl/Knoll)

In angina of effort:

Isoptin decreases myocardial oxygen demand and improves exercise tolerance

By decreasing peripheral vascular resistance and cardiac afterload, Isoptin decreases the workload of the heart and the amount of oxygen consumed by heart muscle. So angina patients on Isoptin are able to exercise significantly longer without pain — from 47% to 67% longer in three well-controlled studies.[1-3]

An agent with two major antianginal actions

In angina at rest:

Isoptin dilates the coronary arteries and prevents coronary vasospasm

While beta blockers may cause coronary vasoconstriction, Isoptin prevents spasm and dilates both normal and atherosclerotic coronary arteries. In a well-controlled comparative study of patients with unstable angina at rest, propranolol did not differ significantly from placebo, while Isoptin reduced nitroglycerin requirements by 84% and the incidence of transient ischemic ECG events by 81%.[4]

Why Isoptin?

Isoptin is an effective first-line agent for patients with angina of effort, angina at rest, or mixed angina, in which both spasm and obstruction may be present.[5,6]

Unlike certain vasodilators and unlike the beta blockers, Isoptin achieves its antianginal effects with minimal effect on heart rate. Patients on Isoptin do not experience any vasodilation-induced, reflex increases in heart rate. And, in patients in whom propranolol 320 mg/day decreased the heart rate 18 to 20 beats/minute, Isoptin 480 mg/day decreased it only 4 to 9 beats/minute.[1,7] Isoptin requires no special caution in patients with asthma, COPD, diabetes, or peripheral vascular disease.

Isoptin is contraindicated in severe left ventricular dysfunction, sick sinus syndrome (except in patients with a functioning artificial ventricular pacemaker), hypotension or cardiogenic shock, and second- or third-degree AV block.

Please see accompanying page for brief summary of prescribing information.

ISOPTIN® TABLETS
(verapamil HCl/Knoll)
80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** ISOPTIN should be avoided in patients with severe left ventricular dysfunction (e.g., ejection fraction <30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before ISOPTIN is used. ISOPTIN may occasionally produce hypotension (usually asymptomatic, orthostatic, mild, and controlled by decrease in ISOPTIN dose). Occasional elevations of liver enzymes have been reported; patients receiving ISOPTIN should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (e.g., W-P-W or L-G-L syndromes) may develop a very rapid ventricular response after receiving ISOPTIN (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema, and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with ISOPTIN. **Precautions:** ISOPTIN should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of ISOPTIN and beta blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, ISOPTIN should be used alone, if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with ISOPTIN and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic ISOPTIN treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when ISOPTIN is given, and the patient carefully monitored. ISOPTIN may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after ISOPTIN administration. Until further data are obtained, combined ISOPTIN and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. *Pregnancy Category C :* There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during ISOPTIN use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, maculae, and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** ISOPTIN (verapamil HCl) is supplied in 80 mg and 120 mg sugar-coated tablets. July 1982

MYOCARDIAL REVASCULARIZATION
MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Myocardial Reperfusion After Acute Occlusion of the Left Main Coronary Artery

Alessandro Salvi, MD
Silvio Klugmann, MD
Erica Della Grazia, MD
Patrizia Maras, MD
Fulvio Camerini, MD

Coronary recanalization with thrombolytic agents represents a new therapeutic approach to the treatment of acute myocardial infarction,[1] and previous experience suggests that patients with myocardial infarction and cardiogenic shock may benefit from this technique.[2]

A 58-year-old woman was admitted 30 minutes after the onset of persistent ischemic pain. Initial examination disclosed a moderately confused, pale, diaphoretic woman with a systolic arterial pressure of 80 mm Hg. Electrocardiography demonstrated sinus rhythm (62 beats/min), S-T segment elevation in leads I, aVL, and V_1 to V_4, with positive, high-voltage T waves in leads V_1 to V_6 and Q waves in lead aVL. Therapy with nitroglycerin (0.9 mg sublingually in 15 minutes), dopamine (7 μg/kg/min), and morphine sulfate (10 mg intravenously) was initiated without apparent effect on the clinical status. Lidocaine (3 mg/min intravenously, after a loading dose of 100 mg) was started and was continued throughout the procedure. Emergency coronary angiography (Judkins technique) to perform coronary recanalization was started 40 minutes after admission. By that time, femoral systolic arterial pressure had decreased to 60 mm Hg. On injection of contrast medium, an occlusion of the left main coronary artery was demonstrated (Fig. 1). Nitroglycerin (0.5 mg endocoronary) did not modify the angiographic appearance. Streptokinase (4,000 IU/min) was then infused through the Judkins catheter, and within 15 minutes patency was achieved in both the anterior descending and circumflex coronary arteries (Fig. 1). The infusion of streptokinase was maintained for 90 minutes employing a total dosage of 360,000 IU. Several episodes of ventricular tachycardia and ventricular fibrillation, treated with direct-current countershocks, took place during this period. At the end of the procedure the femoral arterial pressure was 104/65 mm Hg, ischemic pain had resolved, and sinus rhythm was present. Right coronary angiography, performed after lysis, demonstrated a wide, dominant artery with minimal luminal irregularities and no collateral vessels to the left coronary artery.

Postreperfusion electrocardiography demonstrated Q waves in leads I, aVL, and V_5 with reduced voltage R waves in V_1 to V_4, slight S-T segment elevation in leads aVL and V_8, and moderate S-T depression in leads II, III, and aVF.

Dopamine was discontinued within 24 hours and the patient was treated with heparin (25,000 to 35,000 IU/day), digoxin (0.25 mg/day), and lidocaine (2 to 4 mg/min) for 3 days. The subsequent clinical course was uneventful, the patient remained asymptomatic, and oral acenocoumarin was substituted for heparin therapy on the eighth day. An angiographic control on the 14th hospital day showed evidence of an isolated distal left main coronary artery stenosis of 60% diameter reduction. The left ventricle appeared slightly dilated (left ventricular end diastolic volume 97 ml/m²) with moderate hypokinesia of the anterolateral and septal walls. The ejection fraction was reduced to 0.45 and left ventricular end diastolic pressure was 20 mm Hg.

The patient underwent coronary artery bypass surgery on the 26th hospital day. The anterolateral left ventricular wall appeared akinetic but not fibrotic.

From the Department of Cardiology, University of Trieste, Trieste, Italy.
Manuscript received November 24, 1982; revised manuscript received February 14, 1983, accepted February 15, 1983.

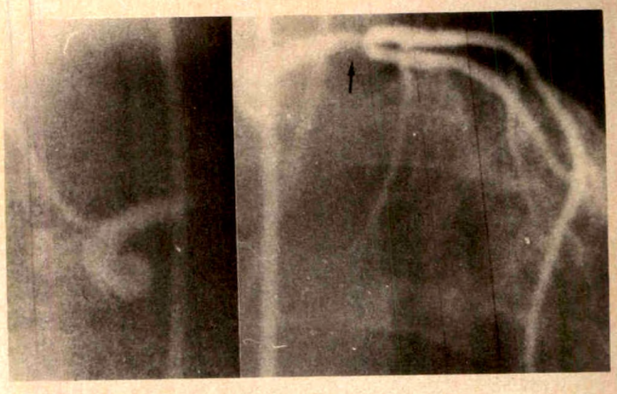

FIGURE 1. Left, left coronary arteriogram in the anteroposterior projection. Occlusion of the distal portion of the left main coronary artery. **Right,** left coronary arteriogram (same projection) 15 minutes after streptokinase infusion. Patency is achieved in both the anterior descending and circumflex coronary arteries with a residual luminal stenosis of 60% diameter reduction (**arrow**).

Only few cases of cardiogenic shock complicating acute myocardial infarction treated with intracoronary streptokinase have been reported.[2–5] Three showed a favorable response, but the thrombotic occlusion was never localized to the left main coronary artery. The case described suggests that a large amount of myocardium at risk was salvaged and therefore underlines the maximal potential therapeutic significance of the new technique of intracoronary thrombolytic infusion in acute myocardial infarction.

Prinzmetal's Variant Angina Unresponsive to Calcium Channel-Blocking Drugs But Responsive to Combined Calcium Channel- and Beta-Blocking Drugs

Claude Bourmayan, MD
Jean Yves Artigou, MD
André G. Barrillon, MD
Alain Juillard, MD
Claude Fournier, MD
Jean Gay, MD
Alain Gerbaux, MD

The reputation of beta-blocking drugs at normal dosage in patients with spastic angina is so poor[1–3] that an aggravation of angina under such treatment suggests the diagnosis of spastic angina.[4] One case is described here showing that this reputation may not always be deserved.

On March 30, 1981, a 77-year-old man was admitted for spontaneous attacks of angina pectoris. The electrocardiogram during attacks showed the typical pattern of Prinzmetal's variant angina (Fig. 1). From March 31 to April 12, the patient had 11 spontaneous attacks of anginal pain, despite a dose-escalating calcium channel-blocking treatment that ended up as follows: diltiazem, 60 mg 4 times daily; nifedipine, 10 mg 4 times daily; and intravenous infusion of nitroglycerin (10 gamma/min). The failure of the calcium-channel blocking drugs led to the trial addition of 60 mg of propranolol per day to the treatment. This was thought useful because a marked increase in heart rate often occurred after the perception of pain. For 13 consecutive days, no attacks occurred (Fig. 2). The angina returned 48 hours after bradycardia (45 beats/min), and fatigue forced a reduction in propranolol to 40 mg/day (giving a propranolol serum concentration of 0.08 μmol/liter 4 hours after administration of 10 mg). During the 6 days of therapy with 40 mg of propranolol 4 attacks of angina occurred (Fig. 2). The treatment with 60 mg of propranolol was restarted (propranolol serum concentration 0.30 μmol/liter 4 hours after administration of 20 mg) and the patient complained of no pain until May 5, the day he left the hospital. Serum creatine kinase was always normal. After the same treatment when seen in November 1981 and 1982, he was found to have remained free of angina, and results of a Holter recording proved negative.

From the Centre de Soins Cardiaques Intensifs, Hôpital Boucicaut, 78 Rue de la Convention, 75730 Paris, cedex 15, France. Manuscript received January 17, 1983; revised manuscript received and accepted March 15, 1983.

The hypothesis of the effectiveness of the treatment with propranolol in this patient is based on the complete disappearance of anginal pain from the start of treatment until 48 hours after the dose reduction, and on the renewed cessation of pain after the return to the initial dosage. Although variant angina is well known to evolve capriciously,[5] the possibility of these findings being due to chance alone seems highly unlikely. Even though the 2 dosages of propranolol used were very close, their consequences on the heart rate were quite different; as soon as the dose reduction took place, the heart rate increased permanently from 45 to 60 beats/min. In addition, the serum concentration dosages differed widely, reaching the therapeutic zone (0.15 to 0.58 μmol/liter) when the patient was taking 60 mg/day and remaining well below it when he was taking only 40 mg/day. This beneficial effect may be explained by an acceleration of the heart rate during the anginal attacks, increasing from 57 to 75 beats/min during some anginal attacks. Poggi[6] also reported on 1 patient with variant angina successfully treated with propranol. This patient's heart rate increased from 68 to 80 beats/min during the anginal attacks.

Our case shows that propranolol administered at moderate doses can potentialize the effects of calcium channel-blocking drugs in an elderly subject with Prinzmetal's variant angina when there is sinus tachycardia during the anginal attacks. It would be worthwhile to test this hypothesis on a large number of patients.

Cysts in Left Atrial Myxomas Identified by Transesophageal Cross-Sectional Echocardiography

Wolfgang Thier, MD
Michael Schlüter, PhD
Hans-Joachim Krebber, MD
Michael-Jürgen Polonius, MD
Günter Klöppel, MD
Klaus Becker, MD
Peter Hanrath, MD

Two-dimensional echocardiography performed from the thorax is the standard technique for the recognition of intracavitary cardiac structures. Two patients with left atrial myxoma are reported, in whom transesophageal cross-sectional echocardiography[1,2] revealed cysts within the tumors, a finding not observed by standard external approach. (The transthoracic echocardiograms were recorded with a 2.25 MHz transducer on a Diasonics 3400 R phased-array sector scanner. The same scanner was used for the transesophageal studies that were performed with a 3.5 MHz transducer.)

In a 59-year-old woman (Patient 1) transthoracic echocardiography revealed a left atrial mass the size of a plum which prolapsed into the mitral ostium in ventricular diastole. The mass was attached to the atrial septum and appeared homogeneous (Fig. 1). Transesophageal cross-sectional echocardiography revealed several isolated echolucencies within the mass (Fig. 2). Operation disclosed the mass to be a myxoma containing multiple cysts filled with serous fluid, measuring up to 10 mm in diameter (Fig. 3).

A similar finding was documented in a 65-year-old man (Patient 2). In the transthoracic cross-sectional echocardiogram, the tumor was seen in all 3 standard views, extending deep into the left ventricle in ventricular diastole (Fig. 4). Transesophageal cross-sectional echocardiography revealed a vast, mobile left atrial mass which was connected to the atrial septum by a small stalk. Several reproducible zones of echolucency with a maximum diameter of 10 mm was visualized within the tumor (Fig. 5). Examination disclosed a large tumor containing cysts filled with clear serous fluid (Fig. 6). Histologically, the tumor was a typical myxoma.

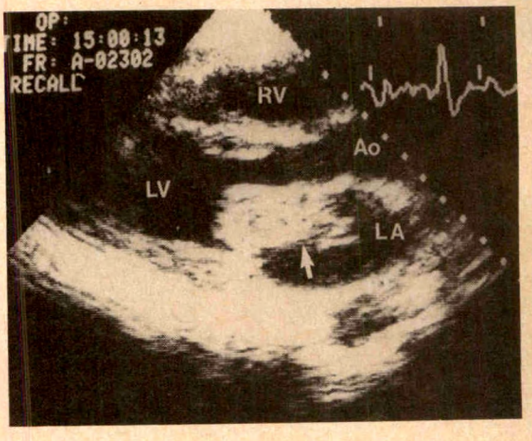

FIGURE 1. Transthoracic echocardiogram (parasternal long-axis view) from Patient 1, taken at end-diastole. The left atrial tumor (**arrow**) completely fills the mitral ostium. Ao = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle.

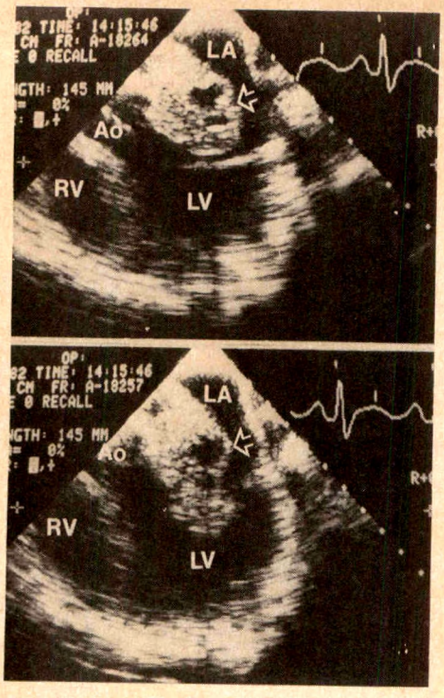

FIGURE 2. Transesophageal echocardiograms from Patient 1. **Upper panel,** frame taken at end-systole. **Lower panel,** frame was taken in diastole when the left atrial tumor mass is seen to extend into the left ventricle. Both frames show 2 areas of echolucency within the tumor (**arrows**). Abbreviations as in Figure 1.

Apart from an echocardiogram described by Come et al[3] and a recent brief report on tumor hemorrhages in atrial myxomas,[4] regions of echolucency within cardiac tumors have not been reported. Despite thorough searching for cysts from the standard external views (parasternal long- and short-axis, apical 4- and 2-chamber, subcostal long- and short-axis), we could identify the cysts only with the transesophageal approach. This fact is probably related to the vicinity of the esophagus and the left atrium, to the different cross-sectional planes obtainable, and to a lesser extent, the higher frequency of the transesophageal probe.

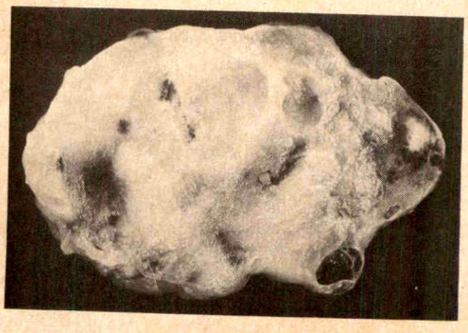

FIGURE 3. Section through the tumor specimen from Patient 1, showing several cysts that correspond to the echolucencies noted on the transesophageal echocardiograms.

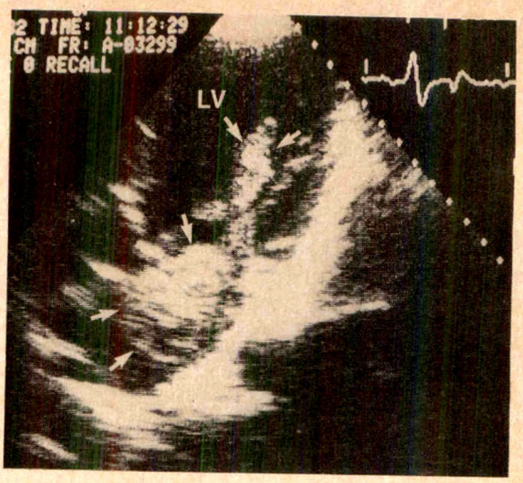

FIGURE 4. Apical 2-chamber view (right anterior oblique equivalent) from Patient 2. The contour of the left atrial myxoma is marked by **arrows.** This end-diastolic frame shows an extension of the tumor reaching into the left ventricle (LV).

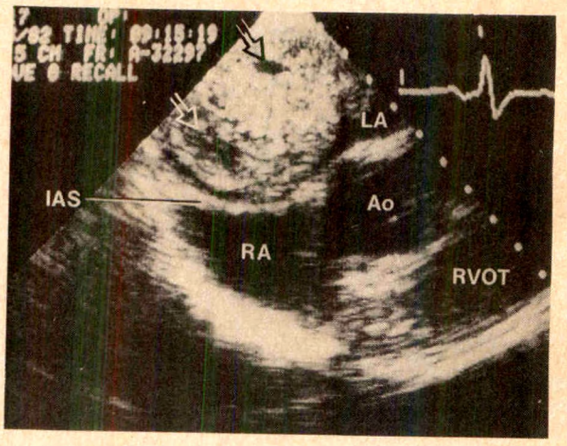

FIGURE 5. Transesophageal echocardiogram from Patient 2. The tumor fills nearly all of the left atrium in this view. Two cysts are marked by **arrows.** IAS = interatrial septum; RA = right atrium; RVOT = right ventricular outflow tract; other abbreviations as before.

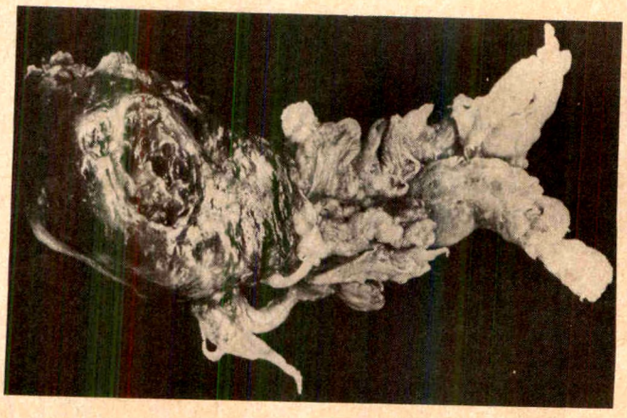

FIGURE 6. Resected tumor from Patient 2. The section through the tumor base shows 2 cysts. The villiferous surface of the distal part of the tumor is obvious.

Structural Changes in Ventriculoaortic Porcine Valved Conduit Implanted in a Child

Uberto Bortolotti, MD
Aldo Milano, MD
Giuseppe Faggian, MD
Enrico Talenti, MD
Alessandro Mazzucco, MD
Gaetano Thiene, MD
Vincenzo Gallucci, MD

The implantation of a left ventricular (LV) apicoaortic composite conduit is a well-established procedure for the relief of severe LV outflow obstruction.[1,2] Although the use of valve-bearing conduits in the right side of the heart seems to be limited by a high rate of early obstruction, the fate of the left-sided ones is poorly known and rarely pathologically documented.

A 15-year-old boy was admitted for surgical repair of severe aortic stenosis. At operation, the calcified and hypoplastic aortic valve was excised, but the small diameter of its anulus (17 mm) prevented the insertion of a prosthesis. The aortic outflow was closed by a Dacron ® patch, and a Hancock composite conduit was inserted between the LV apex and the ascending aorta. There was prompt postoperative recovery.

The patient was asymptomatic for 2 years, when exertional dyspnea and fatigue appeared. Cardiac catheterization confirmed the presence of severe aortic regurgitation. No pressure gradient was measured across the conduit. Angiocardiography showed marked regurgitation of the conduit valve and moderate mitral regurgitation. Reoperation was performed 26 months after the first operation. The mitral valve, which appeared diffusely calcified, was replaced with a #29 Sorin tilting-disc prosthesis; the Hancock conduit was excised and replaced with another Dacron conduit containing a #21 Sorin prosthesis. The patient died from infective complications 14 days later. The excised conduit was slightly bent at the aortic extremity and its inner surface was partially lined by fibrous tissue (Fig. 1); the porcine valve cusps were torn and calcified (Fig. 2).

LV apicoaortic porcine conduits are being implanted in an increasing number of young subjects.[1,2] To date, dysfunction of such conduits has been reported in only 3 cases.[3,4] In a recent multicenter study,[3] 227 children were evaluated as late survivors of porcine valve replacement; in 20, the valve degenerated. Eight patients in this series received an apicoaortic conduit; in 1, both valve and conduit were removed because of valve calcification. Chen et al[4] described the clinicopathologic findings in 2 patients in whom an apicoaortic porcine conduit was excised due to degeneration. In both, the porcine valve was severely calcified and deformed. The case reported here confirms that porcine valves in LV apicoaortic conduits behave like heterografts inserted in the aortic position. Thus, when implanted in children,

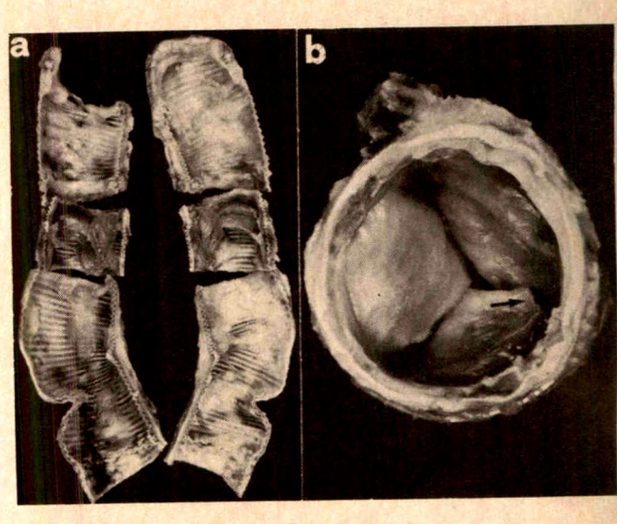

FIGURE 1. a, gross appearance of the explanted conduit. Its inner surface is lined by a thin, nonobstructive fibrous peel. **b,** view of the explanted Dacron conduit valve which was severely incompetent due to a torn commissure (**arrow**); no gross calcific deposits are evident.

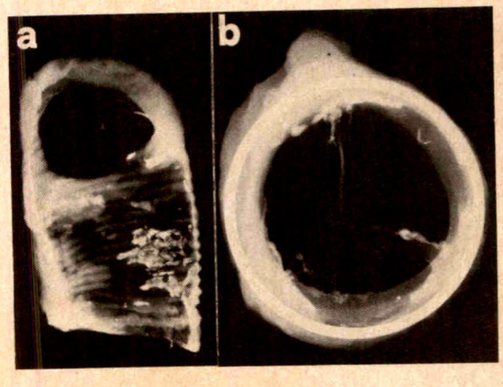

FIGURE 2. a, roentgenographic examination of the explanted Dacron conduit: note the presence of scattered calcific deposits. **b,** roentgenogram of the conduit porcine valve which demonstrates fine calcification at the commissure and base of the cusps.

From the Departments of Cardiovascular Surgery, Radiology, and Pathology, University of Padova Medical School, Padova, Italy. This study was supported in part by Grant 81 01818.04 of the Consiglio Nazionale delle Ricerche, Rome, Italy. they are prone to calcify like those inserted in either the mitral and aortic position.[5]

The fate of the Dacron tube of a composite conduit seems to depend on which side of the heart it is inserted. In conduits used for reconstruction of the right ventricular outflow, formation of a fibrous "peel" has been observed, progressively thickening as the result of the thrombus organization between the peel and the conduit wall.[6] In our patient, the inner surface of the left-sided conduit appeared lined with a calcified but thin, nonobstructing peel, most likely because in this position the high velocity of the bloodstream prevents thrombus formation and organization.

Noninvasive Diagnosis of Interrupted Inferior Vena Cava: Gated Pulsed Doppler Application

Samuel B. Ritter, MD
Fredrick Z. Bierman, MD

Interruption of the inferior vena cava (IVC) with drainage by way of the azygous system is an uncommon lesion frequently associated with complex intracardiac anomalies. Comprehensive imaging of this vascular anomaly requires direct visualization of the isolated intrahepatic caval segment and discrimination of the azygous system from other vertical vascular channels, such as the thoracoabdominal aorta and anomalous pulmonary venous communications.[1] Recognition of this anomaly before cardiac catheterization avoids unnecessary wire and catheter manipulation and attendant irradiation. This report illustrates the combined use of 2-dimensional (2-D) and gated pulsed Doppler echocardiography for noninvasive identification of interruption of the IVC with hemiazygous continuation.

From the Department of Pediatrics, Division of Pediatric Cardiology, Babies Hospital, College of Physicians and Surgeons, Columbia University, New York, New York. Manuscript received January 5, 1983; revised manuscript received and accepted March 15, 1983.

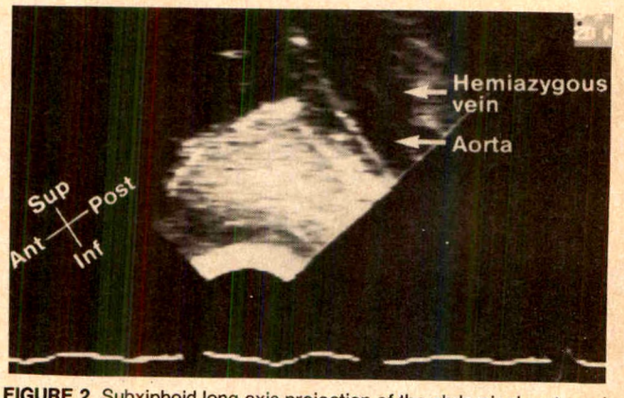

FIGURE 2. Subxiphoid long-axis projection of the abdominal aorta and hemiazygous vein parallel to the sagittal plane of the trunk. Ant = anterior; Inf = inferior; Post = posterior; Sup = superior.

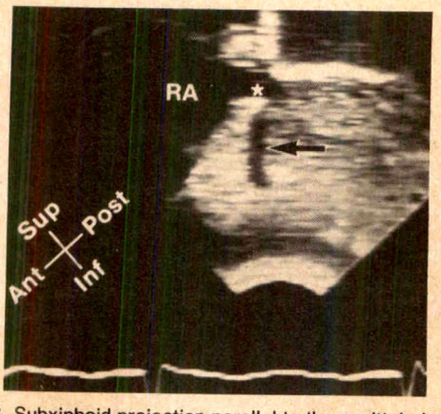

FIGURE 3. Subxiphoid projection parallel to the sagittal plane of the trunk demonstrating the hepatic segment of the inferior vena cava receiving the hepatic veins and entering the right atrium (RA). The infrahepatic suprarenal segment of inferior vena cava is absent. The **arrow** indicates the hepatic veins; the hepatic vena cava is indicated by an **asterisk.** Abbreviations as in Figure 2.

A 5-year-old girl had a known ventricular septal defect with mild pulmonary artery hypertension. The infradiaphragmatic systemic venous return was evaluated by combined 2-D and gated pulsed Doppler echocardiography. A left-sided suprarenal continuation of the IVC was demonstrated by subxyphoid projections parallel to the horizontal and sagittal planes of the trunk[2,3] (Fig. 1 and 2). Projections parallel to the horizontal plane of the trunk displayed the left-sided suprarenal hemiazygous continuation of the IVC posterior to the abdominal aorta (Fig. 1). Orthogonal projections parallel to the long axis of the trunk identified contiguous left-sided vertical vascular channels adjacent to the lumbar spine (Fig. 2), and isolated hepatic segment of IVC receiving hepatic veins (Fig. 3). The left-sided vertical channels were identified by branching patterns, that is, celiac and superior mesenteric arteries, and gated pulsed Doppler spectral wave forms. Doppler examination of the more anterior vertical channel revealed the typical wave form of the descending aorta (Fig. 4). Examination of the posterior vascular channel (Fig. 5) demonstrated a low frequency

broad band spectral distribution with inspiratory acceleration.

The combination of the 2-D echocardiographic anatomic detail and gated pulsed Doppler flow characteristics facilitate identification of vascular structures in the thorax and abdomen. The proximal abdominal aortic branches, that is, celiac and superior mesenteric arteries, and renal veins are landmarks for localization of the suprarenal segment of the IVC. In situs solitus, the left renal vein junction with the IVC marks the superior extent of the infrarenal IVC.[4] Absence of the IVC between this caval-renal vein junction and the hepatic vein confluence and the presence of a left-sided hemiazygous continuation identifies suprarenal IVC interruption. The resultant contiguous vertical thoracoabdominal vessels, left-sided aorta and hemiazygous vein, also may be identified by their distinctive gated pulsed Doppler flow characteristics. The pulsatile wave-form of the thoracoabdominal aorta (Fig. 4, right) is distinguishable from the heterogeneous low frequency wave form of the central systemic veins (Fig. 5, top right). The central venous Doppler wave form is influenced by the intrathoracic pressure variation and manifests baseline variation with the respiratory cycle.

In conclusion, interruption of the IVC with hemiazygous extension is demonstrated by the absence of continuity between the IVC at the level of the left renal vein and the hepatic segment of vena cava. The hemiazygous continuation is established by its direct visualization and its distinctive gated pulsed Doppler flow characteristics.

Congenital Absence of Pulmonary Valve Associated With Tetralogy of Fallot: Diagnosis by 2-Dimensional Echocardiography

Elio Di Segni, MD
Stanley Einzig, MD, PhD
John L. Bass, MD
Jesse E. Edwards, MD

Congenital absence of the pulmonary valve is a rare cardiac malformation usually associated with tetralogy of Fallot.[1] This syndrome usually presents early in life and is characterized by cyanosis, a to-and-fro precordial murmur, and frequently respiratory distress.[1] This report describes 2-dimensional (2-D) echocardiographic findings in 2 newborns with absent pulmonary valve in association with tetralogy of Fallot.

Case 1: *A full-term newborn boy was seen at 1 day of age because of cyanosis. A to-and-fro 3/6 systolic and diastolic murmur was heard at the left sternal border. The electrocardiogram gave normal results. The thoracic roentgenogram showed mild cardiomegaly and a normal pulmonary vasculature. A right cineventriculogram revealed a ventricular septal defect with an overriding aorta, large pulsating pulmonary arteries, a narrowed pulmonary valve anulus, and no evidence of pulmonary valve tissue except for a concentric ridge of tissue at the expected site of the pulmonary valve (Fig. 1).*

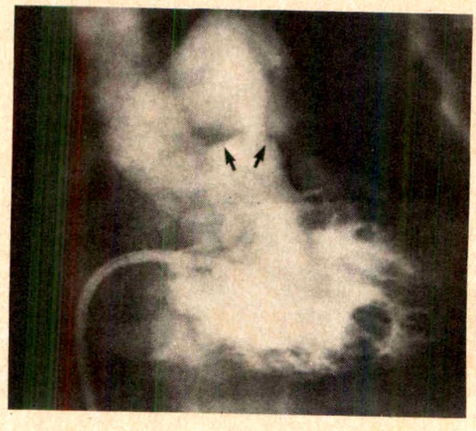

FIGURE 1. Case 1. Right cineventriculogram in anteroposterior projection. The aorta and pulmonary artery are simultaneously opacified. A concentric ridge of nonmobile tissue (**arrows**) is seen at the pulmonary anulus which contributes to stenosis of the tract. The pulmonary artery is markedly dilated.

Two-D echocardiography was performed at 1 day of age with a mechanical sector scanner (Smith-Kline) using a 30° 5-MHz transducer. An overriding aorta, subaortic ventricular septal defect, and dilated pulmonary arteries were demonstrated. At the expected site of the pulmonary valve, 2 ridges, each 2 mm thick, with markedly decreased mobility were seen. Ventricular septal motion was normal (Fig. 2).

Case 2: *A full-term newborn boy was referred because of cyanosis. A 3/6 harsh systolic and diastolic murmur at the lower left sternal border was heard. Bilateral rales and rhonchi were present over the lungs. The liver was palpable 4 cm below the right costal margin. The electrocardiogram showed right atrial enlargement. The thoracic roentgeno-*

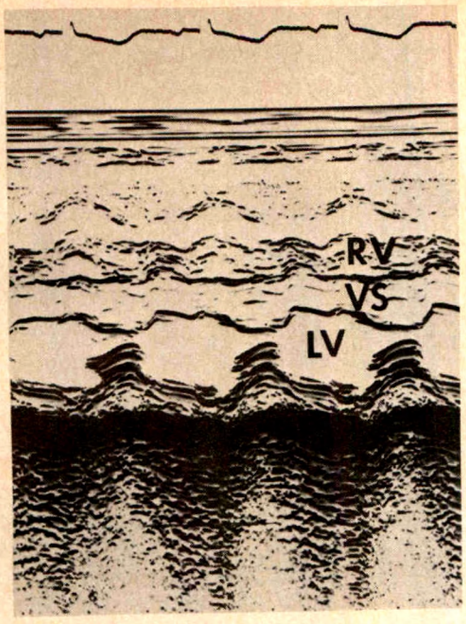

FIGURE 2. Case 1. M-mode recording of the right and left ventricles at the level of the mitral chordae. Normal ventricular septal motion is demonstrated. Echoes within the right ventricular cavity are reflected from the tricuspid valve supporting apparatus. LV = left ventricle; RV = right ventricle; VS = ventricular septum.

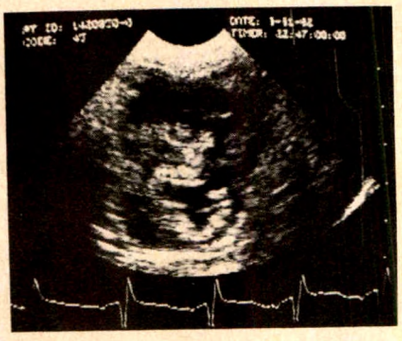
gram showed moderate cardiomegaly and enlarged pulmonary arteries. Right ventricular cineangiography showed a hypertrophic right ventricle and a narrowed pulmonary valve anulus. The aneurysmal dilatation of the right pulmonary artery was so marked as to impinge on the left atrium. Pulmonary valve leaflets were not identified.

Two-D echocardiography was performed at 1 day of age with an Advanced Technology Laboratory mechanical sector scanner using an 80° 5-MHz transducer. In contrast to the findings in Case 1, a large mass of muscle continuous with the mid- and lower portion of the ventricular septum was present at the right ventricular apex. The large mass of muscle attached to the ventricular septum appeared to extend into the right ventricular outflow tract. Multiple bright echo-reflecting areas were recorded within the ventricular myocardium (Fig. 3). Similar to Case 1, thick ridges at the pulmonary valve anulus extended for 2 to 3 mm into the lumen of the pulmonary artery (Fig. 4). These structures did not move. The main, right, and left pulmonary arteries were markedly dilated. Ventricular septal motion was normal. A subcostal 4-chamber view demonstrated what appeared to be a continuous "membrane" transecting the left atrium (Fig. 5). Although this initially suggested the diagnosis of cor triatriatum, short-axis angulation of the transducer demonstrated that the posterior chamber was continuous with the main pulmonary artery and represented the right pulmonary artery.

At 2 days of age, 24 hours after cardiac catheterization, the patient died. At autopsy, trabeculation of the ventricular septum was present as previously identified on the 2-D



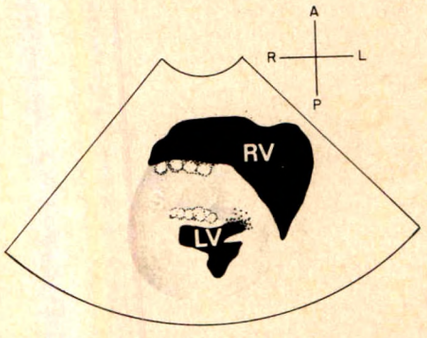


FIGURE 3. Case 2. Parasternal short-axis 2-dimensional echocardiogram and corresponding schematic drawing. The ventricular septum appears thick because of large trabeculations on the right ventricular aspect. Multiple bright echo reflecting areas (**arrows**) of myocardial calcification are seen in the ventricular septum. A = anterior; L = left; LV = left ventricle; P = posterior; R = right; RV = right ventricle; S = ventricular septum.

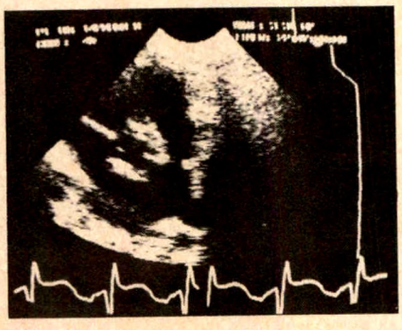

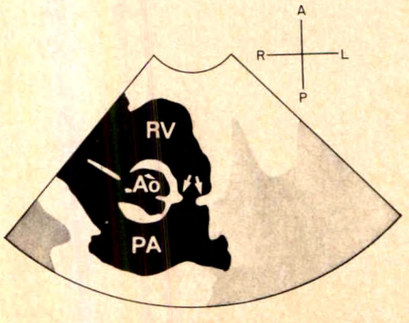

FIGURE 4. Case 2. Parasternal short-axis 2-dimensional echocardiogram obtained in a plane superior to that of Figure 3 and corresponding schematic drawing. Two ridges (**arrows**) represent the rudimentary pulmonary valve causing stenosis of the tract. The main and right pulmonary arteries are markedly dilated. A = anterior; Ao = aorta; L = left; P = posterior; PA = pulmonary artery; R = right; RV = right ventricle.

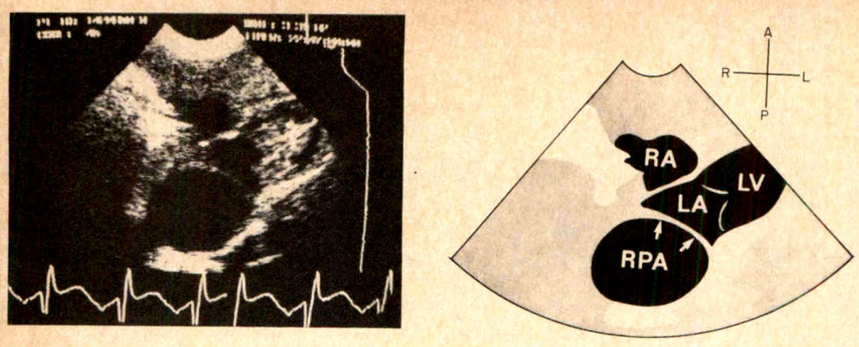

FIGURE 5. Case 2. Subcostal "4-chamber" 2-dimensional echocardiogram and corresponding schematic drawing. The aneurysmal right pulmonary artery impinges on the left atrium and mimics cor triatriatum. A = anterior; L = left; LA = left atrium; LV = left ventricle; P = posterior; R = right; RA = right atrium; RPA = right pulmonary artery.

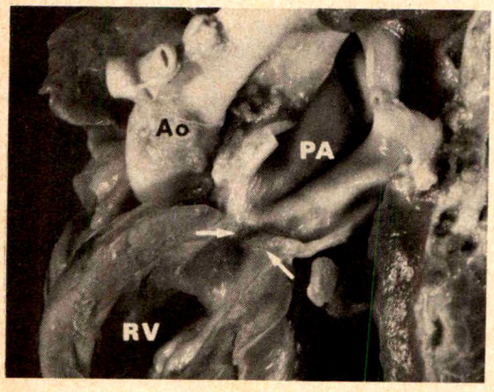

FIGURE 6. Case 2. Specimen of the heart showing opened right ventricle and pulmonary artery. The pulmonary valve is absent. At the pulmonary anulus a circumferential ridge (**arrows**) of fibrous tissue is present. The pulmonary anulus is narrowed. Main and right pulmonary arteries are aneurysmally dilated. Ao = ascending aorta; PA = pulmonary artery; RV = right ventricle.

echocardiogram. A well-developed crista supraventricularis slightly obstructed the infundibulum. The pulmonary valve was replaced by a continuous fibrous ridge inserted on a stenotic anulus which measured 1.5 cm in circumference (Fig. 6). Marked dilatation of the main and right pulmonary arteries was present. The right pulmonary artery impinged on the left atrium and compressed the right main stem bronchus. Multiple calcified foci were present in the myocardium including the ventricular septum.

In each of our 2 patients with absent pulmonary valve, the 2-D echocardiogram demonstrated marked enlargement of the pulmonary arteries and the presence of thick ridges instead of fully developed pulmonary valve leaflets. The echocardiographic image of the dysplastic and rudimentary pulmonary valve elements was best shown in the short-axis view at the left sternal border. The ridges extended a few millimeters into the lumen of the pulmonary artery and did not have the typical motion of a pulmonary valve leaflet.

A few reports have dealt with echocardiography in congenital absence of the pulmonary valve[2–4] in tetralogy of Fallot. Cheatham et al[4] reported on 9 infants with tetralogy of Fallot and absent pulmonary valve, in 6 of whom 2-D echocardiograms were obtained. These investigators suggest that echocardiographic findings of abnormal interventricular septal motion, right ventricular dilatation, aneurysmal dilatation of the pulmonary arteries, and overriding aorta appear to be unique echocardiographic features of this syndrome.

The limitations of suggested echocardiographic criteria and possible diagnostic pitfalls are exemplified by our own cases. Although many features described by Cheatham's group were present in our 2 patients, neither infant had abnormal ventricular septal motion, although marked pulmonary regurgitation was apparently present in our Case 2. Moreover, the presence of calcium in the ventricular myocardium of this patient suggests the possibility that he may have had cardiac failure with myocardial necrosis in utero secondary to severe pulmonary regurgitation.

Of particular interest, the dilated right pulmonary artery in Case 2 impinged on the left atrial wall. This pathologic change caused a peculiar appearance of the 2-D echocardiographic subcostal 4-chamber view. On this view, the left atrium appeared to be partitioned by a membrane yielding an echocardiographic image mimicking that of cor triatriatum.[5] However, the absence of a fenestration in the "membrane" and the demonstration that the posterior "chamber" was, in fact, the right pulmonary artery led to the correct diagnosis.

Thus, a precise image of the anatomic features of congenital absence of the pulmonary valve in tetralogy of Fallot can be obtained by 2-D echocardiography. Our cases demonstrate that one cannot confidently rely on the presence of abnormal septal motion to suggest the diagnosis of absent pulmonary valve in tetralogy of Fallot. The echocardiographic diagnosis should rely on the direct demonstration of all the anatomic lesions, including the appearance of ridges at the pulmonary anulus representing rudimentary pulmonary valvular tissue.

False Aneurysm of Mitral-Aortic Intervalvular Fibrosa: Diagnosis by 2-Dimensional Contrast Echocardiography at Cardiac Catheterization

Cheryl L. Reid, MD
Charles McKay, MD
David T. Kawanishi, MD
Charles Edwards, MD
Shahbudin H. Rahimtoola, MB, FRCP
P. Anthony N. Chandraratna, MD, MRCP

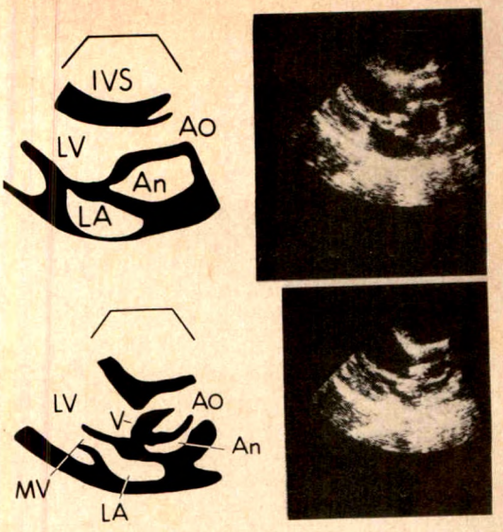

FIGURE 1. Parasternal long-axis view shows the aneurysmal sac (An) as an echo-free space between the posterior aortic wall (Ao) and the left atrium (LA). The aneurysm appears to increase in size during systole (**upper panel**) and to decrease in size during diastole (**lower panel**) as shown by the simultaneously recorded electrocardiogram. A large aortic valve vegetation (V) prolapses into the left ventricle (LV) during diastole (**lower panel**). The anterior leaflet of the mitral valve (MV) has an abnormal bulge at the base present during diastole (**lower panel**). IVS = interventricular septum.

False aneurysm of the mitral-aortic intervalvular fibrosa may occur as a complication of aortic valve infective endocarditis.[1] These aneurysms may rupture causing death, may develop thrombi that may embolize, and may cause detachment of the aortic or mitral valve.[1,2] Accurate and early diagnosis is important for successful surgical therapy. We describe a patient in whom the diagnosis was made before surgery by contrast 2-dimensional (2-D) echocardiography.

A 28-year-old man had symptoms of night sweats for 6 weeks. Aortic systolic ejection and early diastolic murmurs (both grade 3/6) were heard; an S_3 gallop was present. Blood cultures grew group D enterococcus; he was treated with intravenous ampicillin and gentamicin. On 2-D echocardiography, a large aortic valve vegetation was seen prolapsing into the left ventricle. A large aneurysmal sac was present between the posterior aortic wall and the left atrium, which expanded during systole (Fig. 1, upper panel) and decreased during diastole (Fig. 1, lower panel). The left ventricle was dilated. Peripheral venous 2-D contrast echocardiography was unremarkable. At catheterization, right heart pressure and blood oxygen saturation were within normal limits. The presence of severe aortic regurgitation was confirmed. Contrast 2-D echocardiography, performed through the intracardiac catheter, demonstrated that the aneurysmal sac filled from the left ventricle and not from the aorta, and no mitral regurgitation was seen (Fig. 2). The origin of the aneurysm, demonstrated by 2-D contrast echocardiography, was later confirmed by cineangiography. During surgery, the aortic valve was bicuspid and extensively destroyed by vegetation. The ostium of the false aneurysm measured 2 × 2 cm and was located beneath the aortic valve noncoronary cusp in the fibrous continuity between the mitral and aortic valves. The false aneurysm extended onto the superior aspect of the left atrium, ending in a blind pouch. The mitral valve was normal. The opening of the false aneurysm was closed and the aortic valve replaced with a bioprosthesis. Postoperative echocardiography showed the region of the aneurysm to be indistinct, probably because of thrombus formation. Contrast echocardiography performed through the left atrial line showed no filling of the false aneurysm by the contrast material, confirming the security of the surgical closure.

Aneurysms of the mitral-aortic intervalvular fibrosa are due to the spread of infection from the aortic valve. The intervalvular fibrosa attaches to the aortic root and to the anterior leaflet of the mitral valve. Perforation from infection in this area may cause an aneurysm to develop in the epicardial tissue between the aorta and

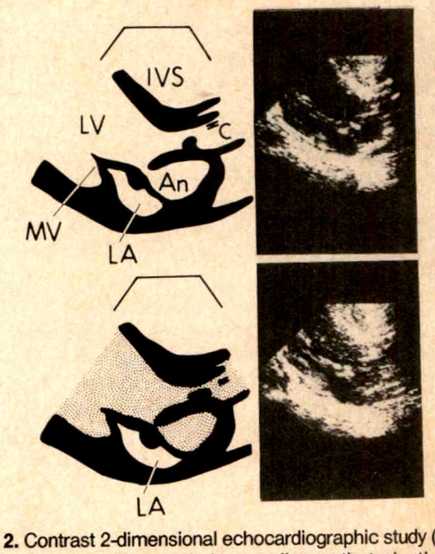

FIGURE 2. Contrast 2-dimensional echocardiographic study (parasternal long-axis views) performed during cardiac catheterization with the catheter (C) positioned in the aortic root (**upper panel**). The left ventricle (LV) filled with contrast during the first diastolic interval after injection. The aneurysm (An) then filled with the first systole after injection (**lower panel**). No contrast material is seen in the left atrium (LA). IVS = interventricular septum; MV = mitral valve.

Manuscript received February 4, 1983; revised manuscript received and accepted March 7, 1983.

left atrium which is in direct communication with the pericardial space.

Angiographic studies have been the standard method for detecting these aneurysms. However, precise definition of structures by angiography is difficult because the left ventricular outflow tract may be obscured by overlapping contrast-filled structures. In addition, the number of views is limited by the amount of contrast material that can be used in an individual patient. In our patient, contrast 2-D echocardiography was useful (1) to define that the aneurysm originated from the left side of the heart, (2) to demonstrate that the aneurysm filled from the left ventricle, and (3) to confirm obliteration of the aneurysm postoperatively. Two-dimensional echocardiography was particularly helpful because of the added spatial orientation. An echo-free space lying between the posterior aortic root and the left atrium expanded during systole. Contrast 2-D echocardiography was then used to define its relation to the intracardiac chambers. Our case, the first to describe an aneurysm of the mitral-aortic intervalvular fibrosa by 2-D echocardiography, demonstrates the usefulness of contrast 2-D echocardiography during cardiac catheterization in defining this "complex" cardiac lesion.

Acknowledgment: We acknowledge with gratitude the technical assistance of Michael Butler.

Platypnea and Interatrial Right-to-Left Shunting After Lobectomy

Robert M. Springer, MD

Platypnea is dyspnea in the upright position relieved in the supine position. This unusual symptom has been reported after pneumonectomy due to a new onset of right-to-left shunting through a previously unrecognized atrial septal defect or a patent foramen ovale in the absence of pulmonary hypertension.[1–5]

A 63-year-old man presented with cough and hoarseness. X-ray disclosed a mass in the lower lobe of the right lung, and aspiration biopsy disclosed adenocarcinoma. Right lower lobectomy was performed. He was readmitted to the hospital 4 months later for dyspnea. Electrocardiography revealed sinus tachycardia and nonspecific ST-T changes. At pulmonary angiography which was negative for emboli, the 7F pigtail catheter slipped repeatedly into the left atrium. It was apparent that the patient was dyspneic and cyanotic only when erect and was comfortable in the supine position. Arterial blood gases on 40% oxygen were: pH 7.42, partial pressure of carbon dioxide 29 mm Hg, partial pressure of oxygen 81 mm Hg in the supine position, and 7.44, 25 mm Hg, and 44 mm Hg, respectively, in the upright position. On 100% oxygen, partial pressure of oxygen was 56 mm Hg. The diagnosis of right-to-left shunt was made conclusively by contrast echocardiography. Boluses of 10 ml of saline solution were injected into the right atrium. Contrast echoes appeared in all 4 cardiac chambers only when the patient was in the sitting position (Fig. 1). Right-sided cardiac catheterization was performed (Table I). Oxygen saturation measurements (Table I) revealed a significant right-to-left atrial level shunt only in the upright position. The systemic-to-pulmonary flow ratio (Qs/Qp) was 2.1. Because the patient was confined to bed, being dyspneic and cyanotic only in the upright position, percutaneous closure of the defect was attempted using an umbrella prosthesis. The umbrella failed to fix to the atrial septum and migrated into

TABLE I Hemodynamics

	Supine	Sitting
Pressures (mm Hg)		
Right atrium (mean)	4	2
Right ventricle	20/3	17/2
Pulmonary artery	20/10	17/7
Pulmonary artery wedge	10	7
Oxygen saturations (%)		
Mixed venous	68	62
Pulmonary artery	69	64
Pulmonary vein	98	98
Radial artery	94	80
Qs/Qp	1.2	2.1

the left ventricle. Median sternotomy was performed. The heart and mediastinum were shifted to the right, but there was no compression on the cardiac chambers. A patent foramen ovale, which could be stretched to a diameter of 2.5 cm, was found. The umbrella prosthesis was extracted from the left ventricle and the atrial septal defect was closed. The patient did well postoperatively with the disappearance of platypnea and orthostatic cyanosis (on 100% oxygen the partial pressure of oxygen was 436 mm Hg in the upright position).

Five cases of new-onset interatrial right-to-left shunting after left or right pneumonectomy for carcinoma of the lung have been reported previously. A few months after pneumonectomy, each patient developed dyspnea, worse in the upright position. Although right-sided cardiac catheterization confirmed the diagnosis of right-to-left shunt, none of the patients had hemodynamic measurements in the upright position. At thoractomy a patent foramen ovale or a secundum type atrial septal defect was found and repaired, resulting in symptomatic relief. Our patient developed platypnea and orthostatic cyanosis after only lobectomy. Shunting was present only in the upright position and pulmonary hypertension was absent. New onset right-to-left shunting after pneumonectomy is rare. We suspect that the condition is probably more common than recognized because the shunt may be present only in the upright position. Physical examination and arterial blood gas studies performed in the supine position may be within normal limits. Our patient is the first reported with platypnea after only lobectomy in the presence of normal upright pulmonary arterial pressure. This condition can be diagnosed noninvasively and corrected surgically with complete symptomatic relief to the patient. The pathophysiologic aspects of this condition are poorly understood.

FAMILIAL AGGREGATION OF CORONARY HEART DISEASE AND ITS RELATION TO KNOWN GENETIC RISK FACTORS

Ten Kate et al[1] are to be congratulated for a thoughtful study on the relevance of family history, exclusive of traditional risk factors, to coronary heart disease (CAD). We recently examined this issue from a slightly different perspective and reached similar conclusions: that there is something related to family history and yet *not* tightly related to epidemiologically oriented risk factors which increases the risk of CAD.

We studied 204 men before angiography, characterizing them on a host of signs, symptoms, and risk factors.[2] We examined the association of these risk factors with the angiographically determined extent of CAD and then followed our patients for 1 year to determine the relation between risk factors and subsequent morbidity. As ten Kate et al noted, we found that a family history of heart disease (defined as onset of CAD in a parent or sibling before age 60) was of significant importance in predicting subsequent cardiac morbidity.[3] However, a family history of heart disease had an interesting relation to vessel disease per se. When we excluded the men free of significant CAD, we examined what risk factors might predict severe extensive CAD versus less extensive CAD in the remaining 171 patients. Family history alone was significantly associated ($p < 0.05$) with extensive CAD; no other risk factor bore a relation to extensive CAD.[4] With multiple regression analysis, the most important variables associated with extensive CAD were family history, age, smoking, and cholesterol (listed in declining order of importance).

These findings lend further support to ten Kate's findings that although there is a virulence associated with a family history of CAD, the pathophysiology of such a relation remains unclear.

COMPRESSION OF THE SUPERIOR VENA CAVA AND RIGHT ATRIUM IN CARDIAC TAMPONADE

We read with interest the article by Miller et al,[1] which carefully depicts the static (abnormal right atrial contour) and dynamic (caval compression) angiographic features in patients with pericardial tamponade. The finding of right atrial (RA) collapse by 2-dimensional echocardiography was particularly striking. However, our impression was that the latter finding was not specific for tamponade. Therefore, we retrospectively reviewed 22 consecutive echocardiographic studies on patients with moderate- or large-sized pericardial effusions. Clinical findings were reviewed as to the presence or absence of clinical tamponade (tachycardia >120 beats/min, hypotension and pulsus paradoxus >20 mm Hg). Echocardiographic studies were reviewed specifically as the size of the effusion, tachycardia, swinging motion, "a" kick dependent right ventricular (RV) filling,[2] RV compression (<5 mm), accentuated RA or left atrial (LA) wall motion with atrial systole ("a") and RA collapse, as described by Miller et al. The findings are shown in Table I.

We would, therefore, like to supplement the findings of Miller et al with the following: (1) RA collapse appears to be a sensitive sign for tamponade, but it lacks specificity in that it was present in 5 of 13 large effusions without tamponade, (2) RA collapse must be differentiated carefully from visualization of wall motion during atrial systole, which is common and due to the wall being "freed-up" by the effusion, (3) pericardial fluid behind the left atrium with visualization of LA systole is also common in large effusions (9 of 15 patients), and (4) as previously sited, "a" kick dependent RV filling appears to be the more specific sign for tamponade.

2. **Armstrong WF, Schilt BF, Helper DJ, Dillon JC, Feigenbaum H.** Diastolic collapse of the right ventricle with cardiac tamponade: an echocardiographic study. Circulation 1982;65:1491–1497.

REPLY: It is important to note that the 2-dimensional echocardiographic findings included in our report were drawn from a specifically selected group of patients with cardiac tamponade and, as such, cannot be used to define either the sensitivity or specificity of RA inversion as a marker of this hemodynamic phenomenon. These patients were simply included to further elucidate the mechanism of the reported angiographic phenomenon and to demonstrate that this same finding can be observed using a noninvasive imaging method. Although our patients were clearly selected for the presence of tamponade and therefore cannot be used to assess sensitivity or specificity, it is likewise clear that one cannot define the specificity with sufficiently narrow confidence intervals to distinguish an estimated 77% (10 of 13) specificity for RA "a" kick from an estimated 62% (8 of 13) specificity for RA collapse when these estimates are based on a study which includes only 2 true-positive cases. However, the observation of Pinero et al is useful for the design of future prospective studies.

SUBJECT INDEX: VOLUME 51

Action potential
Long-term recording of monophasic action potentials from human endocardium, 1629
Nature of "residual fast channel" dependent action potentials and slow conduction in guinea pig ventricular muscle and its modification by isoproterenol, 1433
Adenosine
Effect of atrial fibrillation on atrial blood flow in conscious dogs, 1722
Adolescence
R-wave amplitude change during aerobic exercise in hypertensive adolescents after treatment, 459
Symptomatic sick sinus syndrome in children and adolescents as the only manifestation of cardiac abnormality or associated with unoperated congenital heart disease, 1133
Adrenergic system
New developments in alpha-adrenergic receptor pharmacology: implications for the initial treatment of hypertension, 639
Amiodarone
Amiodarone therapy during pregnancy, 1231
Electrophysiologic testing in the management of survivors of out-of-hospital cardiac arrest, 85
Intravenous amiodarone in the acute treatment of recurrent symptomatic ventricular tachycardia, 156
Transesophageal pacing for prognostic evaluation of preexcitation syndrome and assessment of protective therapy, 513
Ventricular flutter during treatment with amiodarone, 609
Amyloidosis
Amyloidosis limited to small arteries causing angina pectoris and sudden death, 1234
Myocardial texture characterization by two-dimensional echocardiography, 817
Sensitivity of technetium-99m—pyrophosphate scintigraphy in diagnosing cardiac amyloidosis, 826
Aneurysms
Determinants of ventricular tachycardia in patients with coronary artery disease and ventricular aneurysm. Clinical, hemodynamic, and angiographic factors, 61
False aneurysm of mitral-aortic intervalvular fibrosa: diagnosis by 2-dimensional contrast echocardiography at cardiac catheterization, 1801
Improved cross-sectional echocardiographic technique for visualization of the retrocardiac descending aorta in its long axis. Normal findings and abnormalities in saccular and/or dissecting aneurysms, 1029
Massive right ventricular outflow tract aneurysm after ventriculotomy for subvalvular pulmonic stenosis associated with peripheral pulmonary arterial stenoses, 1460
Relation between site of origin of ventricular tachycardia and relative left ventricular myocardial perfusion and wall motion, 1329
Angina pectoris
AJC in June 1958, 1789
Amyloidosis limited to small arteries causing angina pectoris and sudden death, 1234
Anomalous right coronary artery: a surgically correctable cause of angina pectoris, 1235
Antianginal efficacy and improved exercise performance with timolol. Twice-daily beta blockade in ischemic heart disease, 13
Comparison of slow-release pindolol, standard pindolol, and propranolol in angina pectoris, 1062
Coronary dilatory capacity in idiopathic dilated cardiomyopathy: analysis of 16 patients, 1657
Effect of oral sustained-release nitroglycerin on exercise capacity in angina pectoris: dose-response relation and duration of action during double-blind crossover randomized acute therapy, 1595
Efficacy and safety of verapamil in patients with angina pectoris after 1 year of continuous, high-dose therapy, 1251
Exercise 2-dimensional echocardiography. Quantitation of left ventricular performance in patients with severe angina pectoris, 1
Frequency and importance of unprovoked coronary spasm in patients with angina pectoris undergoing percutaneous transluminal coronary angioplasty, 1067
Influence of partial sympathetic denervation on the results of myocardial revascularization in variant angina, 661
Intravenous nitroglycerin for the treatment of angina at rest unresponsive to standard nitrate therapy, 694
Nifedipine in chronic stable angina: a double-blind placebo-controlled crossover trial, 706
Prinzmetal's variant angina unresponsive to calcium-channel blocking drugs but responsive to combined calcium channel and beta-blocking drugs, 1792
Prolonged angina pectoris and persistent negative T waves in the precordial leads: response to atrial pacing and to methoxamine-induced hypertension, 1599
Regional coronary blood flow during relief of pacing-induced angina by nitroglycerin. Implications for mechanism of action, 19
Variable threshold exertional angina in patients with transient vasospastic myocardial ischemia. Repeat exercise test results and therapeutic implications, 397
Angiocardiography
Angiographic demonstration of coronary occlusion during spontaneous acute myocardial infarction and subsequent angiographically normal coronary arteries, 1227
Assessment of ventricular size and function in congenitally corrected transposition of the great arteries, 244
Determination of the angiographic appearance of coronary collateral vessels: the importance of supplying and recipient arteries, 434
Digital angiography in assessment of ventricular function and wall motion during pacing in patients with coronary artery disease, 668
Early detection of left ventricular dysfunction in chronic aortic regurgitation as assessed by contrast angiography, echocardiography, and rest and exercise scintigraphy, 1542
Equilibrium radionuclide gated angiography in patients with tricuspid regurgitation, 305
Evaluation of left ventricular performance using digital subtraction angiography, 837
Identification of septal ischemia during exercise by Q-wave analysis: correlation with coronary angiography, 440
Juxtaductal aortic coarctation. Analysis of 84 patients studied hemodynamically, angiographically, and morphologically after age 1 year, 537
Pulmonary vein wedge angiography: indications, results, and surgical correlates in 25 patients, 936
Quantitative angiographic and morphologic aspects of aortic valve atresia, 1705
Serial exercise testing up to 6 years after coronary bypass surgery: behavior of exercise parameters in groups with different degrees of revascularization determined by postoperative angiography, 1301
Sinus node coronary arteries studied with angiography, 749
Validation of the angiographic accuracy of digital left ventriculography, 224
Angiocardiography, radionuclide
Quantitation of aortic and mitral regurgitation in the pediatric population: evaluation by radionuclide angiocardiography, 252
Angioplasty
Coronary arterial rupture during coronary angioplasty, 902
Vessel wall arachidonate metabolism after angioplasty: possible mediators of postangioplasty vasospasm, 1441
Angioplasty, percutaneous transluminal coronary
Angiographic changes produced by percutaneous transluminal coronary angioplasty, 676
Frequency and importance of unprovoked coronary spasm in patients with angina pectoris undergoing percutaneous transluminal coronary angioplasty, 1067
Frequency in nonangioplasty patients of morphologic findings reported in coronary arteries treated with transluminal angioplasty, 689
Percutaneous transluminal angioplasty of congenital coarctation of the aorta, 562
Status of the major epicardial coronary arteries 80 to 150 days after percutaneous transluminal coronary angioplasty. Analysis of 3 necropsy patients, 81
Anthracycline
Clinical and morphologic cardiac findings

after anthracycline chemotherapy. Analysis of 64 patients studied at necropsy, 1167
Antiarrhythmic therapy
Biphasic nature of propranolol's microelectrophysiologic effects, 145
Hemodynamic effects of a new antiarrhythmic agent, flecainide (R-818), in coronary heart disease, 422
Intravenous amiodarone in the acute treatment of recurrent symptomatic ventricular tachycardia, 156
Possible contribution of encainide metabolites to the long-term antiarrhythmic efficacy of encainide, 1182
Antimyosin
Relation of immediate and delayed thallium-201 distribution to localization of iodine-125 antimyosin antibody in acute experimental myocardial infarction, 1428
Aorta
How should we describe hearts in which the aorta is connected to the right ventricle and the pulmonary trunk to the left ventricle? A matter for reason and logic, 911
Improved cross-sectional echocardiographic technique for visualization of the retrocardiac descending aorta in its long axis. Normal findings and abnormalities in saccular and/or dissecting aneurysms, 1029
Aortic arch
Two-dimensional echocardiographic recognition of the right aortic arch, 1507
Aortic atresia
Quantitative angiographic and morphologic aspects of aortic valve atresia, 1705
Aortic coarctation
Juxtaductal aortic coarctation. Analysis of 84 patients studied hemodynamically, angiographically, and morphologically after age 1 year, 537
Percutaneous transluminal angioplasty of congenital coarctation of the aorta, 562
Prognosis of symptomatic coarctation of the aorta in infancy, 299
Reoperation for isthmic coarctation of the aorta: follow-up of 26 patients, 1690
Results after repair of coarctation of the aorta beyond infancy: a 10 to 28 year follow-up with particular reference to late systemic hypertension, 1481
Aortic insufficiency
Radionuclide stroke count ratios for assessment of right and left ventricular volume overload in children, 261
Aortic regurgitation
Comparison of late degenerative changes in porcine bioprostheses in the mitral and aortic valve position in the same patient, 965
Coronary vascular reserve in left ventricular hypertrophy secondary to chronic aortic regurgitation, 315
Early detection of left ventricular dysfunction in chronic aortic regurgitation as assessed by contrast angiography, echocardiography, and rest and exercise scintigraphy, 1542
Effect of elevating the wrist on the radial pulse in aortic regurgitation: Corrigan revisited, 1551
Left ventricular volume and ejection fraction response to exercise in aortic regurgitation, 1379
Quantitation of aortic and mitral regurgitation in the pediatric population: evaluation by radionuclide angiocardiography, 252
Radionuclide ventriculographic study of adaptations to exercise in aortic regurgitation, 483
Regurgitation of prosthetic heart valves: dependence on heart rate and cardiac output, 321
Serial changes in left ventricular function after correction of chronic aortic regurgitation. Dependence on early changes in preload and subsequent regression of hypertrophy, 476
Aortic stenosis
Accuracy of 2-dimensional echocardiographic diagnosis of congenitally bicuspid aortic valve: echocardiographic-anatomic correlation in 115 patients, 1469
AJC in May 1958, 1455
Aortic valve systolic flutter as a screening test for severe aortic stenosis, 981
Comparison of late degenerative changes in porcine bioprostheses in the mitral and aortic valve position in the same patient, 965
Influence of aortic stenosis on the hemodynamic importance of coronary artery narrowing in dogs without left ventricular hypertrophy, 865
Left ventricular wall stress in compensated aortic stenosis in children, 946
Supravalvular aortic stenosis. A 20-year clinical perspective and experience with patch aortoplasty, 256
Aortic valve
Accuracy of 2-dimensional echocardiographic diagnosis of congenitally bicuspid aortic valve: echocardiographic-anatomic correlation in 115 patients, 1469
Aortic valve systolic flutter as a screening test for severe aortic stenosis, 981
Noninvasive diagnosis of aortic and mitral valve disease with pulsed-Doppler spectral analysis, 1122
Quantitative angiographic and morphologic aspects of aortic valve atresia, 1705
Serial changes in left ventricular function after correction of chronic aortic regurgitation. Dependence on early changes in preload and subsequent regression of hypertrophy, 476
Aortoplasty
Supravalvular aortic stenosis. A 20-year clinical perspective and experience with patch aortoplasty, 256
Apexcardiography
The apex impulse in mitral stenosis: graphic explanation of the palpable movements at the cardiac apex, 311
Arrhythmias
Cryosurgery for cardiac arrhythmias: acute and chronic effects on coronary arteries, 149
Effects of oral digoxin on ventricular ectopy and its relation to left ventricular function, 765
Electrophysiologic studies before and after myocardial revascularization in patients with life-threatening ventricular arrhythmias, 519
Fetal echocardiography. A tool for evaluation of in utero cardiac arrhythmias and monitoring of in utero therapy: analysis of 71 patients, 237
Hemodynamics and intracardiac conduction after operative repair of tetralogy of Fallot, 552
Late prognostic value of scintigraphic parameters of acute myocardial infarction size in complicated myocardial infarction without heart failure, 1045
Possible contribution of encainide metabolites to the long-term antiarrhythmic efficacy of encainide, 1182
Prosthetic mitral valve motion during cardiac dysrhythmias as determined by echocardiography, 996
Vulnerability of patients with obstructive hypertrophic cardiomyopathy to ventricular arrhythmia induction in the operating room. Analysis of 17 patients, 811
Arteries
Amyloidosis limited to small arteries causing angina pectoris and sudden death, 1234
Angiographic demonstration of coronary occlusion during spontaneous acute myocardial infarction and subsequent angiographically normal coronary arteries, 1227
Sinus node coronary arteries studied with angiography, 749
Aspirin
In vivo quantitation of platelet deposition on human peripheral arterial bypass grafts using indium-111-labeled platelets. Effect of dipyridamole and aspirin, 796
Trial of combined warfarin plus dipyridamole or aspirin therapy in prosthetic heart valve replacement: danger of aspirin compared with dipyridamole, 1537
Atherosclerosis
Cardiovascular disease in the very elderly. Analysis of 40 necropsy patients aged 90 years or over, 403
Frequency in nonangioplasty patients of morphologic findings reported in coronary arteries treated with transluminal angioplasty, 689
Atrial fibrillation
Effect of atrial fibrillation on atrial blood flow in conscious dogs, 1722
Effects of exercise and isoproterenol during atrial fibrillation in patients with Wolff-Parkinson-White syndrome, 1203
Electrophysiologic studies in atrial fibrillation. Slow conduction of premature impulses: a possible manifestation of the background for reentry, 122
Electrophysiologic testing in the management of patients with the Wolff-Parkinson-White syndrome and atrial fibrillation, 1623
Prevalence of submitral (anular) calcium and its correlates in a general population-based sample (the Framingham Study), 1375
Atrial function
Normal left atrial function determined by 2-dimensional echocardiography, 336
Prosthetic mitral valve motion during cardiac dysrhythmias as determined by echocardiography, 996
Atrial refractoriness
Enhanced parasympathetic tone shortens atrial refractoriness in man, 96

Atrial septal defect
Clinical follow-up study of paroxysmal supraventricular tachyarrhythmias after operative repair of a secundum type atrial septal defect in adults, 273
Right ventricular function in adults with pulmonary hypertension with and without atrial septal defect, 1144
Atrioventricular block
High-degree atrioventricular block after radiation therapy, 1233
Septal ischemia as a mechanism of complete atrioventricular block: demonstration by thallium scintigraphy, 1559
Atrioventricular canal
Cleft anterior leaflet of the mitral valve with intact septa. A study of 20 cases, 919
Subxyphoid 2-dimensional echocardiographic identification of left ventricular papillary muscle anomalies in complete common atrioventricular canal, 1695
Atrioventricular conduction
Transvenous ablation of the atrioventricular conduction system in dogs: electrophysiologic and histologic observations, 1775
Atrioventricular node
Cardiac electrophysiologic effects of flecainide acetate for paroxysmal reentrant junctional tachycardias, 770
Supraventricular nonreentrant tachycardia due to simultaneous conduction through dual atrioventricular nodal pathways, 897
Atrium, left
Cysts in left atrial myxomas identified by transesophageal cross-sectional echocardiography, 1793
Left atrial mass: diagnostic value of transesophageal 2-dimensional echocardiography and indium-111 platelet scintigraphy, 1563
Atrium, right
Two-dimensional echocardiographic detection of right atrial thrombi, 615
Autonomic nervous system
Enhanced parasympathetic tone shortens atrial refractoriness in man, 96

Bed rest
Mechanisms for decreased exercise capacity after bed rest in normal middle-aged men, 344
Beta-adrenergic blockade
Alterations in left ventricular filling with beta-adrenergic blockade, 161
Antianginal efficacy and improved exercise performance with timolol. Twice-daily beta blockade in ischemic heart disease, 13
Biphasic nature of propranolol's microelectrophysiologic effects, 145
Comparative effects of beta-adrenergic blocking drugs on experimental ventricular fibrillation threshold, 1196
Effect of metoprolol on indirect signs of the size and severity of acute myocardial infarction, 1282
First ultra-short–acting beta-adrenergic blocking agent: its effect on size and segmental wall dynamics of reperfused myocardial infarcts in dogs, 1759
Improved exercise ventilatory responses after training in coronary heart disease during long-term beta-adrenergic blockade, 755
New approaches to the therapy of mild hypertension, 621
Pindolol and propranolol in patients with angina pectoris and normal or near-normal ventricular function. Lack of influence of intrinsic sympathomimetic activity on global and segmental left ventricular function assessed by radionuclide ventriculography, 427
Prinzmetal's variant angina unresponsive to calcium-channel blocking drugs but responsive to combined calcium channel and beta-blocking drugs, 1792
Beta$_1$ adrenoreceptor agonist
Effects of a cardioselective beta$_1$ partial agonist (corwin) on left ventricular function and myocardial metabolism in patients with previous myocardial infarction, 1267
Biopsy
Clinical and morphologic cardiac findings after anthracycline chemotherapy. Analysis of 64 patients studied at necropsy, 1167
Blood cyst
Blood cyst of the papillary muscle. Clinical, echocardiographic and anatomic observations, 612
Blood flow
Bidirectional blood flow in angiographically normal coronary arteries, 1237
Can tracking of contrast echocardiographic targets be used to measure intracardiac flow velocities? 215
Diastolic synchronized retroperfusion versus reperfusion: effects on regional left ventricular function and myocardial blood flow during acute coronary occlusion in dogs, 1414
Influence of aortic stenosis on the hemodynamic importance of coronary artery narrowing in dogs without left ventricular hypertrophy, 865
Measurement of systemic and pulmonary blood flow and QP/QS ratio using Doppler and two-dimensional echocardiography, 952
Blood flow, atrial
Effect of atrial fibrillation on atrial blood flow in conscious dogs, 1722
Blood flow, coronary
Coronary blood flow during the development and regression of left ventricular hypertrophy in renovascular hypertensive rats, 1744
Coronary vascular reserve in left ventricular hypertrophy secondary to chronic aortic regurgitation, 315
Effect of intravenous and intracoronary nifedipine on coronary blood flow and myocardial oxygen consumption, 712
Effects of reduced coronary flow on thallium-201 accumulation and release in an in vitro rat heart preparation, 891
Regional coronary blood flow during relief of pacing-induced angina by nitroglycerin. Implications for mechanism of action, 19
Blood platelets
Indexes of intravascular hemolysis, quantification of coagulation factors, and platelet survival in patients with porcine heterograft valves, 489
Influence of intracoronary platelet aggregation on ventricular electrical properties during partial coronary artery stenosis, 596
In vivo quantitation of platelet deposition on human peripheral arterial bypass grafts using indium-111-labeled platelets. Effect of dipyridamole and aspirin, 796
Blood pressure
Predictability of blood pressure response to isometric stress, 787
Regional distribution of pulmonary blood volume: an index of pulmonary capillary wedge pressure determined from blood pool scintigraphy, 1404
Blood volume
Radionuclide-determined changes in pulmonary blood volume and thallium lung uptake in patients with coronary artery disease, 741
Regional distribution of pulmonary blood volume: an index of pulmonary capillary wedge pressure determined from blood pool scintigraphy, 1404
Books received
Books received, 1656

Calcium
Calcium phosphorus metabolism in dialysis patients with and without mitral anular calcium. Analysis of 30 patients, 497
Long-term failure rate and morphologic correlations in porcine bioprosthetic heart valves, 957
Prevalence of submitral (anular) calcium and its correlates in a general population-based sample (the Framingham Study), 1375
Calcium antagonists
Comparative effects of nifedipine, verapamil, and diltiazem on experimental pulmonary hypertension, 195
Comparison of the antithrombotic action of calcium antagonist drugs with dipyridamole in dogs, 591
Effects of verapamil on coronary hemodynamic function and vasomobility relative to its mechanism of antianginal action, 699
Efficacy and safety of verapamil in patients with angina pectoris after 1 year of continuous, high-dose therapy, 1251
Ergonovine provocation to assess efficacy of long-term therapy with calcium antagonists in Prinzmetal's variant angina, 684
Hemodynamic and myocardial performance characteristics after verapamil use in congestive heart failure, 1339
Immediate hemodynamic effects of a new calcium-channel blocking agent (nitrendipine) in essential hypertension, 783
Nifedipine in chronic stable angina: a double-blind placebo-controlled crossover trial, 706
Pharmacokinetic and pharmacodynamic effects of diltiazem, 1369
Prinzmetal's variant angina unresponsive to calcium-channel blocking drugs but responsive to combined calcium channel and beta-blocking drugs, 1792
Captopril
Long-term converting-enzyme inhibition as a guide to surgical curability of hypertension associated with renovascular disease, 1317
Quantitative differences in the hemodynamic effects of captopril and nitroprusside in severe chronic heart failure, 183

Cardiac arrest
Clinical evaluation of the internal automatic cardioverter-defibrillator in survivors of sudden cardiac death, 1608
Electrophysiologic testing in the management of survivors of out-of-hospital cardiac arrest, 85
Hyperkalemia and cardiac arrest from fluoride exposure during hemodialysis, 901
Terminal cardiac electrical activity in pediatric patients, 557
Cardiac catheterization
Analysis of surgical versus medical therapy in active complicated native valve infective endocarditis, 1650
False aneurysm of mitral-aortic intervalvular fibrosa: diagnosis by 2-dimensional contrast echocardiography at cardiac catheterization, 1801
Preoperative invasive testing in mitral stenosis: indications based on assessment of diagnostic yield, 1116
Cardiac conduction
Clinical and echocardiographic characteristics of patients with mitral anular calcification. Comparison with age- and sex-matched control subjects, 992
Cardiokymography
Cardiokymography during exercise testing: a new device for the detection of coronary artery disease and left ventricular wall motion abnormalities, 1307
Cardiomyopathy
AJC in May 1958, 1455
Cardiac localization of transvascular bioptome using 2-dimensional echocardiography, 219
Clinical and morphologic cardiac findings after anthracycline chemotherapy. Analysis of 64 patients studied at necropsy, 1167
Coronary dilatory capacity in idiopathic dilated cardiomyopathy: analysis of 16 patients, 1657
Hypertrophic obstructive cardiomyopathy: ten- to 21-year follow-up after partial septal myectomy, 1160
Quantitative morphologic findings of the myocardium in idiopathic dilated cardiomyopathy, 501
Regression of myocardial cellular hypertrophy with vasodilator therapy in chronic congestive heart failure associated with idiopathic dilated cardiomyopathy, 1392
Relation of electrocardiographic abnormalities and patterns of left ventricular hypertrophy identified by 2-dimensional echocardiography in patients with hypertrophic cardiomyopathy, 189
Significance of ventricular tachycardia in idiopathic dilated cardiomyopathy: observations in 35 patients, 507
Survival in men with severe chronic left ventricular failure due to either coronary heart disease or idiopathic dilated cardiomyopathy, 831
Vulnerability of patients with obstructive hypertrophic cardiomyopathy to ventricular arrhythmia induction in the operating room. Analysis of 17 patients, 811
Cathepsin D
Beneficial effects of ibuprofen in pacing-induced myocardial ischemia, 751
Chemotherapy
Clinical and morphologic cardiac findings after anthracycline chemotherapy. Analysis of 64 patients studied at necropsy, 1167
Chest pain
Implications of increased myocardial isoenzyme level in the presence of normal serum creatine kinase activity, 24
Children
Epicardial and endocardial activation in patients with endocardial cushion defect, 277
Left ventricular wall stress in compensated aortic stenosis in children, 946
Pulmonary vascular disease in secundum atrial septal defect in childhood, 265
Radionuclide stroke count ratios for assessment of right and left ventricular volume overload in children, 261
Structural changes in ventriculoaortic procine valved conduit implanted in a child, 1795
Symptomatic sick sinus syndrome in children and adolescents as the only manifestation of cardiac abnormality or associated with unoperated congenital heart disease, 1133
Clonidine
Clonidine in congestive heart failure: a vasodilator with negative inotropic effects, 791
Computed tomography
Evaluation of intracardiac thrombus with computed tomography, 843
Conduction
Nature of "residual fast channel" dependent action potentials and slow conduction in guinea pig ventricular muscle and its modification by isoproterenol, 1433
Congenital heart defects
Assessment of ventricular size and function in congenitally corrected transposition of the great arteries, 244
Cleft anterior leaflet of the mitral valve with intact septa. A study of 20 cases, 919
Fetal echocardiography. A tool for evaluation of in utero cardiac arrhythmias and monitoring of in utero therapy: analysis of 71 patients, 237
Impact of 2-dimensional echocardiography on the management of distressed newborns in whom cardiac disease is suspected, 288
Juxtaductal aortic coarctation. Analysis of 84 patients studied hemodynamically, angiographically, and morphologically after age 1 year, 537
Prognostic value of left ventricular size measured by echocardiography in infants with total anomalous pulmonary venous drainage, 1155
Rest and exercise ventricular function in adults with congenital ventricular septal defects, 293
Symptomatic sick sinus syndrome in children and adolescents as the only manifestation of cardiac abnormality or associated with unoperated congenital heart disease, 1133
The univentricular heart: combined 2-dimensional–pulsed Doppler (duplex) echocardiographic evaluation, 1149
Congenital heart disease
Familial congenital heart disease: how are the various types related? 942
Two-dimensional echocardiographic recognition of the right aortic arch, 1507
Congestive heart failure
Acute hemodynamic effects of endralazine: a new vasodilator for chronic refractory congestive heart failure, 1353
Association of hyponatremia with increased renin activity in chronic congestive heart failure: impact of diuretic therapy, 1635
Clonidine in congestive heart failure: a vasodilator with negative inotropic effects, 791
Congestive heart failure: a propitious time for intensified research, 603
Determinants of variable exercise performance among patients with severe left ventricular dysfunction, 52
Effects of discontinuing maintenance digoxin therapy in patients with ischemic heart disease and congestive heart failure in sinus rhythm, 1243
Efficacy of prazosin in the management of chronic congestive heart failure: a 6-month randomized, double-blind, placebo-controlled study, 1346
Failure of dobutamine to increase exercise capacity despite hemodynamic improvement in severe chronic heart failure, 177
Hemodynamic and myocardial performance characteristics after verapamil use in congestive heart failure, 1339
Hemodynamic effects of dibutyryl cyclic AMP in congestive heart failure, 1364
Intermittent, continuous outpatient dobutamine infusion in the management of congestive heart failure, 455
Quantitative differences in the hemodynamic effects of captopril and nitroprusside in severe chronic heart failure, 183
Regression of myocardial cellular hypertrophy with vasodilator therapy in chronic congestive heart failure associated with idiopathic dilated cardiomyopathy, 1392
Respiratory gas analysis during exercise as a noninvasive measure of lactate concentration in chronic congestive heart failure, 1639
Contrast media
Hemodynamic and electrocardiographic effects in man of a new nonionic contrast agent (iohexol): advantages over standard ionic agents, 1218
Validation of the angiographic accuracy of digital left ventriculography, 224
Coronary arteries
Bidirectional blood flow in angiographically normal coronary arteries, 1237
Cardiovascular disease in the very elderly. Analysis of 40 necropsy patients aged 90 years or over, 403
Compensatory cardiac mechanisms evoked by septal ischemia in dogs, 201
Cryosurgery for cardiac arrhythmias: acute and chronic effects on coronary arteries, 149
Determination of the angiographic appearance of coronary collateral vessels: the importance of supplying and recipient arteries, 434
Five coronary ostia: duplicate left anterior

descending and right conus coronary arteries, 1562
Frequency in nonangioplasty patients of morphologic findings reported in coronary arteries treated with transluminal angioplasty, 689
Relation of left ventricular mass to geometry of the proximal coronary arteries in the dog, 1728

Coronary arteries, epicardial
Status of the major epicardial coronary arteries 80 to 150 days after percutaneous transluminal coronary angioplasty. Analysis of 3 necropsy patients, 81

Coronary artery disease
AJC in May 1958, 1455
A more meaningful scoring system for determining the severity of coronary heart disease, 606
Angiographic changes produced by percutaneous transluminal coronary angioplasty, 676
Can noninvasive exercise test criteria identify patients with left main or 3-vessel coronary disease after a first myocardial infarction? 361
Cardiokymography during exercise testing: a new device for the detection of coronary artery disease and left ventricular wall motion abnormalities, 1307
Cardiovascular disease in the very elderly. Analysis of 40 necropsy patients aged 90 years or over, 403
Determinants of ventricular tachycardia in patients with coronary artery disease and ventricular aneurysm. Clinical, hemodynamic, and angiographic factors, 61
Differentiation between right and circumflex coronary artery disease on thallium myocardial perfusion scanning, 1052
Digital angiography in assessment of ventricular function and wall motion during pacing in patients with coronary artery disease, 668
Effect of coronary artery bypass grafting on subsequent hospitalization, 353
Effect of oral sustained-release nitroglycerin on exercise capacity in angina pectoris: dose-response relation and duration of action during double-blind crossover randomized acute therapy, 1595
Effects of a cardioselective $beta_1$ partial agonist (corwin) on left ventricular function and myocardial metabolism in patients with previous myocardial infarction, 1267
Effects of provocation on transcardiac thromboxane in patients with coronary artery disease, 727
Exercise versus cold temperature stimulation during radionuclide cineangiography: diagnostic accuracy in coronary artery disease, 1091
Hemodynamic effects of a new antiarrhythmic agent, flecainide (R-818), in coronary heart disease, 422
Importance of complete revascularization in performance of the coronary bypass operation, 7
Improved exercise ventilatory responses after training in coronary heart disease during long-term beta-adrenergic blockade, 755
Influence of aortic stenosis on the hemodynamic importance of coronary artery narrowing in dogs without left ventricular hypertrophy, 865
Ischemia-associated intraventricular conduction disturbances during exercise testing as a predictor of proximal left anterior descending coronary artery disease, 1098
Left and right ventricular function at rest and during bicycle exercise in the supine and sitting positions in normal subjects and patients with coronary artery disease. Assessment by radionuclide ventriculography, 36
Negative effects of diuretic drugs on metabolic risk factors for coronary heart disease: possible alternative drug therapies, 632
Predictors of dropout from cardiac exercise rehabilitation. Ontario Exercise-Heart Collaborative Study, 70
Prognostic and predictive value of exertional hypotension in suspected coronary heart disease, 1261
Programmed electrical stimulation of the heart in coronary artery disease, 531
Radionuclide-determined changes in pulmonary blood volume and thallium lung uptake in patients with coronary artery disease, 741
Relation of exercise to the recurrence rate of myocardial infarction in men. Ontario Exercise-Heart Collaborative Study, 65
Spectrum of global left ventricular responses to supine exercise. Limitation in the use of ejection fraction in identifying patients with coronary artery disease, 28
Survival in men with severe chronic left ventricular failure due to either coronary heart disease or idiopathic dilated cardiomyopathy, 831
The changing "natural history" of symptomatic coronary artery disease: basis versus bias, 449
Treadmill walking protocol for the diagnostic evaluation and exercise programming of cardiac patients, 1081
Variable threshold exertional angina in patients with transient vasospastic myocardial ischemia. Repeat exercise test results and therapeutic implications, 397

Coronary artery, left main
Myocardial reperfusion after acute occlusion of the left main coronary artery, 1791
Survival after sudden obstruction of the left main coronary artery, 900

Coronary artery occlusion
Effects of ortho-iodo sodium benzoate on acute myocardial ischemia, hemodynamic function, and infarct size after coronary artery occlusion in dogs, 1422
Sustained limitation of myocardial necrosis 24 hours after coronary artery occlusion: verapamil infusion in dogs with small myocardial infarcts, 1409

Coronary artery, right
Anomalous right coronary artery: a surgically correctable cause of angina pectoris, 1235
Enhanced detection of proximal right coronary artery stenosis with the additional analysis of right ventricular thallium-201 uptake in stress scintigrams, 1256
Myocardial ischemia in anomalous origin of the right coronary artery from the pulmonary trunk. Proof of a coronary steal, 610

Coronary flow
Effects of reduced coronary flow on thallium-201 accumulation and release in an in vitro rat heart preparation, 891
Determination of the angiographic appearance of coronary collateral vessels: the importance of supplying and recipient arteries, 434

Coronary spasm
Assessment of plexectomy in the treatment of severe coronary spasm in patients with normal coronary arteries, 1072
Frequency and importance of unprovoked coronary spasm in patients with angina pectoris undergoing percutaneous transluminal coronary angioplasty, 1067
Influence of partial sympathetic denervation on the results of myocardial revascularization in variant angina, 661

Corwin
Effects of a cardioselective $beta_1$ partial agonist (corwin) on left ventricular function and myocardial metabolism in patients with previous myocardial infarction, 1267

Creatine kinase
Enzymatic estimation of myocardial infarct size when early creatine kinase values are not available, 1294
Implications of increased myocardial isoenzyme level in the presence of normal serum creatine kinase activity, 24

Cryosurgery
Cryosurgery for cardiac arrhythmias: acute and chronic effects on coronary arteries, 149
Cryosurgery of the fetal ductus arteriosus, 1446

Cyanosis
Management of adults with congenital bidirectional cardiac shunts, cyanosis, and pulmonary vascular obstruction: successful operative repair in 3 patients, 1495

Death, sudden
Programmed electrical stimulation of the heart in coronary artery disease, 531
Ventricular electrical instability: a predictor of death after myocardial infarction, 75
Vulnerability of patients with obstructive hypertrophic cardiomyopathy to ventricular arrhythmia induction in the operating room. Analysis of 17 patients, 811

Defibrillator
Clinical evaluation of the internal automatic cardioverter-defibrillator in survivors of sudden cardiac death, 1608

Denervation
Sympathetic denervation limited to a region of acutely ischemic canine myocardium increases excitability threshold and duration of bipolar electrograms, 1768

Diastolic function
Left ventricular isovolumic pressure decay and diastolic mechanics after postextrasystolic potentiation and during exercise, 583

Dibutyryl cyclic AMP
Hemodynamic effects of dibutyryl cyclic AMP in congestive heart failure, 1364
Digoxin
Cardiac effects of treatment with quinidine and digoxin, alone and in combination, 777
Effects of discontinuing maintenance digoxin therapy in patients with ischemic heart disease and congestive heart failure in sinus rhythm, 1243
Effects of oral digoxin on ventricular ectopy and its relation to left ventricular function, 765
Tissue digoxin concentrations during the quinidine-digoxin interaction, 1717
Diltiazem
Comparative effects of nifedipine, verapamil, and diltiazem on experimental pulmonary hypertension, 195
Pharmacokinetic and pharmacodynamic effects of diltiazem, 1369
Dipyridamole
Comparison of the antithrombotic action of calcium antagonist drugs with dipyridamole in dogs, 591
In vivo quantitation of platelet deposition on human peripheral arterial bypass grafts using indium-111-labeled platelets. Effect of dipyridamole and aspirin, 796
Trial of combined warfarin plus dipyridamole or aspirin therapy in prosthetic heart valve replacement: danger of aspirin compared with dipyridamole, 1537
Disopyramide
Disopyramide: evaluation of electrophysiologic effects and clinical efficacy in patients with sustained ventricular tachycardia or ventricular fibrillation, 759
Effects of disopyramide on left ventricular function: assessment by radionuclide cineangiography, 1554
Diuretic drugs
Association of hyponatremia with increased renin activity in chronic congestive heart failure: impact of diuretic therapy, 1635
Effect of antihypertensive agents on lipid metabolism, 628
Negative effects of diuretic drugs on metabolic risk factors for coronary heart disease: possible alternative drug therapies, 632
New approaches to the therapy of mild hypertension, 621
Treating the patient with mild hypertension and renal insufficiency, 651
Dobutamine
Failure of dobutamine to increase exercise capacity despite hemodynamic improvement in severe chronic heart failure, 177
Intermittent, continuous outpatient dobutamine infusion in the management of congestive heart failure, 455
Doppler ultrasound
Measurement of systemic and pulmonary blood flow and QP/QS ratio using Doppler and two-dimensional echocardiography, 952
Noninvasive diagnosis of aortic and mitral valve disease with pulsed-Doppler spectral analysis, 1122
Noninvasive diagnosis of interrupted inferior vena cava: gated pulsed Doppler application, 1796
The univentricular heart: combined 2-dimensional–pulsed Doppler (duplex) echocardiographic evaluation, 1149
Down syndrome
Quantitative analysis of pulmonary vascular disease in simple cardiac anomalies with the Down syndrome, 1502
Drug therapy
Negative effects of diuretic drugs on metabolic risk factors for coronary heart disease: possible alternative drug therapies, 632
New choices for the initial drug therapy of hypertension, 1786

Echocardiography
Aortic valve systolic flutter as a screening test for severe aortic stenosis, 981
Assessment of the cardiac effects of hemodialysis with systolic time intervals and echocardiography, 332
Blood cyst of the papillary muscle. Clinical, echocardiographic and anatomic observations, 612
Can tracking of contrast echocardiographic targets be used to measure intracardiac flow velocities? 215
Cardiac disease after radiation therapy for Hodgkin's disease: analysis of 48 patients, 1679
Cardiovascular effects of a newly synthesized cardiotonic agent (TA-064) on normal and diseased hearts, 802
Clinical and echocardiographic characteristics of patients with mitral anular calcification. Comparison with age- and sex-matched control subjects, 992
Cysts in left atrial myxomas identified by transesophageal cross-sectional echocardiography, 1793
Detection and estimation of rheumatic mitral regurgitation in the presence of mitral stenosis by pulsed Doppler echocardiography, 986
Fetal echocardiography. A tool for evaluation of in utero cardiac arrhythmias and monitoring of in utero therapy: analysis of 71 patients, 237
Improved cross-sectional echocardiographic technique for visualization of the retrocardiac descending aorta in its long axis. Normal findings and abnormalities in saccular and/or dissecting aneurysms, 1029
Left atrial mass: diagnostic value of transesophageal 2-dimensional echocardiography and indium-111 platelet scintigraphy, 1563
Myocardial function in Rocky Mountain spotted fever: echocardiographic assessment, 341
Prevalence and correlates of posterior extra echocardiographic spaces in a free-living population based sample (the Framingham study), 1207
Prognostic value of left ventricular size measured by echocardiography in infants with total anomalous pulmonary venous drainage, 1155
Prosthetic mitral valve motion during cardiac dysrhythmias as determined by echocardiography, 996
Relation of hemodynamic load to left ventricular hypertrophy and performance in hypertension, 171
Subepicardial adipose tissue producing echocardiographic appearance of pericardial effusion. Documentation by computed tomography and necropsy, 565
The valve of the foramen ovale in interatrial right-to-left shunt: echocardiographic cineangiocardiographic and hemodynamic observations, 1489
Transient right atrial thrombus during acute myocardial infarction: diagnosis by echocardiography, 1228
Usefulness of echocardiographic right ventricular measurements in estimating right ventricular hypertrophy and right ventricular systolic pressure, 1036
Variability of digitized echocardiography: size, source, and means of reduction, 576
Ejection fraction
Alterations in left ventricular filling with beta-adrenergic blockade, 161
Analysis of ventricular emptying and filling indexes during acute increases in arterial pressure, 468
Beat-to-beat left ventricular performance in atrial fibrillation: radionuclide assessment with the computerized nuclear probe, 1189
Comparison of digital intravenous ventriculography with direct left ventriculography for quantitation of left ventricular volumes and ejection fractions, 1399
Increased left ventricular ejection fraction after a meal: potential source of error in performance of radionuclide angiography, 1709
Intracoronary thrombolysis in acute myocardial infarction: an attempt to quantitate its effect by comparison of enzymatic estimate of myocardial necrosis with left ventricular ejection fraction, 1573
Left and right ventricular function at rest and during bicycle exercise in the supine and sitting positions in normal subjects and patients with coronary artery disease. Assessment by radionuclide ventriculography, 36
Left ventricular volume and ejection fraction response to exercise in aortic regurgitation, 1379
Radionuclide analysis of peak filling rate, filling fraction, and time to peak filling rate. Response to supine bicycle exercise in normal subjects and patients with coronary disease, 43
Radionuclide ventriculographic study of adaptations to exercise in aortic regurgitation, 483
Spectrum of global left ventricular responses to supine exercise. Limitation in the use of ejection fraction in identifying patients with coronary artery disease, 28
Elderly patients
Cardiovascular disease in the very elderly. Analysis of 40 necropsy patients aged 90 years or over, 403
Electrical stimulation
Programmed electrical stimulation of the heart in coronary artery disease, 531
Ventricular electrical instability: a predictor of death after myocardial infarction, 75

Electrocardiography
Comparative rates of resolution of QRS changes after operative and nonoperative acute myocardial infarcts, 378
Conduction disturbances related to the site and severity of mitral anular calcification: a 2-dimensional echocardiographic and electrocardiographic correlative study, 1644
Determinants of the incidence and severity of ventricular arrhythmias in aortic valve disease, 1103
Electrocardiographic criteria for the diagnosis of combined inferior myocardial infarction and left anterior hemiblock, 718
Ergonovine provocation to assess efficacy of long-term therapy with calcium antagonists in Prinzmetal's variant angina, 684
Evaluation of a QRS scoring system for estimating myocardial infarct size: III. Correlation with quantitative anatomic findings for inferior infarcts, 382
Hemodynamic and electrocardiographic effects in man of a new nonionic contrast agent (iohexol): advantages over standard ionic agents, 1218
Identity and the electrocardiogram, with a note on twins and altered identities, 1784
Improved electrocardiographic criteria for the diagnosis of left anterior hemiblock, 723
Relation between late potentials on the body surface and directly recorded fragmented electrograms in patients with ventricular tachycardia, 105
Relation of electrocardiographic abnormalities and patterns of left ventricular hypertrophy identified by 2-dimensional echocardiography in patients with hypertrophic cardiomyopathy, 189
Electrophysiologic studies
Biphasic nature of propranolol's microelectrophysiologic effects, 145
Cardiac electrophysiologic effects of flecainide acetate for paroxysmal reentrant junctional tachycardias, 770
Cellular electrophysiologic abnormalities of diseased human ventricular myocardium, 137
Electrophysiologic mechanism of exercise-induced sustained ventricular tachycardia, 525
Electrophysiologic studies before and after myocardial revascularization in patients with life-threatening ventricular arrhythmias, 519
Electrophysiologic studies in atrial fibrillation. Slow conduction of premature impulses: a possible manifestation of the background for reentry, 122
Mexiletine for control of drug-resistant ventricular tachycardia: clinical and electrophysiologic results in 44 patients, 1175
Electrophysiologic testing
Electrophysiologic effects of lorcainide on the accessory pathway in the Wolff-Parkinson-White syndrome, 1618
Electrophysiologic testing in the management of survivors of out-of-hospital cardiac arrest, 85
Electrophysiologic testing in the management of patients with the Wolff-Parkinson-White syndrome and atrial fibrillation, 1623
Quinidine for ventricular arrhythmias: value of electrophysiologic testing, 90
Sustained ventricular tachycardia after repair of tetralogy of Fallot: new electrophysiologic findings, 1137
Transvenous ablation of the atrioventricular conduction system in dogs: electrophysiologic and histologic observations, 1775
Encainide
Possible contribution of encainide metabolites to the long-term antiarrhythmic efficacy of encainide, 1182
Endocardial cushion defect
Epicardial and endocardial activation in patients with endocardial cushion defect, 277
Endocardial fibroelastosis
AJC in June 1958, 1789
Endocarditis
Analysis of surgical versus medical therapy in active complicated native valve infective endocarditis, 1650
Long-term failure rate and morphologic correlations in porcine bioprosthetic heart valves, 957
Endocardium
Epicardial and endocardial activation in patients with endocardial cushion defect, 277
Long-term recording of monophasic action potentials from human endocardium, 1629
Endralazine
Acute hemodynamic effects of endralazine: a new vasodilator for chronic refractory congestive heart failure, 1353
Enzyme inhibition
Long-term converting-enzyme inhibition as a guide to surgical curability of hypertension associated with renovascular disease, 1317
Epicardium
Epicardial and endocardial activation in patients with endocardial cushion defect, 277
Epidemiologic studies
Prevalence and correlates of posterior extra echocardiographic spaces in a free-living population based sample (the Framingham study), 1207
Prevalence of submitral (anular) calcium and its correlates in a general population-based sample (the Framingham Study), 1375
Ergonovine maleate
Ergonovine provocation to assess efficacy of long-term therapy with calcium antagonists in Prinzmetal's variant angina, 684
Exercise
Comparative functional and physiologic status of active and dropout coronary bypass patients of a rehabilitation program, 1087
Comparison of slow-release pindolol, standard pindolol, and propranolol in angina pectoris, 1062
Effect of oral sustained-release nitroglycerin on exercise capacity in angina pectoris: dose-response relation and duration of action during double-blind crossover randomized acute therapy, 1595
Effects of exercise and isoproterenol during atrial fibrillation in patients with Wolff-Parkinson-White syndrome, 1203
Exercise intolerance in patients with chronic left heart failure: relation to oxygen transport and ventilatory abnormalities, 1358
Failure of dobutamine to increase exercise capacity despite hemodynamic improvement in severe chronic heart failure, 177
Left ventricular isovolumic pressure decay and diastolic mechanics after postextrasystolic potentiation and during exercise, 583
Left ventricular response to isometric exercise and its value in predicting the change in ventricular function after mitral valve replacement for mitral regurgitation, 1110
Nifedipine in chronic stable angina: a double-blind placebo-controlled crossover trial, 706
Prevalence and significance of an abnormal S-T segment response to exercise in a young athletic population, 1663
Radionuclide-determined changes in pulmonary blood volume and thallium lung uptake in patients with coronary artery disease, 741
Respiratory gas analysis during exercise as a noninvasive measure of lactate concentration in chronic congestive heart failure, 1639
Exercise testing
Antianginal efficacy and improved exercise performance with timolol. Twice-daily beta blockade in ischemic heart disease, 13
Can noninvasive exercise test criteria identify patients with left main or 3-vessel coronary disease after a first myocardial infarction? 361
Cardiac performance in thyrotoxicosis: analysis of 10 untreated patients, 349
Cardiokymography during exercise testing: a new device for the detection of coronary artery disease and left ventricular wall motion abnormalities, 1307
Determinants of variable exercise performance among patients with severe left ventricular dysfunction, 52
Effect of exercise protocol on the left ventricular response to exercise, 859
Effects of early postmyocardial infarction exercise testing on self-perception and subsequent physical activity, 1076
Electrophysiologic mechanism of exercise-induced sustained ventricular tachycardia, 525
Exercise 2-dimensional echocardiography. Quantitation of left ventricular performance in patients with severe angina pectoris, 1
Exercise-induced cardiac dysfunction in sickle cell anemia. A radionuclide study, 570
Exercise versus cold temperature stimulation during radionuclide cineangiography: diagnostic accuracy in coronary artery disease, 1091
Identification of septal ischemia during exercise by Q-wave analysis: correlation with coronary angiography, 440
Ischemia-associated intraventricular conduction disturbances during exercise testing as a predictor of proximal left anterior descending coronary artery disease, 1098
Left and right ventricular function at rest and during bicycle exercise in the

supine and sitting positions in normal subjects and patients with coronary artery disease. Assessment by radionuclide ventriculography, 36
Left ventricular volume and ejection fraction response to exercise in aortic regurgitation, 1379
Mechanisms for decreased exercise capacity after bed rest in normal middle-aged men, 344
Predictability of blood pressure response to isometric stress, 787
Predictors of dropout from cardiac exercise rehabilitation. Ontario Exercise-Heart Collaborative Study, 70
Radionuclide analysis of peak filling rate, filling fraction, and time to peak filling rate. Response to supine bicycle exercise in normal subjects and patients with coronary disease, 43
Radionuclide ventriculographic study of adaptations to exercise in aortic regurgitation, 483
Relation of exercise to the recurrence rate of myocardial infarction in men. Ontario Exercise-Heart Collaborative Study, 65
Role of myocardial ischemia in the genesis of stress-induced S-T segment elevation in previous anterior myocardial infarction, 1289
R-wave amplitude change during aerobic exercise in hypertensive adolescents after treatment, 459
Serial exercise testing up to 6 years after coronary bypass surgery: behavior of exercise parameters in groups with different degrees of revascularization determined by postoperative angiography, 1301
Spectrum of global left ventricular responses to supine exercise. Limitation in the use of ejection fraction in identifying patients with coronary artery disease, 28
Treadmill walking protocol for the diagnostic evaluation and exercise programming of cardiac patients, 1081
Variable threshold exertional angina in patients with transient vasospastic myocardial ischemia. Repeat exercise test results and therapeutic implications, 397

Flecainide acetate
Cardiac electrophysiologic effects of flecainide acetate for paroxysmal reentrant junctional tachycardias, 770
Hemodynamic effects of a new antiarrhythmic agent, flecainide (R-818), in coronary heart disease, 422
Fluoride
Hyperkalemia and cardiac arrest from fluoride exposure during hemodialysis, 901
Flurbiprofen
Effects of flurbiprofen in altering the size of myocardial infarcts in dogs: reduction or delay? 884
Foramen ovale
The valve of the foramen ovale in interatrial right-to-left shunt: echocardiographic cineangiocardiographic and hemodynamic observations, 1489
Framingham study
Prevalence and correlates of posterior extra echocardiographic spaces in a free-living population based sample (the Framingham study), 1207
Prevalence of submitral (anular) calcium and its correlates in a general population-based sample (the Framingham Study), 1375
Frank-Starling mechanism
Compensatory cardiac mechanisms evoked by septal ischemia in dogs, 201

Genetics
Familial congenital heart disease: how are the various types related? 942
Grafts
In vivo quantitation of platelet deposition on human peripheral arterial bypass grafts using indium-111-labeled platelets. Effect of dipyridamole and aspirin, 796

Heart block
Effect of local lidocaine anesthesia on ventricular escape intervals during permanent pacemaker implantation in patients with complete heart block, 101
Electrocardiographic criteria for the diagnosis of combined inferior myocardial infarction and left anterior hemiblock, 718
Improved electrocardiographic criteria for the diagnosis of left anterior hemiblock, 723
Heart failure
Exercise intolerance in patients with chronic left heart failure: relation to oxygen transport and ventilatory abnormalities, 1358
Hemodialysis
Assessment of the cardiac effects of hemodialysis with systolic time intervals and echocardiography, 332
Hemodynamics
Acute hemodynamic effects of endralazine: a new vasodilator for chronic refractory congestive heart failure, 1353
Cardiovascular effects of a newly synthesized cardiotonic agent (TA-064) on normal and diseased hearts, 802
Effects of ortho-iodo sodium benzoate on acute myocardial ischemia, hemodynamic function, and infarct size after coronary artery occlusion in dogs, 1422
Effects of verapamil on coronary hemodynamic function and vasomobility relative to its mechanism of antianginal action, 699
Failure of dobutamine to increase exercise capacity despite hemodynamic improvement in severe chronic heart failure, 177
Hemodynamic and electrocardiographic effects in man of a new nonionic contrast agent (iohexol): advantages over standard ionic agents, 1218
Hemodynamic and myocardial performance characteristics after verapamil use in congestive heart failure, 1339
Hemodynamic effects of a new antiarrhythmic agent, flecainide (R-818), in coronary heart disease, 422
Hemodynamic effects of dibutyryl cyclic AMP in congestive heart failure, 1364
Hemodynamics and intracardiac conduction after operative repair of tetralogy of Fallot, 552
Immediate hemodynamic effects of a new calcium-channel blocking agent (nitrendipine) in essential hypertension, 783
Influence of aortic stenosis on the hemodynamic importance of coronary artery narrowing in dogs without left ventricular hypertrophy, 865
Juxtaductal aortic coarctation. Analysis of 84 patients studied hemodynamically, angiographically, and morphologically after age 1 year, 537
Left ventricular end-systolic pressure-volume relation. A combined radionuclide and hemodynamic study, 1057
Quantitative differences in the hemodynamic effects of captopril and nitroprusside in severe chronic heart failure, 183
Regurgitation of prosthetic heart valves: dependence on heart rate and cardiac output, 321
Significance of ventricular tachycardia in idiopathic dilated cardiomyopathy: observations in 35 patients, 507
Survival in men with severe chronic left ventricular failure due to either coronary heart disease or idiopathic dilated cardiomyopathy, 831
Symptomatic, electrocardiographic, metabolic, and hemodynamic alterations during pacing-induced myocardial ischemia, 1589
Heterogeneity
Heterogeneity of left ventricular segmental wall thickening and excursion in 2-dimensional echocardiograms of normal human subjects, 1667
Hodgkin's disease
Cardiac disease after radiation therapy for Hodgkin's disease: analysis of 48 patients, 1679
High-degree atrioventricular block after radiation therapy, 1233
Hydralazine
Contrasting acute effects of vasodilators (nitroglycerin, nitroprusside, and hydralazine) on right ventricular performance in patients with chronic obstructive pulmonary disease and pulmonary hypertension: a combined radionuclide-hemodynamic study, 1682
Hyperkalemia
Hyperkalemia and cardiac arrest from fluoride exposure during hemodialysis, 901
Hypertension
Alterations in left ventricular filling with beta-adrenergic blockade, 161
Comparative effects of nifedipine, verapamil, and diltiazem on experimental pulmonary hypertension, 195
Coronary blood flow during the development and regression of left ventricular hypertrophy in renovascular hypertensive rats, 1744
Effectiveness of prazosin as initial antihypertensive therapy, 644
Effect of antihypertensive agents on lipid metabolism, 628
Immediate hemodynamic effects of a new calcium-channel blocking agent (nitrendipine) in essential hypertension, 783

Increased plasma concentrations of prostacyclin metabolite 6-keto-$PGF_{1\alpha}$ in essential hypertension. Influence of therapy with labetalol, 464
Intravascular volume, extracellular fluid volume, and total body water in obese and nonobese hypertensive patients, 165
Long-term converting-enzyme inhibition as a guide to surgical curability of hypertension associated with renovascular disease, 1317
Negative effects of diuretic drugs on metabolic risk factors for coronary heart disease: possible alternative drug therapies, 632
New approaches to the therapy of mild hypertension, 621
New choices for the initial drug therapy of hypertension, 1786
New developments in alpha-adrenergic receptor pharmacology: implications for the initial treatment of hypertension, 639
Nifedipine tablets for systemic hypertension: a study using continuous ambulatory intraarterial recording, 1323
Prolonged angina pectoris and persistent negative T waves in the precordial leads: response to atrial pacing and to methoxamine-induced hypertension, 1599
Relation of hemodynamic load to left ventricular hypertrophy and performance in hypertension, 171
Results after repair of coarctation of the aorta beyond infancy: a 10 to 28 year follow-up with particular reference to late systemic hypertension, 1481
R-wave amplitude change during aerobic exercise in hypertensive adolescents after treatment, 459
Treating the patient with mild hypertension and renal insufficiency, 651

Hypertension, pulmonary
Atrial septostomy as palliative therapy for refractory primary pulmonary hypertension, 1560
Pulmonary vascular disease in secundum atrial septal defect in childhood, 265
Quantitative analysis of pulmonary vascular disease in simple cardiac anomalies with the Down syndrome, 1502

Hypertrophic cardiomyopathy
Atrial systole and left ventricular filling in hypertrophic cardiomyopathy: effect of verapamil, 1386

Hypertrophy
Coronary blood flow during the development and regression of left ventricular hypertrophy in renovascular hypertensive rats, 1744
Coronary vascular reserve in left ventricular hypertrophy secondary to chronic aortic regurgitation, 315
Regression of myocardial cellular hypertrophy with vasodilator therapy in chronic congestive heart failure associated with idiopathic dilated cardiomyopathy, 1392
Relation of hemodynamic load to left ventricular hypertrophy and performance in hypertension, 171
Relation of left ventricular mass to geometry of the proximal coronary arteries in the dog, 1728
Serial changes in left ventricular function after correction of chronic aortic regurgitation. Dependence on early changes in preload and subsequent regression of hypertrophy, 476
Usefulness of echocardiographic right ventricular measurements in estimating right ventricular hypertrophy and right ventricular systolic pressure, 1036
Vulnerability of patients with obstructive hypertrophic cardiomyopathy to ventricular arrhythmia induction in the operating room. Analysis of 17 patients, 811

Hyperventilation
Transmural ischemia during preexercise hyperventilation, 613

Hyponatremia
Association of hyponatremia with increased renin activity in chronic congestive heart failure: impact of diuretic therapy, 1635

Hypotension
Prognostic and predictive value of exertional hypotension in suspected coronary heart disease, 1261

Ibuprofen
Beneficial effects of ibuprofen in pacing-induced myocardial ischemia, 751
Scar thinning due to ibuprofen administration after experimental myocardial infarction, 877

Imaging, cardiac blood pool
Absolute left ventricular volume from gated blood pool imaging with use of esophageal transmission measurement, 853

Infants
Impact of 2-dimensional echocardiography on the management of distressed newborns in whom cardiac disease is suspected, 288
Percutaneous transluminal angioplasty of congenital coarctation of the aorta, 562
Prognosis of symptomatic coarctation of the aorta in infancy, 299
Prognostic value of left ventricular size measured by echocardiography in infants with total anomalous pulmonary venous drainage, 1155
Pulmonary atresia with and without ventricular septal defect: a different etiology and pathogenesis for the atresia in the 2 types? 932
Supraventricular tachycardia in infants: use of the "diving reflex", 286

Infarction
Sustained limitation of myocardial necrosis 24 hours after coronary artery occlusion: verapamil infusion in dogs with small myocardial infarcts, 1409

Inotropy
Cardiovascular effects of a newly synthesized cardiotonic agent (TA-064) on normal and diseased hearts, 802
Clonidine in congestive heart failure: a vasodilator with negative inotropic effects, 791

Ischemia
Antianginal efficacy and improved exercise performance with timolol. Twice-daily beta blockade in ischemic heart disease, 13
Beneficial effects of ibuprofen in pacing-induced myocardial ischemia, 751
Compensatory cardiac mechanisms evoked by septal ischemia in dogs, 201
Coronary constriction by leukotriene C_4, D_4, and E_4 in the intact pig heart, 1451
Diastolic synchronized retroperfusion versus reperfusion: effects on regional left ventricular function and myocardial blood flow during acute coronary occlusion in dogs, 1414
Effects of discontinuing maintenance digoxin therapy in patients with ischemic heart disease and congestive heart failure in sinus rhythm, 1243
Effects of ortho-iodo sodium benzoate on acute myocardial ischemia, hemodynamic function, and infarct size after coronary artery occlusion in dogs, 1422
End-systolic dimension-wall thickness relations during myocardial ischemia in conscious dogs. A new approach for defining regional function, 1750
Exercise versus cold temperature stimulation during radionuclide cineangiography: diagnostic accuracy in coronary artery disease, 1091
Identification of septal ischemia during exercise by Q-wave analysis: correlation with coronary angiography, 440
Influence of intracoronary platelet aggregation on ventricular electrical properties during partial coronary artery stenosis, 596
Intravenous nitroglycerin for the treatment of angina at rest unresponsive to standard nitrate therapy, 694
Ischemia-associated intraventricular conduction disturbances during exercise testing as a predictor of proximal left anterior descending coronary artery disease, 1098
Myocardial ischemia in anomalous origin of the right coronary artery from the pulmonary trunk. Proof of a coronary steal, 610
Role of myocardial ischemia in the genesis of stress-induced S-T segment elevation in previous anterior myocardial infarction, 1289
Septal ischemia as a mechanism of complete atrioventricular block: demonstration by thallium scintigraphy, 1559
Sustained limitation of myocardial necrosis 24 hours after coronary artery occlusion: verapamil infusion in dogs with small myocardial infarcts, 1409
Sympathetic denervation limited to a region of acutely ischemic canine myocardium increases excitability threshold and duration of bipolar electrograms, 1768
Symptomatic, electrocardiographic, metabolic, and hemodynamic alterations during pacing-induced myocardial ischemia, 1589
Transmural ischemia during preexercise hyperventilation, 613
Variable threshold exertional angina in patients with transient vasospastic myocardial ischemia. Repeat exercise test results and therapeutic implications, 397

Isoproterenol
Effects of exercise and isoproterenol during atrial fibrillation in patients with Wolff-Parkinson-White syndrome, 1203
Nature of "residual fast channel" dependent action potentials and slow conduction in guinea pig ventricular muscle and its modification by isoproterenol, 1433

Pharmacologically induced changes in wall thickening dynamics and mid-ventricular volumes in dogs assessed by prospectively gated computed tomography, 1739

Kawasaki disease
Surgery for coronary heart disease due to mucocutaneous lymph node syndrome (Kawasaki disease). Report of 6 patients, 444

Labetalol
Comparative effects of beta-adrenergic blocking drugs on experimental ventricular fibrillation threshold, 1196
Increased plasma concentrations of prostacyclin metabolite 6-keto-$PGF_{1\alpha}$ in essential hypertension. Influence of therapy with labetalol, 464
Lactate
Respiratory gas analysis during exercise as a noninvasive measure of lactate concentration in chronic congestive heart failure, 1639
Left bundle branch block
Clinical spectrum of ventricular tachycardia with left bundle branch morphology, 113
Left ventricular filling
Atrial systole and left ventricular filling in hypertrophic cardiomyopathy: effect of verapamil, 1386
Left ventricular function
Left ventricular isovolumic pressure decay and diastolic mechanics after postextrasystolic potentiation and during exercise, 583
Left ventricular wall stress in compensated aortic stenosis in children, 946
Letters
Abnormal electrocardiograms in highly trained athletes, 1572
Aortocoronary bypass in asymptomatic or mildly symptomatic coronary patients, 1043
Apical hypertrophic cardiomyopathy, 1570
Atrioventricular nodal reentry, 1567
Blind reviews, 1041
Catheter defibrillation, 1566
Comparison of verapamil and nifedipine in chronic stable angina pectoris, 1566
Compression of the superior vena cava and right atrium in cardiac tamponade, 1804
Degeneration of antidromic tachycardia into atrial fibrillation in the Wolff-Parkinson-White syndrome, 1569
Discriminant function analysis using thallium-201 scintiscans and exercise stress variables to predict coronary heart disease, 1565
Enhancement of left ventricular function by glucose-insulin-potassium in acute myocardial infarction, 1041
Factors influencing left ventricular hypertrophy in systemic hypertension, 1044
Familial aggregation of coronary heart disease and its relation to known genetic risk factors, 1804
Follow-up of patients having either transvenous catheter ablation of the atrioventricular junction or direct surgical His bundle disruption, 1566
Functional consequences of right coronary artery originating from left sinus of Valsalva, 1241
Gerontologic pharmacology, 1041
Glucose-insulin-potassium infusion in acute myocardial infarction, 1566
Holter versus electrophysiologic studies in the management of malignant ventricular arrhythmias, 1464
Hyperprolactinemia-galactorrhea induced by verapamil, 1466
Import of exercise-induced ventricular arrhythmia in malignant ventricular arrhythmia, 1570
Intranodal conduction pathways in complete transposition of the great arteries, 1242
Knee-elbow position to detect the aortic diastolic murmur of aortic regurgitation, 918
Left ventricular aneurysm by angiogram: a problem of definition, 918
Polymorphous ventricular tachycardia, 1571
Prolongation of Q-T interval and increased amplitude of the T wave after termination of ventricular tachycardia, 1467
PTCA: need for prospective randomized controlled trials, 1467
Results of medical versus surgical treatment of unstable angina pectoris, 918
Sensitivity and specificity of M-mode echocardiographic signs of mitral valve prolapse, 1241
State of Maryland pacemaker experience (1979-1980): conflicting views regarding the frequency of unnecessary pacemaker implants, 1042
Sudden death in a marathon runner with origin of the right coronary artery from the left sinus of Valsalva, 1467
Term obliteration obsession (TOO), 1242
Ventricular activation time with left ventricular hypertrophy, 1571
Ventricular function before and after repair of tetralogy of Fallot, 1568
Leukotrienes
Coronary constriction by leukotriene C_4, D_4, and E_4 in the intact pig heart, 1451
Lidocaine
Effect of local lidocaine anesthesia on ventricular escape intervals during permanent pacemaker implantation in patients with complete heart block, 101
Lipoma
Lipoma of the mitral valve and papillary muscle, 1459
Lobectomy
Platypnea and interatrial right-to-left shunting after lobectomy, 1802
Lorcainide
Electrophysiologic effects of lorcainide on the accessory pathway in the Wolff-Parkinson-White syndrome, 1618

Maprotiline
Q-T prolongation and torsades de pointes ventricular tachycardia produced by the tetracyclic antidepressant agent maprotiline, 904
Methoxamine
Prolonged angina pectoris and persistent negative T waves in the precordial leads: response to atrial pacing and to methoxamine-induced hypertension, 1599
Metoprolol
Comparative effects of beta-adrenergic blocking drugs on experimental ventricular fibrillation threshold, 1196
Effect of metoprolol on indirect signs of the size and severity of acute myocardial infarction, 1282
Mexiletine
Mexiletine for control of drug-resistant ventricular tachycardia: clinical and electrophysiologic results in 44 patients, 1175
Microspheres
Relation of immediate and delayed thallium-201 distribution to localization of iodine-125 antimyosin antibody in acute experimental myocardial infarction, 1428
Mitral anular calcification
Clinical and echocardiographic characteristics of patients with mitral anular calcification. Comparison with age- and sex-matched control subjects, 992
Conduction disturbances related to the site and severity of mitral anular calcification: a 2-dimensional echocardiographic and electrocardiographic correlative study, 1644
Morphologic features of the normal and abnormal mitral valve, 1005
Mitral anular disease
Calcium phosphorus metabolism in dialysis patients with and without mitral anular calcium. Analysis of 30 patients, 497
Mitral regurgitation
Comparison of late degenerative changes in porcine bioprostheses in the mitral and aortic valve position in the same patient, 965
Detection and estimation of rheumatic mitral regurgitation in the presence of mitral stenosis by pulsed Doppler echocardiography, 986
Isolated cleft mitral valve: a variety of congenital mitral regurgitation identified by 2-dimensional echocardiography, 927
Left ventricular response to isometric exercise and its value in predicting the change in ventricular function after mitral valve replacement for mitral regurgitation, 1110
Morphologic features of the normal and abnormal mitral valve, 1005
Quantitation of aortic and mitral regurgitation in the pediatric population: evaluation by radionuclide angiocardiography, 252
Surgery for coronary heart disease due to mucocutaneous lymph node syndrome (Kawasaki disease). Report of 6 patients, 444
Mitral stenosis
Detection and estimation of rheumatic mitral regurgitation in the presence of mitral stenosis by pulsed Doppler echocardiography, 986
Morphologic features of the normal and abnormal mitral valve, 1005
Preoperative invasive testing in mitral stenosis: indications based on assessment of diagnostic yield, 1116
The apex impulse in mitral stenosis: graphic explanation of the palpable movements at the cardiac apex, 311

Mitral valve
Cleft anterior leaflet of the mitral valve with intact septa. A study of 20 cases, 919
Evaluation of intracardiac thrombus with computed tomography, 843
Isolated cleft mitral valve: a variety of congenital mitral regurgitation identified by 2-dimensional echocardiography, 927
Left ventricular response to isometric exercise and its value in predicting the change in ventricular function after mitral valve replacement for mitral regurgitation, 1110
Lipoma of the mitral valve and papillary muscle, 1459
Prosthetic mitral valve motion during cardiac dysrhythmias as determined by echocardiography, 996
Real-time 2-dimensional echocardiographic visualization of thrombus on a Bjork-Shiley mitral valve prosthesis. Emergency cesarean section and mitral valve replacement in late pregnancy, 908

Mitral valve disease
Cardiovascular disease in the very elderly. Analysis of 40 necropsy patients aged 90 years or over, 403
Morphologic features of the normal and abnormal mitral valve, 1005
Noninvasive diagnosis of aortic and mitral valve disease with pulsed-Doppler spectral analysis, 1122

M-mode echocardiography
M-mode and 2-dimensional echocardiographic characteristics of the Ionescu-Shiley valve in the mitral and aortic positions, 973
Prevalence and significance of an abnormal S-T segment response to exercise in a young athletic population, 1663

Mucocutaneous lymph node syndrome
Surgery for coronary heart disease due to mucocutaneous lymph node syndrome (Kawasaki disease). Report of 6 patients, 444

Myectomy
Hypertrophic obstructive cardiomyopathy: ten- to 21-year follow-up after partial septal myectomy, 1160

Myocardial infarction
AJC in June 1958, 1789
Angiographic demonstration of coronary occlusion during spontaneous acute myocardial infarction and subsequent angiographically normal coronary arteries, 1227
Angiographic evidence of hemorrhagic myocardial infarction after intracoronary thrombolysis with streptokinase, 906
Can noninvasive exercise test criteria identify patients with left main or 3-vessel coronary disease after a first myocardial infarction? 361
Cardiovascular disease in the very elderly. Analysis of 40 necropsy patients aged 90 years or over, 403
Comparative rates of resolution of QRS changes after operative and nonoperative acute myocardial infarcts, 378
Dynamic evaluation of prognosis from time-dépendent variables in acute myocardial infarction, 1579
Effect of metoprolol on indirect signs of the size and severity of acute myocardial infarction, 1282
Effects of a cardioselective beta$_1$ partial agonist (corwin) on left ventricular function and myocardial metabolism in patients with previous myocardial infarction, 1267
Effects of early postmyocardial infarction exercise testing on self-perception and subsequent physical activity, 1076
Effects of flurbiprofen in altering the size of myocardial infarcts in dogs: reduction or delay? 884
Electrocardiographic criteria for the diagnosis of combined inferior myocardial infarction and left anterior hemiblock, 718
Enzymatic estimation of myocardial infarct size when early creatine kinase values are not available, 1294
Evaluation of a QRS scoring system for estimating myocardial infarct size. III. Correlation with quantitative anatomic findings for inferior infarcts, 382
Evaluation of intracardiac thrombus with computed tomography, 843
First ultra-short–acting beta-adrenergic blocking agent: its effect on size and segmental wall dynamics of reperfused myocardial infarcts in dogs, 1759
Implications of increased myocardial isoenzyme level in the presence of normal serum creatine kinase activity, 24
Intracoronary thrombolysis in acute myocardial infarction: an attempt to quantitate its effect by comparison of enzymatic estimate of myocardial necrosis with left ventricular ejection fraction, 1573
Late prognostic value of scintigraphic parameters of acute myocardial infarction size in complicated myocardial infarction without heart failure, 1045
Mechanisms of spontaneous and induced ventricular arrhythmias in the 24-hour infarcted dog heart, 207
Papillary muscle rupture complicating acute myocardial infarction: analysis of 17 patients, 373
Precordial S-T segment depression in inferior myocardial infarction. Evaluation by quantitative thallium-201 scintigraphy and technetium-99m ventriculography, 734
Predictors of dropout from cardiac exercise rehabilitation. Ontario Exercise-Heart Collaborative Study, 70
Prevalence and prognosis after a first nontransmural myocardial infarction, 1584
Quantitative detection of regional left ventricular contraction abnormalities by 2-dimensional echocardiography. Comparison of myocardial thickening and thinning and endocardial motion in a canine model, 1732
Relation of exercise to the recurrence rate of myocardial infarction in men. Ontario Exercise-Heart Collaborative Study, 65
Relation of immediate and delayed thallium-201 distribution to localization of iodine-125 antimyosin antibody in acute experimental myocardial infarction, 1428
Relation of segmental wall motion to global left ventricular function in acute myocardial infarction, 1275
Role of myocardial ischemia in the genesis of stress-induced S-T segment elevation in previous anterior myocardial infarction, 1289
Scar thinning due to ibuprofen administration after experimental myocardial infarction, 877
Segmental right ventricular function after acute myocardial infarction: two-dimensional echocardiographic study in 63 patients, 390
Topographic changes in the left ventricle after experimentally induced myocardial infarction in the rat, 872
Transient right atrial thrombus during acute myocardial infarction: diagnosis by echocardiography, 1228
Ventricular electrical instability: a predictor of death after myocardial infarction, 75

Myocardial perfusion
Differentiation between right and circumflex coronary artery disease on thallium myocardial perfusion scanning, 1052
Relation between site of origin of ventricular tachycardia and relative left ventricular myocardial perfusion and wall motion, 1329

Myocardial reperfusion
Myocardial reperfusion after acute occlusion of the left main coronary artery, 1791

Myocardial texture
Myocardial texture characterization by two-dimensional echocardiography, 817

Myocarditis
Cardiac localization of transvascular bioptome using 2-dimensional echocardiography, 219
Myocardial function in Rocky Mountain spotted fever: echocardiographic assessment, 341

Myocardium
Cellular electrophysiologic abnormalities of diseased human ventricular myocardium, 137
Intracoronary thrombolysis in acute myocardial infarction: an attempt to quantitate its effect by comparison of enzymatic estimate of myocardial necrosis with left ventricular ejection fraction, 1573
Myocardial texture characterization by two-dimensional echocardiography, 817
Quantitative detection of regional left ventricular contraction abnormalities by 2-dimensional echocardiography. Comparison of myocardial thickening and thinning and endocardial motion in a canine model, 1732
Quantitative morphologic findings of the myocardium in idiopathic dilated cardiomyopathy, 501
Sympathetic denervation limited to a region of acutely ischemic canine myocardium increases excitability threshold and duration of bipolar electrograms, 1768

Nifedipine
Comparative effects of nifedipine, verapamil, and diltiazem on experimental pulmonary hypertension, 195
Comparison of the antithrombotic action of calcium antagonist drugs with dipyridamole in dogs, 591

Effect of intravenous and intracoronary nifedipine on coronary blood flow and myocardial oxygen consumption, 712
Nifedipine in chronic stable angina: a double-blind placebo-controlled crossover trial, 706
Nifedipine tablets for systemic hypertension: a study using continuous ambulatory intraarterial recording, 1323

Nitrendipine
Immediate hemodynamic effects of a new calcium-channel blocking agent (nitrendipine) in essential hypertension, 783

Nitroglycerin
Antianginal efficacy and improved exercise performance with timolol. Twice-daily beta blockade in ischemic heart disease, 13
Contrasting acute effects of vasodilators (nitroglycerin, nitroprusside, and hydralazine) on right ventricular performance in patients with chronic obstructive pulmonary disease and pulmonary hypertension: a combined radionuclide-hemodynamic study, 1682
Effect of oral sustained-release nitroglycerin on exercise capacity in angina pectoris: dose-response relation and duration of action during double-blind crossover randomized acute therapy, 1595
Exercise 2-dimensional echocardiography. Quantitation of left ventricular performance in patients with severe angina pectoris, 1
Intravenous nitroglycerin for the treatment of angina at rest unresponsive to standard nitrate therapy, 694
Regional coronary blood flow during relief of pacing-induced angina by nitroglycerin. Implications for mechanism of action, 19

Nitroprusside
Contrasting acute effects of vasodilators (nitroglycerin, nitroprusside, and hydralazine) on right ventricular performance in patients with chronic obstructive pulmonary disease and pulmonary hypertension: a combined radionuclide-hemodynamic study, 1682
Quantitative differences in the hemodynamic effects of captopril and nitroprusside in severe chronic heart failure, 183

Nuclear medicine
Beat-to-beat left ventricular performance in atrial fibrillation: radionuclide assessment with the computerized nuclear probe, 1189

Obesity
Intravascular volume, extracellular fluid volume, and total body water in obese and nonobese hypertensive patients, 165

Ortho-iodo sodium benzoate
Effects of ortho-iodo sodium benzoate on acute myocardial ischemia, hemodynamic function, and infarct size after coronary artery occlusion in dogs, 1422

Oxygen
Comparative functional and physiologic status of active and dropout coronary bypass patients of a rehabilitation program, 1087
Effect of intravenous and intracoronary nifedipine on coronary blood flow and myocardial oxygen consumption, 712
Effects of ortho-iodo sodium benzoate on acute myocardial ischemia, hemodynamic function, and infarct size after coronary artery occlusion in dogs, 1422
Exercise intolerance in patients with chronic left heart failure: relation to oxygen transport and ventilatory abnormalities, 1358
Improved exercise ventilatory responses after training in coronary heart disease during long-term beta-adrenergic blockade, 755
Respiratory gas analysis during exercise as a noninvasive measure of lactate concentration in chronic congestive heart failure, 1639
Treadmill walking protocol for the diagnostic evaluation and exercise programming of cardiac patients, 1081

Pacemakers
Effect of local lidocaine anesthesia on ventricular escape intervals during permanent pacemaker implantation in patients with complete heart block, 101
Fatal small bowel obstruction after pacemaker generator implantation in the abdominal wall, 1561
Problems in health data analysis: the Maryland permanent pacemaker experience in 1979 and 1980, 131

Pacing, atrial
Digital angiography in assessment of ventricular function and wall motion during pacing in patients with coronary artery disease, 668
Left ventricular end-systolic pressure-volume relation. A combined radionuclide and hemodynamic study, 1057
Prolonged angina pectoris and persistent negative T waves in the precordial leads: response to atrial pacing and to methoxamine-induced hypertension, 1599
Symptomatic, electrocardiographic, metabolic, and hemodynamic alterations during pacing-induced myocardial ischemia, 1589

Pacing, cardiac
Ultrarapid single-capture train stimulation for termination of ventricular tachycardia, 1334

Pacing, esophageal
Transesophageal pacing for prognostic evaluation of preexcitation syndrome and assessment of protective therapy, 513

Papillary muscle
Blood cyst of the papillary muscle. Clinical, echocardiographic and anatomic observations, 612
Lipoma of the mitral valve and papillary muscle, 1459
Papillary muscle rupture complicating acute myocardial infarction: analysis of 17 patients, 373

Patent ductus arteriosus
Cryosurgery of the fetal ductus arteriosus, 1446

Pediatric cardiology
Impact of 2-dimensional echocardiography on the management of distressed newborns in whom cardiac disease is suspected, 288
Quantitation of aortic and mitral regurgitation in the pediatric population: evaluation by radionuclide angiocardiography, 252
Supraventricular tachycardia in infants: use of the "diving reflex", 286
Terminal cardiac electrical activity in pediatric patients, 557

Pericardial bleeding
Noninvasive detection of active pericardial bleeding using cardiac blood pool scintigraphy, 329

Pericardial disease
Cardiac disease after radiation therapy for Hodgkin's disease: analysis of 48 patients, 1679
Effect of steroids on postoperative constrictive pericarditis, 1238

Pericardial effusion
Prevalence and correlates of posterior extra echocardiographic spaces in a free-living population based sample (the Framingham study), 1207
Respiratory effects on systolic time intervals during pericardial effusion, 1033
Subepicardial adipose tissue producing echocardiographic appearance of pericardial effusion. Documentation by computed tomography and necropsy, 565

Pericardium
Pericardial windows are suboptimal, 607

Pharmacology
New developments in alpha-adrenergic receptor pharmacology: implications for the initial treatment of hypertension, 639

Phonocardiography
Phonocardiographic findings in patients with normally functioning Ionescu-Shiley prostheses, 969
The apex impulse in mitral stenosis: graphic explanation of the palpable movements at the cardiac apex, 311

Pindolol
Comparative effects of beta-adrenergic blocking drugs on experimental ventricular fibrillation threshold, 1196
Comparison of slow-release pindolol, standard pindolol, and propranolol in angina pectoris, 1062
Pindolol and propranolol in patients with angina pectoris and normal or near-normal ventricular function. Lack of influence of intrinsic sympathomimetic activity on global and segmental left ventricular function assessed by radionuclide ventriculography, 427

Platypnea
Platypnea and interatrial right-to-left shunting after lobectomy, 1802

Plexectomy
Assessment of plexectomy in the treatment of severe coronary spasm in patients with normal coronary arteries, 1072

Prazosin
Effectiveness of prazosin as initial antihypertensive therapy, 644
Efficacy of prazosin in the management of chronic congestive heart failure: a 6-month randomized, double-blind, placebo-controlled study, 1346
New approaches to the therapy of mild hypertension, 621

New developments in alpha-adrenergic receptor pharmacology: implications for the initial treatment of hypertension, 639
Treating the patient with mild hypertension and renal insufficiency, 651

Pregnancy
Amiodarone therapy during pregnancy, 1231
Fetal echocardiography. A tool for evaluation of in utero cardiac arrhythmias and monitoring of in utero therapy: analysis of 71 patients, 237
Real-time 2-dimensional echocardiographic visualization of thrombus on a Bjork-Shiley mitral valve prosthesis. Emergency cesarean section and mitral valve replacement in late pregnancy, 908

Prinzmetal's angina
Ergonovine provocation to assess efficacy of long-term therapy with calcium antagonists in Prinzmetal's variant angina, 684

Prognosis
Dynamic evaluation of prognosis from time-dependent variables in acute myocardial infarction, 1579
Late prognostic value of scintigraphic parameters of acute myocardial infarction size in complicated myocardial infarction without heart failure, 1045
Prevalence and prognosis after a first nontransmural myocardial infarction, 1584
Prognostic and predictive value of exertional hypotension in suspected coronary heart disease, 1261

Propranolol
Biphasic nature of propranolol's microelectrophysiologic effects, 145
Comparative effects of beta-adrenergic blocking drugs on experimental ventricular fibrillation threshold, 1196
Comparison of slow-release pindolol, standard pindolol, and propranolol in angina pectoris, 1062
Pindolol and propranolol in patients with angina pectoris and normal or near-normal ventricular function. Lack of influence of intrinsic sympathomimetic activity on global and segmental left ventricular function assessed by radionuclide ventriculography, 427

Prostacyclin
Increased plasma concentrations of prostacyclin metabolite 6-keto-$PGF_{1\alpha}$ in essential hypertension. Influence of therapy with labetalol, 464
Influence of intracoronary platelet aggregation on ventricular electrical properties during partial coronary artery stenosis, 596

Prostaglandins
Comparative effects of nifedipine, verapamil, and diltiazem on experimental pulmonary hypertension, 195
Vessel wall arachidonate metabolism after angioplasty: possible mediators of postangioplasty vasospasm, 1441

Pulmonary arteries
Management of adults with congenital bidirectional cardiac shunts, cyanosis, and pulmonary vascular obstruction: successful operative repair in 3 patients, 1495
Pulmonary atresia with and without ventricular septal defect: a different etiology and pathogenesis for the atresia in the 2 types? 932

Pulmonary atresia
Pulmonary vein wedge angiography: indications, results, and surgical correlates in 25 patients, 936

Pulmonary disease
Contrasting acute effects of vasodilators (nitroglycerin, nitroprusside, and hydralazine) on right ventricular performance in patients with chronic obstructive pulmonary disease and pulmonary hypertension: a combined radionuclide-hemodynamic study, 1682
Prognostic value of left ventricular size measured by echocardiography in infants with total anomalous pulmonary venous drainage, 1155
Quantitative analysis of pulmonary vascular disease in simple cardiac anomalies with the Down syndrome, 1502

Pulmonary hypertension
Contrasting acute effects of vasodilators (nitroglycerin, nitroprusside, and hydralazine) on right ventricular performance in patients with chronic obstructive pulmonary disease and pulmonary hypertension: a combined radionuclide-hemodynamic study, 1682
Right ventricular function in adults with pulmonary hypertension with and without atrial septal defect, 1144

Pulmonary valve
Congenital absence of pulmonary valve associated with tetralogy of Fallot: diagnosis by 2-dimensional echocardiography, 1798
Pulmonary atresia with and without ventricular septal defect: a different etiology and pathogenesis for the atresia in the 2 types? 932

QRS complex
Comparative rates of resolution of QRS changes after operative and nonoperative acute myocardial infarcts, 378
Evaluation of a QRS scoring system for estimating myocardial infarct size. III. Correlation with quantitative anatomic findings for inferior infarcts, 382

Q-T interval
Q-T prolongation and torsades de pointes ventricular tachycardia produced by the tetracyclic antidepressant agent maprotiline, 904

Quinidine
Cardiac effects of treatment with quinidine and digoxin, alone and in combination, 777
Quinidine for ventricular arrhythmias: value of electrophysiologic testing, 90
Tissue digoxin concentrations during the quinidine-digoxin interaction, 1717

Q wave
Identification of septal ischemia during exercise by Q-wave analysis: correlation with coronary angiography, 440
Q-wave infarction versus S-T infarction. Nonspecificity of electrocardiographic criteria for differentiating transmural and nontransmural lesions, 913

Radiation therapy
Cardiac disease after radiation therapy for Hodgkin's disease: analysis of 48 patients, 1679
High-degree atrioventricular block after radiation therapy, 1233

Radionuclide imaging
Beat-to-beat left ventricular performance in atrial fibrillation: radionuclide assessment with the computerized nuclear probe, 1189
Determinants of variable exercise performance among patients with severe left ventricular dysfunction, 52
Effects of disopyramide on left ventricular function: assessment by radionuclide cineangiography, 1554
Efficacy of prazosin in the management of chronic congestive heart failure: a 6-month randomized, double-blind, placebo-controlled study, 1346
Equilibrium radionuclide gated angiography in patients with tricuspid regurgitation, 305
Exercise-induced cardiac dysfunction in sickle cell anemia. A radionuclide study, 570
Exercise versus cold temperature stimulation during radionuclide cineangiography: diagnostic accuracy in coronary artery disease, 1091
Increased left ventricular ejection fraction after a meal: potential source of error in performance of radionuclide angiography, 1709
Left and right ventricular function at rest and during bicycle exercise in the supine and sitting positions in normal subjects and patients with coronary artery disease. Assessment by radionuclide ventriculography, 36
Left ventricular end-systolic pressure-volume relation. A combined radionuclide and hemodynamic study, 1057
Left ventricular volume and ejection fraction response to exercise in aortic regurgitation, 1379
Radionuclide analysis of peak filling rate, filling fraction, and time to peak filling rate. Response to supine bicycle exercise in normal subjects and patients with coronary disease, 43
Radionuclide-determined changes in pulmonary blood volume and thallium lung uptake in patients with coronary artery disease, 741
Radionuclide ventriculographic study of adaptations to exercise in aortic regurgitation, 483
Spectrum of global left ventricular responses to supine exercise. Limitation in the use of ejection fraction in identifying patients with coronary artery disease, 28

Randomization
Randomize the first patient: scientific, ethical, and behavioral bases, 916

Reentry
Mechanisms of spontaneous and induced ventricular arrhythmias in the 24-hour infarcted dog heart, 207

Renal disease
Calcium phosphorus metabolism in dialysis patients with and without mitral anular calcium. Analysis of 30 patients, 497
Treating the patient with mild hypertension and renal insufficiency, 651

Renin
Association of hyponatremia with increased renin activity in chronic congestive heart failure: impact of diuretic therapy, 1635
Renovascular disease
Long-term converting-enzyme inhibition as a guide to surgical curability of hypertension associated with renovascular disease, 1317
Reperfusion
Diastolic synchronized retroperfusion versus reperfusion: effects on regional left ventricular function and myocardial blood flow during acute coronary occlusion in dogs, 1414
Respiratory function
Respiratory effects on systolic time intervals during pericardial effusion, 1033
Retroperfusion
Diastolic synchronized retroperfusion versus reperfusion: effects on regional left ventricular function and myocardial blood flow during acute coronary occlusion in dogs, 1414
Revascularization
Importance of complete revascularization in performance of the coronary bypass operation, 7
Rhabdomyosarcoma
Cardiac rhabdomyosarcoma presenting as hypereosinophilic syndrome, 909
Rocky Mountain spotted fever
Myocardial function in Rocky Mountain spotted fever: echocardiographic assessment, 341
R wave
R-wave amplitude change during aerobic exercise in hypertensive adolescents after treatment, 459

Scintigraphy
Diagnostic accuracy of indium-111 platelet scintigraphy in identifying left ventricular thrombi, 1712
Early detection of left ventricular dysfunction in chronic aortic regurgitation as assessed by contrast angiography, echocardiography, and rest and exercise scintigraphy, 1542
Enhanced detection of proximal right coronary artery stenosis with the additional analysis of right ventricular thallium-201 uptake in stress scintigrams, 1256
Extravascular obstruction of the superior vena cava by hematoma after open-heart surgery and diagnosis by scintigraphy, 1229
Late prognostic value of scintigraphic parameters of acute myocardial infarction size in complicated myocardial infarction without heart failure, 1045
Left atrial mass: diagnostic value of transesophageal 2-dimensional echocardiography and indium-111 platelet scintigraphy, 1563
Noninvasive detection of active pericardial bleeding using cardiac blood pool scintigraphy, 329
Regional distribution of pulmonary blood volume: an index of pulmonary capillary wedge pressure determined from blood pool scintigraphy, 1404
Rest and redistribution thallium-201 myocardial scintigraphy to predict improvement in left ventricular function after coronary arterial bypass grafting, 1312
Sensitivity of technetium-99m—pyrophosphate scintigraphy in diagnosing cardiac amyloidosis, 826
Septal ischemia as a mechanism of complete atrioventricular block: demonstration by thallium scintigraphy, 1559
Segmental wall
First ultra-short–acting beta-adrenergic blocking agent: its effect on size and segmental wall dynamics of reperfused myocardial infarcts in dogs, 1759
Septostomy
Atrial septostomy as palliative therapy for refractory primary pulmonary hypertension, 1560
Shunts
Management of adults with congenital bidirectional cardiac shunts, cyanosis, and pulmonary vascular obstruction: successful operative repair in 3 patients, 1495
Platypnea and interatrial right-to-left shunting after lobectomy, 1802
The valve of the foramen ovale in interatrial right-to-left shunt: echocardiographic cineangiocardiographic and hemodynamic observations, 1489
Sickle cell anemia
Cardiac function in sickle cell anemia, 1674
Exercise-induced cardiac dysfunction in sickle cell anemia. A radionuclide study, 570
Sick sinus syndrome
Symptomatic sick sinus syndrome in children and adolescents as the only manifestation of cardiac abnormality or associated with unoperated congenital heart disease, 1133
Sinus node
Electrophysiologic studies in atrial fibrillation. Slow conduction of premature impulses: a possible manifestation of the background for reentry, 122
Sinus node coronary arteries studied with angiography, 749
Sinus rhythm
Effects of discontinuing maintenance digoxin therapy in patients with ischemic heart disease and congestive heart failure in sinus rhythm, 1243
Stenosis
Cleft anterior leaflet of the mitral valve with intact septa. A study of 20 cases, 919
Enhanced detection of proximal right coronary artery stenosis with the additional analysis of right ventricular thallium-201 uptake in stress scintigrams, 1256
Influence of intracoronary platelet aggregation on ventricular electrical properties during partial coronary artery stenosis, 596
Massive right ventricular outflow tract aneurysm after ventriculotomy for subvalvular pulmonic stenosis associated with peripheral pulmonary arterial stenoses, 1460
Progressive pulmonary arterial stenosis, 1462
Rheumatic tricuspid valve disease: two-dimensional echocardiographic, hemodynamic, and angiographic correlations, 492
Steroids
Effect of steroids on postoperative constrictive pericarditis, 1238
S-T infarction
Q-wave infarction versus S-T infarction. Nonspecificity of electrocardiographic criteria for differentiating transmural and nontransmural lesions, 913
Streptokinase
Angiographic evidence of hemorrhagic myocardial infarction after intracoronary thrombolysis with streptokinase, 906
Long-term results of tricuspid valve replacement and the problem of prosthetic valve thrombosis, 1128
Transient right atrial thrombus during acute myocardial infarction: diagnosis by echocardiography, 1228
S-T segment
Precordial S-T segment depression in inferior myocardial infarction. Evaluation by quantitative thallium-201 scintigraphy and technetium-99m ventriculography, 734
Prevalence and significance of an abnormal S-T segment response to exercise in a young athletic population, 1663
Role of myocardial ischemia in the genesis of stress-induced S-T segment elevation in previous anterior myocardial infarction, 1289
Sudden death
Clinical evaluation of the internal automatic cardioverter-defibrillator in survivors of sudden cardiac death, 1608
Surgery
Analysis of surgical versus medical therapy in active complicated native valve infective endocarditis, 1650
Anomalous right coronary artery: a surgically correctable cause of angina pectoris, 1235
Assessment of plexectomy in the treatment of severe coronary spasm in patients with normal coronary arteries, 1072
Clinical follow-up study of paroxysmal supraventricular tachyarrhythmias after operative repair of a secundum type atrial septal defect in adults, 273
Cryosurgery for cardiac arrhythmias: acute and chronic effects on coronary arteries, 149
Cryosurgery of the fetal ductus arteriosus, 1446
Effect of steroids on postoperative constrictive pericarditis, 1238
Epicardial and endocardial activation in patients with endocardial cushion defect, 277
Extravascular obstruction of the superior vena cava by hematoma after open-heart surgery and diagnosis by scintigraphy, 1229
Hemodynamics and intracardiac conduction after operative repair of tetralogy of Fallot, 552
Influence of partial sympathetic denervation on the results of myocardial revascularization in variant angina, 661
Kent pathways visualized in situ and removed at operation, 1457
Long-term converting-enzyme inhibition as a guide to surgical curability of

hypertension associated with renovascular disease, 1317
Management of adults with congenital bidirectional cardiac shunts, cyanosis, and pulmonary vascular obstruction: successful operative repair in 3 patients, 1495
Pulmonary vein wedge angiography: indications, results, and surgical correlates in 25 patients, 936
Reoperation for isthmic coarctation of the aorta: follow-up of 26 patients, 1690
Results after repair of coarctation of the aorta beyond infancy: a 10 to 28 year follow-up with particular reference to late systemic hypertension, 1481
Serial exercise testing up to 6 years after coronary bypass surgery: behavior of exercise parameters in groups with different degrees of revascularization determined by postoperative angiography, 1301
Surgery for coronary heart disease due to mucocutaneous lymph node syndrome (Kawasaki disease). Report of 6 patients, 444

Surgery, coronary bypass
Comparative functional and physiologic status of active and dropout coronary bypass patients of a rehabilitation program, 1087
Effect of coronary artery bypass grafting on subsequent hospitalization, 353
Electrophysiologic studies before and after myocardial revascularization in patients with life-threatening ventricular arrhythmias, 519
Importance of complete revascularization in performance of the coronary bypass operation, 7
Rest and redistribution thallium-201 myocardial scintigraphy to predict improvement in left ventricular function after coronary arterial bypass grafting, 1312
Serial exercise testing up to 6 years after coronary bypass surgery: behavior of exercise parameters in groups with different degrees of revascularization determined by postoperative angiography, 1301

Sympathetic nervous system
Influence of partial sympathetic denervation on the results of myocardial revascularization in variant angina, 661

Symposium on Initial Therapy in Hypertension
Effectiveness of prazosin as initial antihypertensive therapy, 644
Effect of antihypertensive agents on lipid metabolism, 628
Introduction, 619
Negative effects of diuretic drugs on metabolic risk factors for coronary heart disease: possible alternative drug therapies, 632
New approaches to the therapy of mild hypertension, 621
New developments in alpha-adrenergic receptor pharmacology: implications for the initial treatment of hypertension, 639
Treating the patient with mild hypertension and renal insufficiency, 651

Symposium on Results of the Mustard Operation for Complete Transposition of the Great Arteries
Arrhythmias in transposition of the great arteries after the Mustard operation, 1530
Exercise studies after the Mustard operation in transposition of the great arteries, 1526
Hemodynamic function after the Mustard operation for transposition of the great arteries, 1514
Introduction, 1513
Rest and exercise right and left ventricular function late after the Mustard operation: assessment by radionuclide ventriculography, 1520
Summary, 1535

Systolic dimension
End-systolic dimension-wall thickness relations during myocardial ischemia in conscious dogs. A new approach for defining regional function, 1750

Systolic time intervals
Assessment of the cardiac effects of hemodialysis with systolic time intervals and echocardiography, 332

TA-064
Cardiovascular effects of a newly synthesized cardiotonic agent (TA-064) on normal and diseased hearts, 802

Tachycardia
Cardiac electrophysiologic effects of flecainide acetate for paroxysmal reentrant junctional tachycardias, 770
Clinical follow-up study of paroxysmal supraventricular tachyarrhythmias after operative repair of a secundum type atrial septal defect in adults, 273
Clinical spectrum of ventricular tachycardia with left bundle branch morphology, 113
Determinants of ventricular tachycardia in patients with coronary artery disease and ventricular aneurysm. Clinical, hemodynamic, and angiographic factors, 61
Disopyramide: evaluation of electrophysiologic effects and clinical efficacy in patients with sustained ventricular tachycardia or ventricular fibrillation, 759
Electrophysiologic mechanism of exercise-induced sustained ventricular tachycardia, 525
Intravenous amiodarone in the acute treatment of recurrent symptomatic ventricular tachycardia, 156
Quinidine for ventricular arrhythmias: value of electrophysiologic testing, 90
Relation between late potentials on the body surface and directly recorded fragmented electrograms in patients with ventricular tachycardia, 105
Significance of ventricular tachycardia in idiopathic dilated cardiomyopathy: observations in 35 patients, 507
Supraventricular nonreentrant tachycardia due to simultaneous conduction through dual atrioventricular nodal pathways, 897
Supraventricular tachycardia in infants: use of the "diving reflex", 286

Technetium-99m
Precordial S-T segment depression in inferior myocardial infarction. Evaluation by quantitative thallium-201 scintigraphy and technetium-99m ventriculography, 734
Sensitivity of technetium-99m—pyrophosphate scintigraphy in diagnosing cardiac amyloidosis, 826

Tetralogy of Fallot
Atypical Fallot's tetralogy with doubly committed subarterial ventricular septal defect. Diagnostic value of 2-dimensional echocardiography, 282
Classification of the site of ventricular septal defect by 2-dimensional echocardiography, 1474
Congenital absence of pulmonary valve associated with tetralogy of Fallot: diagnosis by 2-dimensional echocardiography, 1798
Hemodynamics and intracardiac conduction after operative repair of tetralogy of Fallot, 552
Sustained ventricular tachycardia after repair of tetralogy of Fallot: new electrophysiologic findings, 1137

Tetrodotoxin
Cellular electrophysiologic abnormalities of diseased human ventricular myocardium, 137

Thallium-201
Can noninvasive exercise test criteria identify patients with left main or 3-vessel coronary disease after a first myocardial infarction? 361
Effects of reduced coronary flow on thallium-201 accumulation and release in an in vitro rat heart preparation, 891
Enhanced detection of proximal right coronary artery stenosis with the additional analysis of right ventricular thallium-201 uptake in stress scintigrams, 1256
Precordial S-T segment depression in inferior myocardial infarction. Evaluation by quantitative thallium-201 scintigraphy and technetium-99m ventriculography, 734
Relation between site of origin of ventricular tachycardia and relative left ventricular myocardial perfusion and wall motion, 1329
Relation of immediate and delayed thallium-201 distribution to localization of iodine-125 antimyosin antibody in acute experimental myocardial infarction, 1428
Rest and redistribution thallium-201 myocardial scintigraphy to predict improvement in left ventricular function after coronary arterial bypass grafting, 1312

Thermodilution
Regional coronary blood flow during relief of pacing-induced angina by nitroglycerin. Implications for mechanism of action, 19

Thromboembolism
Trial of combined warfarin plus dipyridamole or aspirin therapy in prosthetic heart valve replacement: danger of aspirin compared with dipyridamole, 1537

Thrombolysis
Angiographic evidence of hemorrhagic myocardial infarction after intracoronary thrombolysis with streptokinase, 906
Intracoronary thrombolysis in acute myocardial infarction: an attempt to quantitate its effect by comparison of enzymatic estimate of myocardial necrosis with left ventricular ejection fraction, 1573

Thrombosis
Comparison of the antithrombotic action of calcium antagonist drugs with

dipyridamole in dogs, 591
Long-term results of tricuspid valve replacement and the problem of prosthetic valve thrombosis, 1128
Thromboxane
Beneficial effects of ibuprofen in pacing-induced myocardial ischemia, 751
Effects of provocation on transcardiac thromboxane in patients with coronary artery disease, 727
Increased plasma concentrations of prostacyclin metabolite 6-keto-$PGF_{1\alpha}$ in essential hypertension. Influence of therapy with labetalol, 464
Thrombus
Diagnostic accuracy of indium-111 platelet scintigraphy in identifying left ventricular thrombi, 1712
Evaluation of intracardiac thrombus with computed tomography, 843
Real-time 2-dimensional echocardiographic visualization of thrombus on a Bjork-Shiley mitral valve prosthesis. Emergency cesarean section and mitral valve replacement in late pregnancy, 908
Transient right atrial thrombus during acute myocardial infarction: diagnosis by echocardiography, 1228
Thyrotoxicosis
Cardiac performance in thyrotoxicosis: analysis of 10 untreated patients, 349
Timolol
Comparative effects of beta-adrenergic blocking drugs on experimental ventricular fibrillation threshold, 1196
Tomography
Pharmacologically induced changes in wall thickening dynamics and mid-ventricular volumes in dogs assessed by prospectively gated computed tomography, 1739
Subepicardial adipose tissue producing echocardiographic appearance of pericardial effusion. Documentation by computed tomography and necropsy, 565
Torsades de pointes
Q-T prolongation and torsades de pointes ventricular tachycardia produced by the tetracyclic antidepressant agent maprotiline, 904
Transposition of the great arteries
Anatomic obstruction of the right ventricular outflow tract in transposition of the great arteries, 1701
Assessment of ventricular size and function in congenitally corrected transposition of the great arteries, 244
Tricuspid regurgitation
Equilibrium radionuclide gated angiography in patients with tricuspid regurgitation, 305
Tricuspid valve
Long-term results of tricuspid valve replacement and the problem of prosthetic valve thrombosis, 1128
T waves
Prolonged angina pectoris and persistent negative T waves in the precordial leads: response to atrial pacing and to methoxamine-induced hypertension, 1599
Two-dimensional echocardiography
Accuracy of 2-dimensional echocardiographic diagnosis of congenitally bicuspid aortic valve: echocardiographic-anatomic correlation in 115 patients, 1469
Atypical Fallot's tetralogy with doubly committed subarterial ventricular septal defect. Diagnostic value of 2-dimensional echocardiography, 282
Cardiac localization of transvascular bioptome using 2-dimensional echocardiography, 219
Classification of the site of ventricular septal defect by 2-dimensional echocardiography, 1474
Conduction disturbances related to the site and severity of mitral anular calcification: a 2-dimensional echocardiographic and electrocardiographic correlative study, 1644
Congenital absence of pulmonary valve associated with tetralogy of Fallot: diagnosis by 2-dimensional echocardiography, 1798
Exercise 2-dimensional echocardiography. Quantitation of left ventricular performance in patients with severe angina pectoris, 1
False aneurysm of mitral-aortic intervalvular fibrosa: diagnosis by 2-dimensional contrast echocardiography at cardiac catheterization, 1801
Heterogeneity of left ventricular segmental wall thickening and excursion in 2-dimensional echocardiograms of normal human subjects, 1667
Impact of 2-dimensional echocardiography on the management of distressed newborns in whom cardiac disease is suspected, 288
Isolated cleft mitral valve: a variety of congenital mitral regurgitation identified by 2-dimensional echocardiography, 927
Measurement of systemic and pulmonary blood flow and QP/QS ratio using Doppler and two-dimensional echocardiography, 952
M-mode and 2-dimensional echocardiographic characteristics of the Ionescu-Shiley valve in the mitral and aortic positions, 973
Myocardial texture characterization by two-dimensional echocardiography, 817
Normal left atrial function determined by 2-dimensional echocardiography, 336
Obstruction within the right ventricular body: two-dimensional echocardiographic features, 1498
Quantitative detection of regional left ventricular contraction abnormalities by 2-dimensional echocardiography. Comparison of myocardial thickening and thinning and endocardial motion in a canine model, 1732
Real-time 2-dimensional echocardiographic visualization of thrombus on a Bjork-Shiley mitral valve prosthesis. Emergency cesarean section and mitral valve replacement in late pregnancy, 908
Relation of electrocardiographic abnormalities and patterns of left ventricular hypertrophy identified by 2-dimensional echocardiography in patients with hypertrophic cardiomyopathy, 189
Rheumatic tricuspid valve disease: two-dimensional echocardiographic, hemodynamic, and angiographic correlations, 492
Segmental right ventricular function after acute myocardial infarction: two-dimensional echocardiographic study in 63 patients, 390
Subxyphoid 2-dimensional echocardiographic identification of left ventricular papillary muscle anomalies in complete common atrioventricular canal, 1695
The univentricular heart: combined 2-dimensional–pulsed Doppler (duplex) echocardiographic evaluation, 1149
Two-dimensional echocardiographic detection of right atrial thrombi, 615
Two-dimensional echocardiographic recognition of the right aortic arch, 1507

Ultrasound
In vivo ultrasonic tissue characterization of human intracardiac masses, 231
Measurement of systemic and pulmonary blood flow and QP/QS ratio using Doppler and two-dimensional echocardiography, 952
Myocardial texture characterization by two-dimensional echocardiography, 817
Univentricular heart
The univentricular heart: combined 2-dimensional–pulsed Doppler (duplex) echocardiographic evaluation, 1149

Valve disease
Analysis of surgical versus medical therapy in active complicated native valve infective endocarditis, 1650
Determinants of the incidence and severity of ventricular arrhythmias in aortic valve disease, 1103
M-mode and 2-dimensional echocardiographic characteristics of the Ionescu-Shiley valve in the mitral and aortic positions, 973
Phonocardiographic findings in patients with normally functioning Ionescu-Shiley prostheses, 969
Rheumatic tricuspid valve disease: two-dimensional echocardiographic, hemodynamic, and angiographic correlations, 492
Valve prostheses
Comparison of late degenerative changes in porcine bioprostheses in the mitral and aortic valve position in the same patient, 965
Indexes of intravascular hemolysis, quantification of coagulation factors, and platelet survival in patients with porcine heterograft valves, 489
Long-term failure rate and morphologic correlations in porcine bioprosthetic heart valves, 957
Long-term results of tricuspid valve replacement and the problem of prosthetic valve thrombosis, 1128
M-mode and 2-dimensional echocardiographic characteristics of the Ionescu-Shiley valve in the mitral and aortic positions, 973
Phonocardiographic findings in patients with normally functioning Ionescu-Shiley prostheses, 969
Regurgitation of prosthetic heart valves: dependence on heart rate and cardiac output, 321
Structural changes in ventriculoaortic procine valved conduit implanted in a child, 1795

Vasodilators
Acute hemodynamic effects of endralazine: a new vasodilator for chronic refractory congestive heart failure, 1353
Clonidine in congestive heart failure: a vasodilator with negative inotropic effects, 791
Contrasting acute effects of vasodilators (nitroglycerin, nitroprusside, and hydralazine) on right ventricular performance in patients with chronic obstructive pulmonary disease and pulmonary hypertension: a combined radionuclide-hemodynamic study, 1682
Hemodynamic and myocardial performance characteristics after verapamil use in congestive heart failure, 1339
Hemodynamic effects of dibutyryl cyclic AMP in congestive heart failure, 1364
Regression of myocardial cellular hypertrophy with vasodilator therapy in chronic congestive heart failure associated with idiopathic dilated cardiomyopathy, 1392
Vasospasm
Vessel wall arachidonate metabolism after angioplasty: possible mediators of postangioplasty vasospasm, 1441
Venae cavae
Extravascular obstruction of the superior vena cava by hematoma after open-heart surgery and diagnosis by scintigraphy, 1229
Noninvasive diagnosis of interrupted inferior vena cava: gated pulsed Doppler application, 1796
Ventricle, left
Determinants of variable exercise performance among patients with severe left ventricular dysfunction, 52
How should we describe hearts in which the aorta is connected to the right ventricle and the pulmonary trunk to the left ventricle? A matter for reason and logic, 911
Increased left ventricular ejection fraction after a meal: potential source of error in performance of radionuclide angiography, 1709
Left ventricular wall stress in compensated aortic stenosis in children, 946
Relation of left ventricular mass to geometry of the proximal coronary arteries in the dog, 1728
Relation of segmental wall motion to global left ventricular function in acute myocardial infarction, 1275
Subxyphoid 2-dimensional echocardiographic identification of left ventricular papillary muscle anomalies in complete common atrioventricular canal, 1695
Topographic changes in the left ventricle after experimentally induced myocardial infarction in the rat, 872
Ventricle, right
Anatomic obstruction of the right ventricular outflow tract in transposition of the great arteries, 1701
How should we describe hearts in which the aorta is connected to the right ventricle and the pulmonary trunk to the left ventricle? A matter for reason and logic, 911
Obstruction within the right ventricular body: two-dimensional echocardiographic features, 1498
Ventricular arrhythmias
Determinants of the incidence and severity of ventricular arrhythmias in aortic valve disease, 1103
Electrophysiologic studies before and after myocardial revascularization in patients with life-threatening ventricular arrhythmias, 519
Mechanisms of spontaneous and induced ventricular arrhythmias in the 24-hour infarcted dog heart, 207
Quinidine for ventricular arrhythmias: value of electrophysiologic testing, 90
Ventricular contraction
Premature ventricular contraction or ventricular extrasystole? 1783
Ventricular fibrillation
Comparative effects of beta-adrenergic blocking drugs on experimental ventricular fibrillation threshold, 1196
Electrophysiologic studies before and after myocardial revascularization in patients with life-threatening ventricular arrhythmias, 519
Terminal cardiac electrical activity in pediatric patients, 557
Ventricular function
Alterations in left ventricular filling with beta-adrenergic blockade, 161
Analysis of ventricular emptying and filling indexes during acute increases in arterial pressure, 468
Cardiac performance in thyrotoxicosis: analysis of 10 untreated patients, 349
Digital angiography in assessment of ventricular function and wall motion during pacing in patients with coronary artery disease, 668
Early detection of left ventricular dysfunction in chronic aortic regurgitation as assessed by contrast angiography, echocardiography, and rest and exercise scintigraphy, 1542
Effect of exercise protocol on the left ventricular response to exercise, 859
Effect of verapamil on left ventricular function: a randomized, placebo-controlled study, 1213
Effects of a cardioselective beta$_1$ partial agonist (corwin) on left ventricular function and myocardial metabolism in patients with previous myocardial infarction, 1267
Effects of disopyramide on left ventricular function: assessment by radionuclide cineangiography, 1554
Effects of oral digoxin on ventricular ectopy and its relation to left ventricular function, 765
End-systolic dimension-wall thickness relations during myocardial ischemia in conscious dogs. A new approach for defining regional function, 1750
Evaluation of left ventricular performance using digital subtraction angiography, 837
Exercise 2-dimensional echocardiography. Quantitation of left ventricular performance in patients with severe angina pectoris, 1
Hemodynamic effects of a new antiarrhythmic agent, flecainide (R-818), in coronary heart disease, 422
Increased left ventricular function as an adaptive response in vibration disease, 1223
Left and right ventricular function at rest and during bicycle exercise in the supine and sitting positions in normal subjects and patients with coronary artery disease. Assessment by radionuclide ventriculography, 36
Left ventricular end-systolic pressure-volume relation. A combined radionuclide and hemodynamic study, 1057
Left ventricular response to isometric exercise and its value in predicting the change in ventricular function after mitral valve replacement for mitral regurgitation, 1110
Mechanisms for decreased exercise capacity after bed rest in normal middle-aged men, 344
Pindolol and propranolol in patients with angina pectoris and normal or near-normal ventricular function. Lack of influence of intrinsic sympathomimetic activity on global and segmental left ventricular function assessed by radionuclide ventriculography, 427
Radionuclide ventriculographic study of adaptations to exercise in aortic regurgitation, 483
Relation of segmental wall motion to global left ventricular function in acute myocardial infarction, 1275
Rest and exercise ventricular function in adults with congenital ventricular septal defects, 293
Rest and redistribution thallium-201 myocardial scintigraphy to predict improvement in left ventricular function after coronary arterial bypass grafting, 1312
Right ventricular function in adults with pulmonary hypertension with and without atrial septal defect, 1144
Segmental right ventricular function after acute myocardial infarction: two-dimensional echocardiographic study in 63 patients, 390
Serial changes in left ventricular function after correction of chronic aortic regurgitation. Dependence on early changes in preload and subsequent regression of hypertrophy, 476
Spectrum of global left ventricular responses to supine exercise. Limitation in the use of ejection fraction in identifying patients with coronary artery disease, 28
Survival in men with severe chronic left ventricular failure due to either coronary heart disease or idiopathic dilated cardiomyopathy, 831
Usefulness of echocardiographic right ventricular measurements in estimating right ventricular hypertrophy and right ventricular systolic pressure, 1036
Variability of digitized echocardiography: size, source, and means of reduction, 576
Ventricular hypertrophy
Relation of electrocardiographic abnormalities and patterns of left ventricular hypertrophy identified by 2-dimensional echocardiography in patients with hypertrophic cardiomyopathy, 189
Ventricular muscle
Nature of "residual fast channel" dependent action potentials and slow conduction in guinea pig ventricular

muscle and its modification by isoproterenol, 1433
Subxyphoid 2-dimensional echocardiographic identification of left ventricular papillary muscle anomalies in complete common atrioventricular canal, 1695
Ventricular outflow tract
Anatomic obstruction of the right ventricular outflow tract in transposition of the great arteries, 1701
Ventricular relaxation
Left ventricular isovolumic pressure decay and diastolic mechanics after postextrasystolic potentiation and during exercise, 583
Ventricular septal defect
Atypical Fallot's tetralogy with doubly committed subarterial ventricular septal defect. Diagnostic value of 2-dimensional echocardiography, 282
Classification of the site of ventricular septal defect by 2-dimensional echocardiography, 1474
Pulmonary atresia with and without ventricular septal defect: a different etiology and pathogenesis for the atresia in the 2 types? 932
Rest and exercise ventricular function in adults with congenital ventricular septal defects, 293
Ventricular stimulation
Disopyramide: evaluation of electrophysiologic effects and clinical efficacy in patients with sustained ventricular tachycardia or ventricular fibrillation, 759
Electrophysiologic testing in the management of survivors of out-of-hospital cardiac arrest, 85
Mexiletine for control of drug-resistant ventricular tachycardia: clinical and electrophysiologic results in 44 patients, 1175

BASIC THERAPY FOR THE PREVENTION OF ANGINA PECTORIS*

Report from "Step-Care Therapy for Ischemic Heart Disease"
—a special symposium preceding the annual meeting
of the American College of Cardiology, April 24, 1982.

Synopsis of the Symposium

Step 1: Nitrates

Since nitrates both reduce myocardial oxygen demand and increase myocardial oxygen supply, their use is warranted as initial therapy for the control of angina pectoris. Dosage needs often vary significantly from patient to patient, and attention should be given to ensure that an adequate dosage level has been established.

Step 2: Nitrates and beta blockers

For angina refractory to maximum-dose nitrate therapy, the complementary actions of beta blockers and nitrates provide a rational therapeutic modality. At this point a beta blocker should be added to the nitrate regimen.

Step 3: Nitrates and calcium antagonists

Calcium antagonists have special usefulness in controlling cases where the myocardial oxygen supply is diminished by coronary vasospasm; their use in combination with nitrates is recommended if Step 2 therapy is unsatisfactory (or if the patient has variant or vasospastic angina).

Consensus of the Symposium

Nitrates are basic in step-care therapy for ischemic heart disease

Step 1
Stable or unstable angina: Nitrates

Step 2
If not controlled: Nitrates + beta blockers

Step 3
If still not controlled (or in variant angina): Nitrates + calcium antagonists

The basic antianginal agent in these basic dosage forms

ISORDIL® SUBLINGUAL
Sublingual Tablets, 2.5 mg, 5 mg, and 10 mg

ISORDIL® CHEWABLE
Chewable Tablets, 10 mg

In angina pectoris...

ISORDIL® (ISOSORBIDE DINITRATE)

is basic

*ISORDIL has been evaluated as probably effective when taken by the sublingual or chewable route and possibly effective when taken orally for this indication. See Brief Summary on following page.

Ives®

© 1982 Ives Laboratories Inc.

ISORDIL®
(ISOSORBIDE DINITRATE) IS BASIC

*Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: When taken by the sublingual or chewable route, Isordil Sublingual and Chewable Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.
Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.
Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.
Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

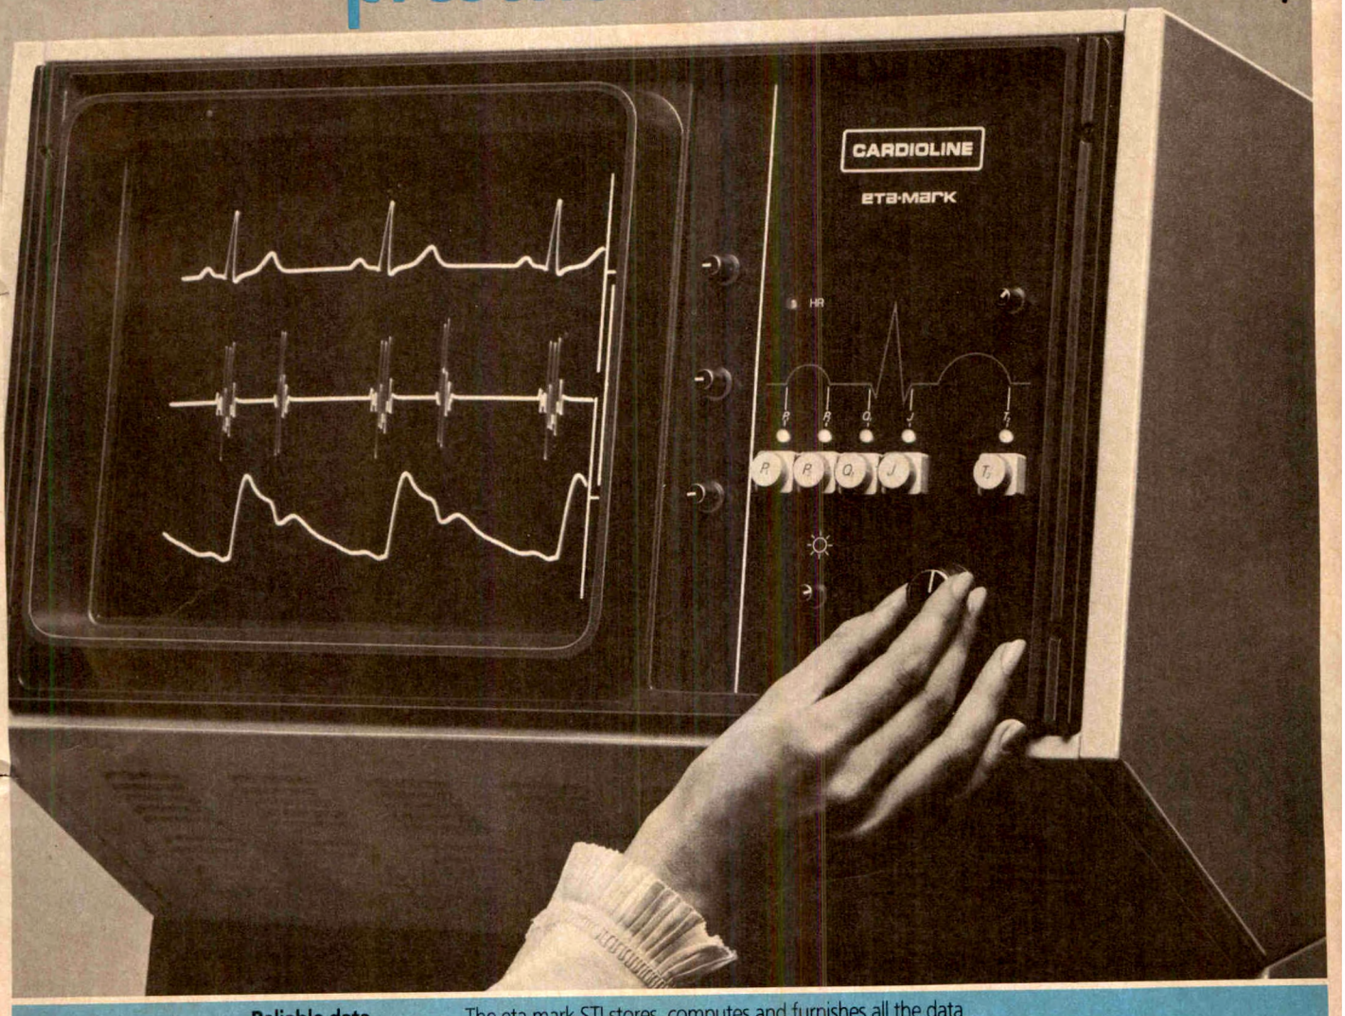
CARDIOLINE®

eta mark STI

polygraph with 3-channel monitor.
A technological advance
assisting cardiological diagnosis

A living presence



Reliable data — The eta mark STI stores, computes and furnishes all the data essential to diagnosis. It also computes systolic time intervals and significant ECG parameters.

Complete data — It provides a complete set of personal, temporal and polycardiographic data, clearly displayed, in as many copies as required.

Functional — The large memory screen has exceptional definition capabilities which allow an interaction with the computer in giving the maximum clarity to displayed signals.

Flexible — The eta mark STI is a complete, flexible instrument which is ideal for statistical work, qualitative and quantitative analysis.

Intelligence — eta mark STI is a precious time saver which leaves more time for the final diagnosis, a decisive step which should be taken by the doctor only.

A THERAPEUTIC STEP AHEAD

LOPID®
(gemfibrozil)

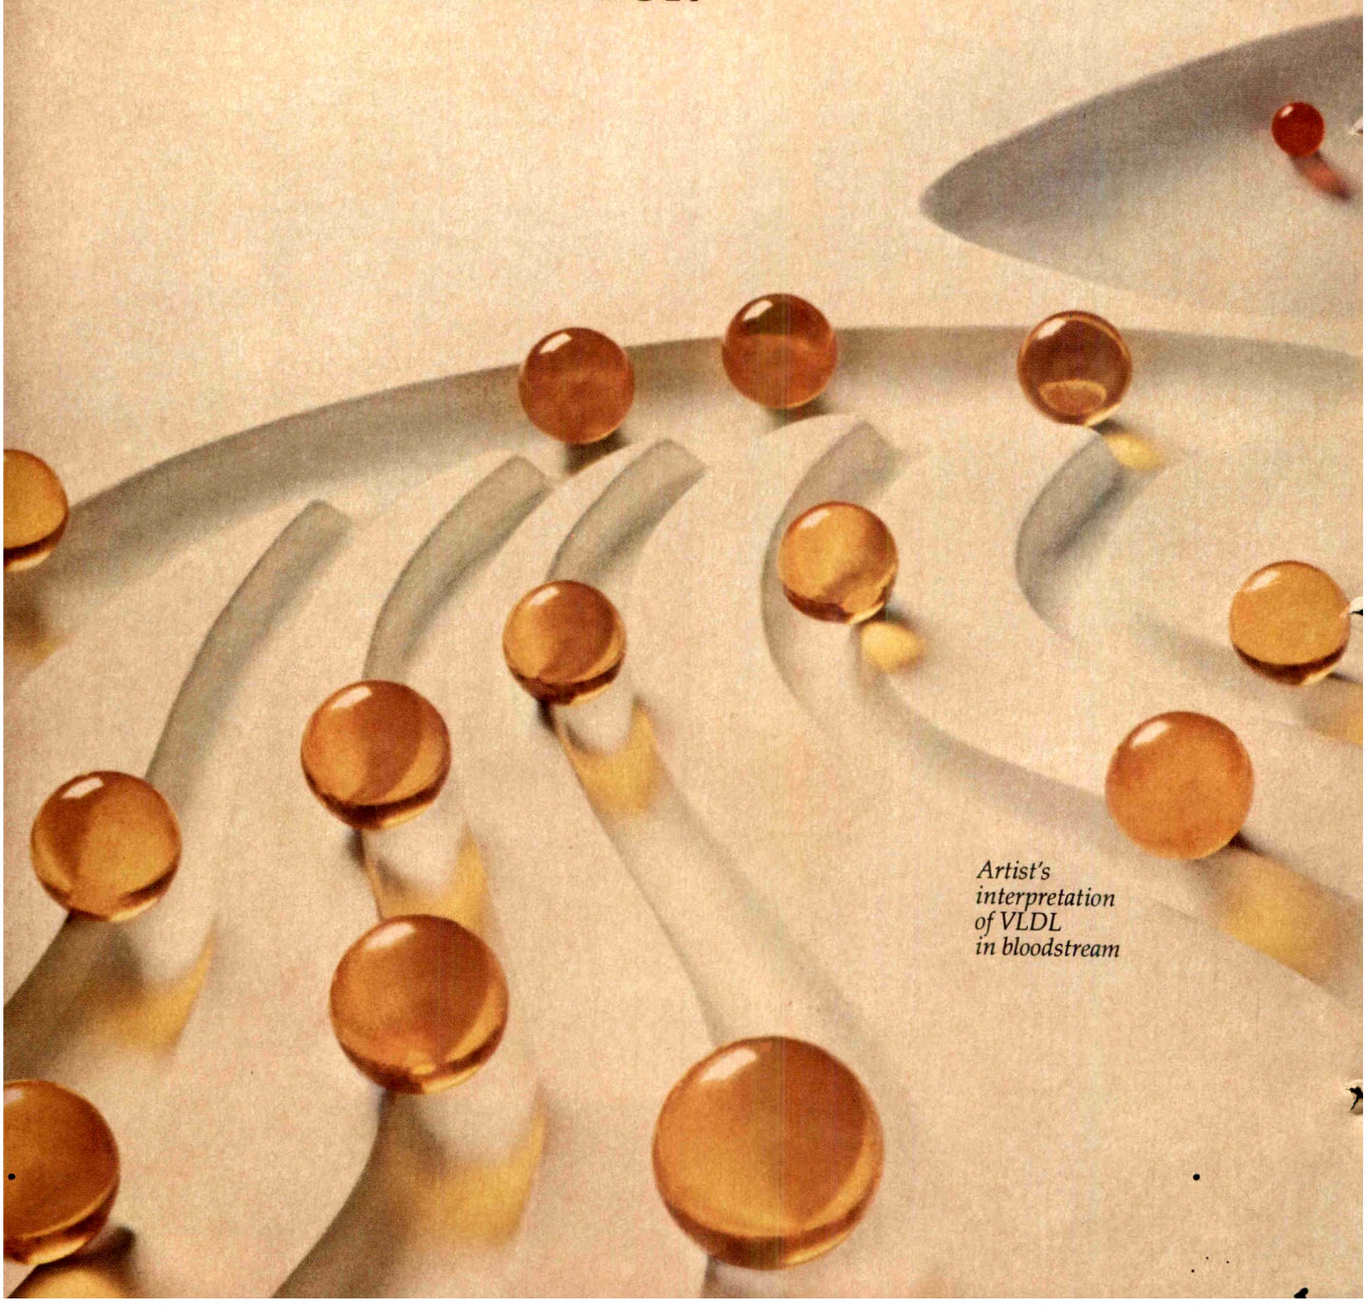
MORE THAN A LIPID-LOWERING AGENT— A TWO-WAY LIPID REGULATOR

Favorably regulates the balance of lipid fractions in certain dyslipidemias:

1/LOWERS elevated serum levels of triglyceride-rich VLDL and, to a lesser extent, cholesterol-rich LDL (very-low- and low-density lipoproteins implicated in dyslipidemia)

2/May also RAISE serum levels of HDL (high-density lipoproteins believed to transport cholesterol to the liver for catabolism and excretion)

LOPID is indicated for treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond adequately to diet.

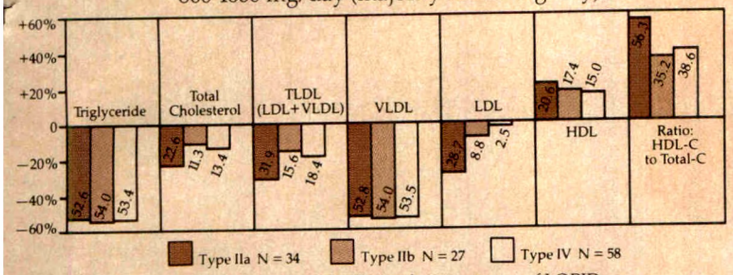


Artist's interpretation of VLDL in bloodstream

Lipid-regulating efficacy demonstrated in 1,437 patients with dyslipidemia[1]

Results of open-label phase of US multicenter study (119 patients) at end of 12 lunar months*

Average % change from baseline at doses ranging from 800-1600 mg/day (majority at 1200 mg/day)†



*Visit every 4 weeks during long-term use of LOPID.
†Data cited on this graph reflect clinical experience based on the multicenter trial. They do not imply an indication for Types IIa and IIb dyslipidemias.

Well tolerated, well accepted in clinical trials[1]

Profile of side effects similar to that of placebo.

No significant abnormalities seen in clinical and laboratory evaluations.

Less than 1% patient dropout in largest US study.

Convenient BID dosage

Diet, exercise, and weight loss are the first choice in therapy of lipid disorders.

LOPID®
(gemfibrozil)
A LIPID REGULATOR

LOPID® (gemfibrozil) Capsules

Before prescribing, please see full prescribing information.
A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO: HDL Cholesterol / Total Cholesterol
		Total	VLDL	LDL	HDL	
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (See WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID (gemfibrozil) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels**—LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias**—Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria
Central Nervous System: headache, dizziness, blurred vision
Musculoskeletal: painful extremities
Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia
Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints
Central Nervous System: vertigo, insomnia, paresthesia, tinnitus
Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)
Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

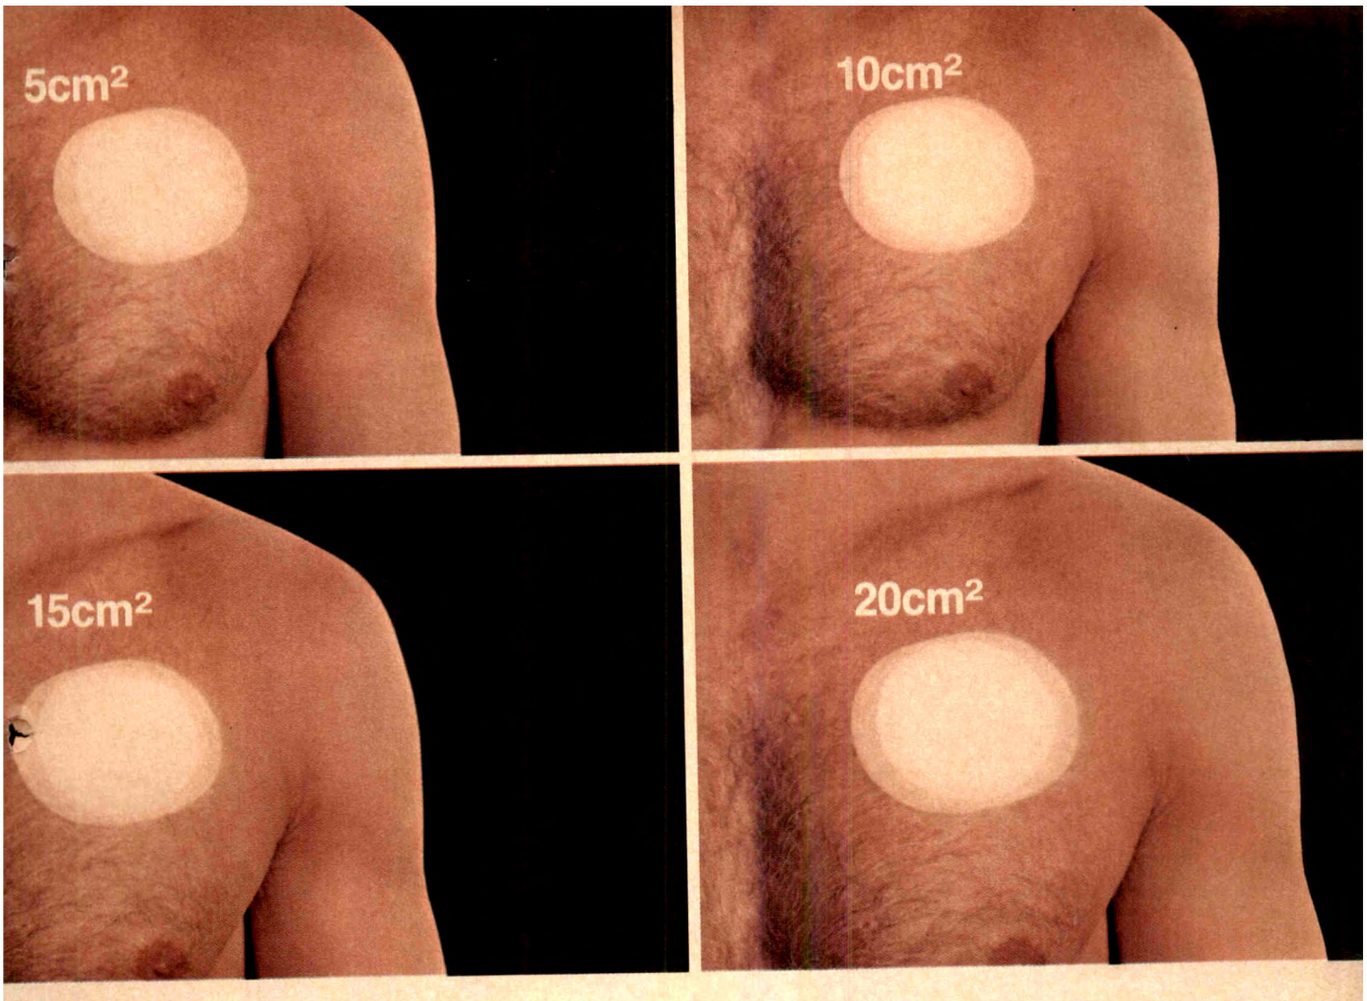
DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

0669G011

PARKE-DAVIS
Division of Warner-Lambert Company
Morris Plains, New Jersey 07950

PD-56-JA-1333-P-1 (11-82)



Two added strengths for ease of titration.

The new 5 cm² size.

Nitro-Dur™ (nitroglycerin) is the only transdermal nitroglycerin with four dosage strengths—5, 10, 15 and 20 cm² (approximately 2.5 mg, 5 mg, 7.5 mg and 10 mg released in 24 hours), permitting titration in increments of 5 cm². This gives Nitro-Dur greater dosage flexibility than any other form of transdermal nitroglycerin.

Nitro-Dur also has a sophisticated product design which includes a wide, microporous adhesive strip. The strip insures firm matrix-to-skin contact and helps keep the system sealed and in place.

Greater dosage flexibility and better adhesion. Two reasons why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

The most widely prescribed transdermal nitroglycerin system.

Please see next page for a summary of prescribing information.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release in vivo of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[1] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

INDICATIONS AND USAGE: Prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without a prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

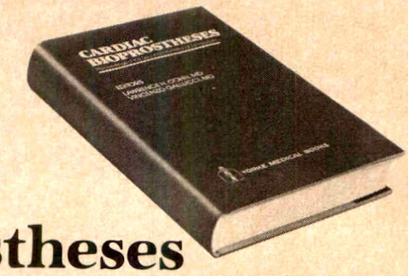
The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.



Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

• Section 1 CLINICAL ANALYSIS • Section 2 HEMODYNAMICS • Section 3 THROMBOEMBOLISM • Section 4 PEDIATRIC VALVE REPLACEMENT • Section 5 EXPERIMENTAL PATHOLOGY • Section 6 EXPLANT PATHOLOGY • Section 7 BIOPROSTHETIC BIOENGINEERING • Section 8 LONG-TERM FOLLOW-UP • Section 9 SUMMING UP • AUTHOR INDEX • SUBJECT INDEX

ORDER FORM AJCF3

Please send me Cardiac Bioprostheses on 30 day approval.
☐ Enclosed is my check for $65.00 plus $1.50 for handling.
Yorke pays postage (same return privilege).
☐ Please charge my ☐ VISA ☐ MasterCard (same return privilege).

Card No. _____ MC Interbank No. _____

Exp. date_____Signature_____

☐ Please bill me plus postage and handling.

Name _____

Address _____

City/State/Zip _____

CONTENTS: VOLUME 51 • NUMBER 1 JANUARY 1, 1983

CORONARY HEART DISEASE

1 **Exercise 2-Dimensional Echocardiography. Quantitation of Left Ventricular Performance in Patients With Severe Angina Pectoris.** Michael H. Crawford, K. Wray Amon, and William S. Vance

7 **Importance of Complete Revascularization in Performance of the Coronary Bypass Operation.** Ellis L. Jones, Joe M. Carver, Robert P. Guyton, David K. Bone, Charles R. Hatcher, Jr., and Norman Riechwald

13 **Antianginal Efficacy and Improved Exercise Performance With Timolol. Twice-Daily Beta Blockade in Ischemic Heart Disease.** Fred J. Harris, Reginald I. Low, Linda Palmer, Ezra A. Amsterdam, and Dean T. Mason

19 **Regional Coronary Blood Flow During Relief of Pacing-Induced Angina by Nitroglycerin. Implications for Mechanism of Action.** Richard M. Fuchs, Jeffrey A. Brinker, Pablo A. Guzman, Dean E. Kross, and Frank Y. C. Yin

24 **Implications of Increased Myocardial Isoenzyme Level in the Presence of Normal Serum Creatine Kinase Activity.** G. V. Heller, Alvin S. Blaustein, and J. Y. Wei, *With the technical assistance of* Daniel Geer

28 **Spectrum of Global Left Ventricular Responses to Supine Exercise. Limitation in the Use of Ejection Fraction in Identifying Patients With Coronary Artery Disease.** Mary D. Osbakken, Charles A. Boucher, Robert D. Okada, John B. Bingham, H. William Strauss, and Gerald M. Pohost

36 **Left and Right Ventricular Function at Rest and During Bicycle Exercise in the Supine and Sitting Positions in Normal Subjects and Patients With Coronary Artery Disease. Assessment by Radionuclide Ventriculography.** Dante E. Manyari and William J. Kostuk, *With the technical assistance of* Paul P. Purves

43 **Radionuclide Analysis of Peak Filling Rate, Filling Fraction, and Time to Peak Filling Rate. Response to Supine Bicycle Exercise in Normal Subjects and Patients With Coronary Disease.** G. B. John Mancini, Robert A. Slutsky, Sharon L. Norris, Valmik Bhargava, William L. Ashburn, and Charles B. Higgins

52 **Determinants of Variable Exercise Performance Among Patients With Severe Left Ventricular Dysfunction.** Michael B. Higginbotham, Kenneth G. Morris, Eric H. Conn, R. Edward Coleman, and Frederick R. Cobb

61 **Determinants of Ventricular Tachycardia in Patients With Coronary Artery Disease and Ventricular Aneurysm. Clinical, Hemodynamic, and Angiographic Factors.** Marc Cohen, Isaac Weiner, Augusto Pichard, James Holt, Harry Smith, Jr., and Richard Gorlin

65 **Relation of Exercise to the Recurrence Rate of Myocardial Infarction in Man: Ontario Exercise-Heart Collaborative Study.** Peter A. Rechnitzer, David A. Cunningham, George M. Andrew, Carol W. Buck, Norman L. Jones, Terence Kavanagh, Neil B. Oldridge, John O. Parker, Roy J. Shephard, John R. Sutton, and Allan P. Donner

70 **Predictors of Dropout From Cardiac Exercise Rehabilitation. Ontario Exercise-Heart Collaborative Study.** Neil B. Oldridge, Allan P. Donner, Carol W. Buck, Norman L. Jones, George M. Andrew, John O. Parker, David A. Cunningham, Terence Kavanagh, Peter A. Rechnitzer, and John R. Sutton

75 **Ventricular Electrical Instability: A Predictor of Death After Myocardial Infarction.** David A. Richards, David V. Cody, Alan R. Denniss, Paul A. Russell, Alan A. Young, and John B. Uther

81 **Status of the Major Epicardial Coronary Arteries 80 to 150 Days After Percutaneous Tranaluminal Coronary Angioplasty. Analysis of 3 Necropsy Patients.** Bruce F. Waller, Bruce M. McManus, H. Joel Gorfinkel, Joan C. Kishel, Edward C. H. Schmidt, Kenneth M. Kent, and William C. Roberts

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

85 **Electrophysiologic Testing in the Management of Survivors of Out-of-Hospital Cardiac Arrest.** Fred Morady, Melvin M. Scheinman, David S. Hess, Ruey J. Sung, Edward Shen, and William Shapiro

90 **Qunidine for Ventricular Arrhythmias: Value of Electrophysiologic Testing.** John P. DiMarco, Hasan Garan, and Jeremy N. Ruskin

96 **Enhanced Parasympathetic Tone Shortens Atrial Refractoriness in Man.** Eric N. Prystowksy, Gerald V. Naccarelli, Warren M. Jackman, Robert L. Rinkenberger, James J. Heger, and Douglas P. Zipes

101 **Effect of Local Lidocaine Anesthesia on Ventricular Escape Intervals During Permanent Pacemaker Implantation in Patients With Complete Heart Block.** Bernard D. Kosowsky, Shahid I. Mufti, Gurinder S. Grewal, Richard H. S. Moon, W. Linda Cashin, John O. Pastore, and K. Ramaswamy

105 **Relation Between Late Potentials on the Body Surface and Directly Recorded Fragmented Electrograms in Patients With Ventricular Tachycardia.** Michael B. Simson, William J. Untereker, Scott R. Spielman, Leonard N. Horowitz, Norman H. Marcus, Rita A. Falcone, Alden H. Harken, and Mark E. Josephson

113 **Clinical Spectrum of Ventricular Tachycardia With Left Bundle Branch Morphology.** Michael J. Reiter, Warren J. Smith, and John J. Gallagher

122 **Electrophysiologic Studies in Atrial Fibrillation. Slow Conduction of Premature Impulses: A Possible Manifestation of the Background for Reentry.** Francisco G. Cosio, José Palacios, José M. Vidal, Emilio G. Cocina, Miguel A. Gómez-Sánchez, and Luis Tamargo

131 **Problems in Health Data Analysis: The Maryland Permanent Pacemaker Experience in 1979 and 1980.** Leonard Scherlis and Donald H. Dembo

137 **Cellular Electrophysiologic Abnormalities of Diseased Human Ventricular Myocardium.** Robert F. Gilmour, Jr., James J. Heger, Eric N. Prystowsky, and Douglas P. Zipes

145 **Biphasic Nature of Propanolol's Microelectrophysiologic Effects.** David H. S. Iansmith, Clinton B. Nash, and Jack P. Bandura

149 **Cryosurgery for Cardiac Arrhythmias: Acute and Chronic Effects on Coronary Arteries.** William L. Holman, Masatoshi Ikeshita, Ross M. Ungerleider, Peter K. Smith, Raymond E. Ideker, and James L. Cox

156 **Intravenous Amiodarone in the Acute Treatment of Recurrent Symptomatic Ventricular Tachycardia.** Fred Morady, Melvin M. Scheinman, Edward Shen, William Shapiro, Ruey J. Sung, and Lorenzo DiCarlo

160 **Books Received**

SYSTEMIC HYPERTENSION

161 **Alterations in Left Ventricular Filling With Beta-Adrenergic Blockade.** Fetnat M. Fouad, Marek J. Slominski, Robert C. Tarazi, and Joe Gallagher

165 **Intravascular Volume, Extracellular Fluid Volume, and Total Body Water in Obese and Nonobese Hypertensive Patients.** Jocelyne H. Raison, Apostolos D. Achimastos, Jean E. Bouthier, Gerard M. London, and Michel E. Safar

171 **Relation of Hemodynamic Load to Left Ventricular Hypertrophy and Performance in Hypertension.** Richard B. Devereux, Daniel D. Savage, Irene Sachs, and John H. Laragh

CONGESTIVE HEART FAILURE

177 **Failure of Dobutamine to Increase Exercise Capacity Despite Hemodynamic Improvement in Severe Chronic Heart Failure.** Carol S. Maskin, Robert Forman, Edmund H. Sonnenblick, William H. Frishman, and Thierry H. LeJemtel

183 **Quantitative Differences in the Hemodynamic Effects of Captopril and Nitroprusside in Severe Chronic Heart Failure.** Milton Packer, Jose Meller, Norma Medina, and Madeline Yushak

CARDIOMYOPATHY

189 **Relation of Electrocardiographic Abnormalities and Patterns of Left Ventricular Hypertrophy Identified by 2-Dimensional Echocardiography in Patients With Hypertrophic Cardiomyopathy.** Barry J. Maron, James K. Wolfson, Elisabetta Ciró, and Paolo Spirito

EXPERIMENTAL STUDIES

195 **Comparative Effects of Nifedipine, Verapamil, and Diltiazem on Experimental Pulmonary Hypertension.** Thomas E. Young, Lucy J. Lundquist, Elliot Chesler, and E. Kenneth Weir

201 **Compensatory Cardiac Mechanisms Evoked by Septal Ischemia in Dogs.** Målfrid Molaug, Odd Geiran, and Fredrik Kiil

207 **Mechanisms of Spontaneous and Induced Ventricular Arrhythmias in the 24-Hour Infarcted Dog Heart.** Benjamin J. Scherlag, Glenn Kabell, Johannes Brachmann, Lura Harrison, and Ralph Lazzara

214 **Instructions to Authors**

METHODS

215 **Can Tracking of Contrast Echocardiographic Targets Be Used to Measure Intracardiac Flow Velocities?** Lilliam M. Valdes-Cruz, David J. Sahn, Suzana Horowitz, Daniel C. Fisher, Stanley J. Goldberg, and Hugh D. Allen

219 **Cardiac Localization of Transvascular Bioptome Using 2-Dimensional Echocardiography.** James W. French, Richard L. Popp, and Paul T. Pitlick

224 **Validation of the Angiographic Accuracy of Digital Left Ventriculography.** Allen B. Nichols, Eric C. Martin, Thomas P. Fles, Karen M. Stugensky, Lawrence A. Balancio, William J. Casarella, and Melvin B. Weiss

MISCELLANEOUS TOPICS

231 **In Vivo Ultrasonic Tissue Characterization of Human Intracardiac Masses.** Stephen E. Green, Linda E. Joynt, Peter J. Fitzgerald, David S. Rubenson, and Richard L. Popp.

CONGENITAL HEART DISEASE

237 **Fetal Echocardiography. A Tool for Evaluation of In Utero Cardiac Arrhythmias and Monitoring of In Utero Therapy: Analysis of 71 Patients.** Charles S. Kleinman, Richard L. Donnerstein, C. Carl Jaffe, Greggory R. DeVore, Ellen M. Weinstein, Diana C. Lynch, Norman S. Talner, Richard L. Berkowitz, and John C. Hobbins

244 **Assessment of Ventricular Size and Function in Congenitally Corrected Transposition of the Great Arteries.** Thomas P. Graham, Jr., Mark D. Parrish, Robert J. Boucek, Jr., Robert C. Boerth, James A. Breitweser, Sandra Thompson, Rose M. Robertson, John R. Morgan, and Gottlieb C. Friesinger

252 **Quantitation of Aortic and Mitral Regurgitation in the Pediatric Population: Evaluation by Radionuclide Angiocardiography.** Roger A. Hurwitz, Salvador Treves, Michael Freed, Donald A. Girod, and Randall L. Caldwell

256 **Supravalvular Aortic Stenosis. A 20-Year Clinical Perspective and Experience With Patch Aortoplasty.** Greg Flaker, Douglas Teske, James Kilman, Don Hosier, and Charles Wooley

261 **Radionuclide Stroke Count Ratios for Assessment of Right and Left Ventricular Volume Overload in Children.** Mark D. Parrish, Thomas P. Graham, Jr., Mark L. Born, Jerome P. Jones, Robert J. Boucek, Jr., Michael Artman, and C. Leon Partain

265 **Pulmonary Vascular Disease in Secundum Atrial Septal Defect in Childhood.** Sheila G. Haworth

273 **Clinical Follow-Up Study of Paroxysmal Supraventricular Tachyarrhythmias After Operative Repair of a Secundum Type Septal Defect in Adults.** Robert O. Brandenburg, Jr., David R. Holmes, Jr., Robert O. Brandenburg, and Dwight C. McGoon

277 **Epicardial and Endocardial Activation in Patients With Endocardial Cushion Defect.** Robert M. Campbell, Macdonald Dick II, Paul Hees, and Douglas M. Behrendt

282 **Atypical Fallot's Tetralogy With Doubly Committed Subarterial Ventricular Septal Defect. Diagnostic Value of 2-Dimensional Echocardiography.** Horacio Capelli and Jane Somerville

286 **Supraventricular Tachycardia in Infants: Use of the "Diving Reflex."** Velio Sperandeo, Daniele Pieri, Pasquale Palazzolo, Mario Donzelli, and Giuseppe Spataro

288 **Impact of 2-Dimensional Echocardiography on the Management of Distressed Newborns in Whom Cardiac Disease Is Suspected.** Mary J. Rice, James B. Seward, Donald J. Hagler, Douglas D. Mair, Robert H. Feldt, Francisco J. Puga, Gordon K. Danielson, William D. Edwards, and Abdul J. Tajik

293 **Rest and Exercise Ventricular Function in Adults With Congenital Ventricular Septal Defects.** George Jablonsky, J. David Hilton, Peter P. Liu, John E. Morch, Maurice N. Druck, Ben-Zion Bar-Shlomo, and Peter R. McLaughlin, *With the technical assistance of* Kathy M. Winter

299 **Prognosis of Symptomatic Coarctation of the Aorta in Infancy.** Peter S. Hesslein, Howard P. Gutgesell, and Dan G. McNamara

304 **Instructions to Authors**

VALVULAR HEART DISEASE

305 **Equilibrium Radionuclide Gated Angiography in Patients With Tricuspid Regurgitation.** Bruce Handler, Dan G. Pavel, Raymond Pietras, Steven Swiryn, Ernest Byrom, Wilfred Lam, and Kenneth M. Rosen

311 **The Apex Impulse in Mitral Stenosis: Graphic Explanation of the Palpable Movements at the Cardiac Apex.** Jon Floyd, Park W. Willis IV, and Ernest Craige

315 **Coronary Vascular Reserve in Left Ventricular Hypertrophy Secondary to Chronic Aortic Regurgitation.** Augusto D. Pichard, Harry Smith, James Holt, Jose Meller, and Richard Gorlin

321 **Regurgitation of Prosthetic Heart Valves: Dependence on Heart Rate and Cardiac Output.** Kevin C. Dellsperger, David W. Wieting, Debra A. Baehr, Robert J. Bard, Jean-Pierre Brugger, and Earl C. Harrision

MISCELLANEOUS TOPICS

329 **Noninvasive Detection of Active Pericardial Bleeding Using Cardiac Blood Pool Scintigraphy.** Timothy M. Bateman, Rashid Massumi, Richard J. Gray, Aurelio Chaux, Michele A. DeRobertis, David E. Brown, Jack M. Matloff, and Daniel S. Berman

332 **Assessment of the Cardiac Effects of Hemodialysis With Systolic Time Intervals and Echocardiography.** Abraham Bornstein, William H. Gaasch, and John Harrington

336 **Normal Left Atrial Function Determined by 2-Dimensional Echocardiography.** Jack Gutman, Yin Shi Wang, Dennis Wahr, and Nelson B. Schiller

341 **Myocardial Function in Rocky Mountain Spotted Fever: Echocardiographic Assessment.** José Marin-Garcia and Fred F. Barrett

344 **Mechanisms for Decreased Exercise Capacity After Bed Rest in Normal Middle-Aged Men.** Joseph Hung, Danielle Goldwater, Victor A. Convertino, James H. McKillop, Michael L. Goris, and Robert F. DeBusk

349 **Cardiac Performance in Thyrotoxicosis: Analysis of 10 Untreated Patients.** Abdulmassih S. Iskandrian, Leslie Rose, A-Hamid Hakki, Bernard Segal, and Sally Kane

Index to Advertisers on page A36

CORONARY HEART DISEASE

353 **Effect of Coronary Artery Bypass Grafting on Subsequent Hospitalization.** William M. Hamilton, Karl E. Hammermeister, Timothy A. DeRouen, May S. Zia, and Harold T. Dodge

361 **Can Noninvasive Exercise Test Criteria Identify Patients With Left Main or 3-Vessel Coronary Disease After a First Myocardial Infarction?** Randolph E. Patterson, Steven F. Horowitz, Calvin Eng, Jose Meller, Stanley J. Goldsmith, Augusto D. Pichard, Doris A. Halgash, Michael V. Herman, and Richard Gorlin

373 **Papillary Muscle Rupture Complicating Acute Myocardial Infarction: Analysis of 17 Patients.** Rick A. Nishimura, Hartzell V. Schaff, Clarence Shub, Bernard J. Gersh, William D. Edwards, and Abdul J. Tajik

378 **Comparative Rates of Resolution of QRS Changes After Operative and Nonoperative Acute Myocardial Infarcts.** David E. Albert, Robert M. Califf, David A. LeCocq, Ray A. McKinnis, Raymond E. Ideker, and Galen S. Wagner

382 **Evaluation of a QRS Scoring System for Estimating Myocardial Infarct Size. III. Correlation With Quantitative Anatomic Findings for Inferior Infarcts.** Steven F. Roark, Raymond E. Ideker, Galen S. Wagner, Daniel R. Alonso, Sanford P. Bishop, Colin M. Bloor, Dean A. Bramlet, Jesse E. Edwards, John T. Fallon, Geoffrey J. Gottlieb, Donald B. Hackel, Harry R. Phillips, Keith A. Reimer, William J. Rogers, Wayne K. Ruth, Robert M. Savage, Richard D. White, and Ronald H. Selvester

390 **Segmental Right Ventricular Function After Acute Myocardial Infarction: Two-Dimensional Echocardiographic Study in 63 Patients.** Jose Lopez-Sendon, Miguel Angel Garcia-Fernandez, Isabel Coma-Canella, Mar Moreno Yangüela, and Fermin Bañuelos

397 **Variable Threshold Exertional Angina in Patients With Transient Vasospastic Myocardial Ischemia. Repeat Exercise Test Results and Therapeutic Implications.** Stefano de Servi, Giuseppe Specchia, Colomba Falcone, Antonello Gavazzi, Antonio Mussini, Luigi Angoli, Ezio Bramucci, Diego Ardissino, Laura Vaccari, Jorge Salerno, and Piero Bobba

403 **Cardiovascular Disease in the Very Elderly. Analysis of 40 Necropsy Patients Aged 90 Years or Over.** Bruce F. Waller and William C. Roberts

422 **Hemodynamic Effects of a New Antiarrhythmic Agent, Flecainide (R-818), in Coronary Heart Disease.** Victor Legrand, Michel Vandormael, Pierre Collignon, and Henri E. Kulbertus

427 **Pindolol and Propanolol in Patients With Angina Pectoris and Normal or Near-Normal Ventricular Function. Lack of Influence of Intrinsic Sympathomimetric Activity on Global and Segmental Left Ventricular Function Assessed by Radionuclide Ventriculography.** Dante E. Manyari, William J. Kostruk, S. George Carruthers, Donald J. Johnston, and Paul Purves

434 **Determination of the Angiographic Appearance of Coronary Vessels: The Importance of Supplying and Recipient Arteries.** Harvey L. Goldberg, Jonathan Goldstein, Jeffrey S. Borer, Michael B. Collins, Jeffrey W. Moses, and George Ellis, *With the technical assistance of* Richard Quiroz

440 **Identification of Septal Ischemia During Exercise by Q-Wave Analysis: Correlation With Coronary Angiography.** Michael A. Famularo, Yogesh Paliwal, Robert Redd, and Myrvin H. Ellestad

444 **Surgery for Coronary Heart Disease Due to Mucocutaneous Lymph Node Syndrome (Kawasaki Disease). Report of 6 Patients.** Soichiro Kitamura, Kanji Kawachi, Ryoichi Harima, Tetsuo Sakakibara, Hajime Hirose, and Yasunaru Kawashima

449 **The Changing "Natural History" of Symptomatic Coronary Artery Disease: Basis Versus Bias.** Lee Goldman, Gilbert H. Mudge, Jr., and E. Francis Cook

CONGESTIVE HEART FAILURE

455 **Intermittent, Continuous Outpatient Dobutamine Infusion in the Management of Congestive Heart Failure.** Mark M. Applefeld, Kathryn A. Newman, William R. Grove, Frederick J. Sutton, David S. Roffman, William P. Reed, and Steven E. Linberg

SYSTEMIC HYPERTENSION

459 **R-Wave Amplitude Change During Aerobic Exercise in Hypertensive Adolescents After Treatment.** Bonita Falkner, David T. Lowenthal, Melton B. Affrime, and Barbara Hamstra

464 **Increased Plasma Concentrations of Prostacyclin in Metabolite 6-Keto-$PGF_{1\alpha}$ in Essential Hypertension. Influence of Therapy With Labetalol.** Louis Roy, Jawahar Mehta, and Paulette Mehta, *With the technical assistance of* Nancy Ostrowski, Christine Horalek, and Georgia Kelley

468 **Analysis of Ventricular Emptying and Filling Indexes During Acute Increases in Arterial Pressure.** Robert A. Slutsky, G. B. John Mancini, Kenneth H. Gerber, Howard C. Dittrich, and Charles B. Higgins

VALVULAR HEART DISEASE

476 **Serial Changes in Left Ventricular Function After Correction of Chronic Aortic Regurgitation. Dependence on Early Changes in Preload and Subsequent Regression of Hypertrophy.** John D. Carroll, William H. Gaasch, Michael Zile, and Herbert J. Levine

483 **Radionuclide Ventriculographic Study of Adaptations to Exercise in Aortic Regurgitation.** Richard M. Steingart, Corine Yee, Lawrence Weinstein, and James Scheuer

489 **Indexes of Intravascular Hemolysis, Quantification of Coagulation Factors, and Platelet Survival in Patients With Porcine Heterograft Valves.** Mark E. Thompson, Jessica H. Lewis, Frederick L. Porkolab, Ute Hasiba, and Joel A. Spero, *With the technical assistance of* John Wilson and Michael Snyder

492 **Rheumatic Tricuspid Valve Disease: Two-Dimensional Echocardiographic, Hemodynamic, and Angiographic Correlations.** Steven J. Daniels, Gary S. Mintz, and Morris N. Kotler

497 **Calcium Phosphorus Metabolism in Dialysis Patients With and Without Mitral Anular Calcium. Analysis of 30 Patients.** Pasquale F. Nestico, Nicholas L. DePace, Morris N. Kotler, Leslie I. Rose, Joseph H. Brezin, Charles Swartz, Gary S. Mintz, and Allan B. Schwartz

MYOCARDIAL HEART DISEASE

501 **Quantitative Morphologic Findings of the Myocardium in Idiopathic Dilated Cardiomyopathy.** Franz Schwarz, Gerhard Mall, Horst Zebe, Johannes Blickle, Harald Derks, Joachim Manthey, and Wolfgang Kübler

507 **Significance of Ventricular Tachycardia in Idiopathic Dilated Cardiomyopathy: Observations in 35 Patients.** Shoei K. Huang, Joseph V. Messer, and Pablo Denes

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

513 **Transesophageal Pacing for Prognostic Evaluation of Preexcitation Syndrome and Assessment of Protective Therapy.** Giuseppe Critelli, Gino Grassi, Francesco Perticone, Fernando Coltorti, Vittorio Monda, and Mario Condorelli

519 **Electrophysiologic Studies Before and After Myocardial Revascularization in Patients With Life-Threatening Ventricular Arrhythmias.** Hasan Garan, Jeremy N. Ruskin, John P. DiMarco, Wayne M. Derkac, Cary W. Akins, Willard M. Daggett, W. Gerald Austen, and Mortimer J. Buckley

525 **Electrophysiologic Mechanism of Exercise-Induced Sustained Ventricular Tachycardia.** Ruey J. Sung, Edward N. Shen, Fred Morady, Melvin M. Scheinman, David Hess, and Elias H. Botvinick

531 **Programmed Electrical Stimulation of the Heart in Coronary Artery Disease.** Peter R. Kowey, Edward D. Folland, Alfred F. Parisi, and Bernard Lown

CONGENITAL HEART DISEASE

537 **Juxtaductal Aortic Coarctation. Analysis of 84 Patients Studied Hemodynamically, Angiographically, and Morphologically After Age 1 Year.** D. Luke Glancy, Andrew G. Morrow, Allan L. Simon, and William C. Roberts

552 **Hemodynamics and Intracardiac Conduction After Operative Repair of Tetralogy of Fallot.** Dolores Tamer, Grace S. Wolff, Pedro Ferrer, Arthur S. Pickoff, Alfonso Casta, Ashok V. Mehta, Otto Garcia, and Arthur Gelband

557 **Terminal Cardiac Electrical Activity in Pediatric Patients.** Christine Kull Walsh and Ehud Krongrad

562 **Percutaneous Transluminal Angioplasty of Congenital Coarctation of the Aorta.** Donald R. Sperling, Thomas J. Dorsey, Marshall Rowen, and Alan B. Gazzaniga

MISCELLANEOUS TOPICS

565 **Subepicardial Adipose Tissue Producing Echocardiographic Appearance of Pericardial Effusion. Documentation by Computed Tomography and Necropsy.** Jeffrey M. Isner, Barbara L. Carter, William C. Roberts, and Mark S. Bankoff

570 **Exercise-Induced Cardiac Dysfunction in Sickle Cell Anemia. A Radionuclide Study.** Wesley Covitz, Casimir Eubig, Ian C. Balfour, Rajinder Jerath, Bruce S. Alpert, William B. Strong, and Robert H. DuRant, *With the technical assistance of* Bonnie G. Hadden

METHODS

576 **Variability of Digitized Echocardiography: Size, Source, and Means of Reduction.** Charles Pollick, Peter J. Fitzgerald, and Richard L. Popp

583 **Left Ventricular Isovolumic Pressure Decay and Diastolic Mechanics After Postextrasystolic Potentiation and During Exercise.** John D. Carroll, René Widmer, Otto M. Hess, Heinz O. Hirzel, and Hans P. Krayenbuehl

EXPERIMENTAL STUDIES

591 **Comparison of the Antithrombotic Action of Calcium Antagonist Drugs With Dipyridamole in Dogs.** Charles W. Pumphey, Valentin Fuster, Mrinal K. Dewanjee, James H. Chesebro, Ronald E. Vlietstra, and Michael P. Kaye, *With the technical assistance of* John Ritter and James Rosemark

596 **Influence of Intracoronary Platelet Aggregation on Ventricular Electrical Properties During Partial Coronary Artery Stenosis.** Peter R. Kowey, Richard L. Verrier, Bernard Lown, and Robert I. Handin

EDITORIAL

603 **Congestive Heart Failure: A Propitious Time for Intensified Research.** Eugene Braunwald, Michael M. Mock, and John T. Watson

POINT OF VIEW

606 **A More Meaningful Scoring System for Determining the Severity of Coronary Heart Disease.** Goffredo G. Gensini

607 **Pericardial Windows Are Suboptimal.** David H. Spodick

608 **Instructions to Authors**

BRIEF REPORTS

609 **Ventricular Flutter During Treatment With Amiodarone.** Guanggeng Cui, Weimin Huang, and Ferdinand Urthaler

610 **Myocardial Ischemia in Anomalous Origin of the Right Coronary Artery From the Pulmonary Trunk. Proof of a Coronary Steal.** Gary S. Mintz, Abdulmassih S. Iskandrian, Charles E. Bemis, Eldred D. Mundth, and John S. Owens

612 **Blood Cyst of the Papillary Muscle. Clinical, Echocardiographic, and Anatomic Observations.** Andrew M. Hauser, Kamalsingh Rathod, Janet McGill, Barbara F. Rosenberg, Seymour Gordon, and Gerald C. Timmis

613 **Transmural Ischemia During Preexercise Hyperventilation.** Bernard H. Lisker and Sanford E. Leff

615 **Two-Dimensional Echocardiographic Detection of Right Atrial Thrombi.** Bruno V. Manno, Ioannis P. Panidis, Morris N. Kotler, Gary S. Mintz, and John Ross

Index to Advertisers on page A147

PROCEEDINGS OF A SYMPOSIUM: INITIAL THERAPY IN HYPERTENSION

Norman M. Kaplan, Guest Editor

619 **Introduction.** Norman M. Kaplan

621 **New Approaches to the Therapy of Mild Hypertension.** Norman M. Kaplan

628 **Effect of Antihypertensive Agents on Lipid Metabolism.** Ralph Cutler

632 **Negative Effects of Diuretic Drugs on Metabolic Risk Factors for Coronary Heart Disease: Possible Alternative Drug Therapies.** Richard P. Ames

639 **New Developments in Alpha-Adrenergic Receptor Pharmacology: Implications for the Initial Treatment of Hypertension.** Wilson S. Colucci

644 **Effectiveness of Prazosin as Initial Antihypertensive Therapy.** Ronald Okun

651 **Treating the Patient With Mild Hypertension and Renal Insufficiency.** J. Caulie Gunnells, Jr.

657 **Roundtable Discussion**

CORONARY HEART DISEASE

661 **Influence of Partial Sympathetic Denervation on the Results of Myocardial Revascularization in Variant Angina.** Amadeo Betriu, Jose Luis Pomar, Martial G. Bourassa, and Claude M. Grondin

668 **Digital Angiography in Assessment of Ventricular Function and Wall Motion During Pacing in Patients With Coronary Artery Disease.** Jonathan Tobis, Orhan Nalcioglu, Warren D. Johnston, Anthony Seibert, Lloyd T. Iseri, Werner Roeck, and Walter L. Henry

676 **Angiographic Changes Produced by Percutaneous Transluminal Coronary Angioplasty.** David R. Holmes, Jr., Ronald E. Vlietstra, Michael B. Mock, Guy S. Reeder, Hugh C. Smith, Alfred A. Bove, John F. Bresnahan, Jeffrey M. Piehler, Hartzell V. Schaff, and Thomas A. Orszulak

684 **Ergonovine Provocation to Assess Efficacy of Long-Term Therapy With Calcium Antagonists in Prinzmetal's Variant Angina.** Michael D. Winniford, Stacey M. Johnson, David R. Mauritson, and L. David Hillis

689 **Frequency in Nonangioplasty Patients of Morphologic Findings Reported in Coronary Arteries Treated with Transluminal Angioplasty.** Jeffrey M. Isner and Roberta V. Fortin

694 **Intravenous Nitroglycerin for the Treatment of Angina at Rest Unresponsive to Standard Nitrate Therapy.** Kerry Kaplan, Richard Davison, Michele Parker, Jean Przybylek, J. Russell Teagarden, and Michael Lesch

699 **Effects of Verapamil on Coronary Hemodynamic Function and Vasomobility Relative to Its Mechanism of Antianginal Action.** Christopher Y. C. Chew, B. Gregory Brown, Bramah N. Singh, Maylene M. Wong, Cindy Pierce, and Robert Petersen

706 **Nifedipine in Chronic Stable Angina: A Double-Blind Placebo-Controlled Crossover Trial.** Lon G. Sherman and Chang-Seng Liang

712 **Effect of Intravenous and Intracoronary Nifedipine on Coronary Blood Flow and Myocardial Oxygen Consumption.** Peter Schanzenbächer, Gerhart Liebau, Peter Deeg, and Kurt Kochsiek

718 **Electrocardiographic Criteria for the Diagnosis of Combined Inferior Myocardial Infarction and Left Anterior Hemiblock.** Robert A. Warner, Norma E. Hill, Sakti Mookherjee, and Harold Smulyan

723 **Improved Electrocardiographic Criteria for the Diagnosis of Left Anterior Hemiblock.** Robert A. Warner, Norma E. Hill, Sakti Mookherjee, and Harold Smulyan

727 **Effects of Provocation on Transcardiac Thromboxane in Patients With Coronary Artery Disease.** Paul D. Hirsh, Brian G. Firth, William B. Campbell, Gregory J. Dehmer, James T. Willerson, and L. David Hillis

734 **Precordial S-T Segment Depression in Inferior Myocardial Infarction. Evaluation by Quantitative Thallium-201 Scintigraphy and Technetium-99m Ventriculography.** Lawrence Ong, Benilda Valdellon, James Coromilas, Robert Brody, Peter Reiser, and John Morrison

741 **Radionuclide-Determined Changes in Pulmonary Blood Volume and Thallium Lung Uptake in Patients With Coronary Artery Disease.** Richard A. Wilson, Robert D. Okada, Charles A. Boucher, H. William Strauss, and Gerald M. Pohost

749 **Sinus Node Coronary Arteries Studied With Angiography.** Michael K. Kyriakidis, Costas B. Kourouklis, John T. Papaioannou, Stamatis G. Christakos, George P. Spanos, and Dimitris G. Avgoustakis

751 **Beneficial Effects of Ibuprofen in Pacing-Induced Myocardial Ischemia.** Paul Walinsky, J. Bryan Smith, Allan M. Lefer, and Leslie Wiener

755 **Improved Exercise Ventilatory Responses After Training in Coronary Heart Disease During Long-Term Beta-Adrenergic Blockade.** Neil F. Gordon, Pieter E. Krüger, and Jones F. Cilliers

ARRHYTHMIAS AND CONDUCTION DISTURBANCES •

759 **Disopyramide: Evaluation of Electrophysiologic Effects and Clinical Efficacy in Patients With Sustained Ventricular Tachycardia or Ventricular Fibrillation.** Bruce B. Lerman, Harvey L. Waxman, Alfred E. Buxton, and Mark E. Josephson

765 **Effects of Oral Digoxin on Ventricular Ectopy and Its Relation to Left Ventricular Function.** Alan H. Gradman, Moira Cunningham, Mary A. Harbison, Harvey J. Berger, and Barry L. Zaret

770 **Cardiac Electrophysiologic Effects of Flecainide Acetate for Paroxysmal Reentrant Junctional Tachycardias.** Kevin J. Hellestrand, Anthony W. Nathan, Rodney S. Bexton, Roworth A. J. Spurrell, and A. John Camm

777 **Cardiac Effects of Treatment With Quinidine and Digoxin, Alone and in Combination.** Karin Schenck-Gustafsson, Tomas Jogestrand, Lars-Åke Brodin, Rolf Nordlander, and Rune Dahlqvist

SYSTEMIC HYPERTENSION

783 **Immediate Hemodynamic Effect of a New Calcium-Channel Blocking Agent (Nitrendipine) in Essential Hypertension.** Hector O. Ventura, Franz H. Messerli, Willie Oigman, Francis G. Dunn, Efrain Reisin, and Edward D. Frohlich

787 **Predictability of Blood Pressure Response to Isometric Stress.** Robert H. Chaney and Stephan Arndt

CONGESTIVE HEART FAILURE

791 **Clonidine in Congestive Heart Failure: A Vasodilator With Negative Inotropic Effects.** James B. Hermiller, Raymond D. Magorien, Mark E. Leithe, Donald V. Unverferth, and Carl V. Leier

CARDIOVASCULAR PHARMACOLOGY

796 **In Vivo Quantitation of Platelet Deposition on Human Peripheral Arterial Bypass Grafts Using Indium-111–Labeled Platelets. Effect of Dipyridamole and Aspirin.** Charles W. Pumphrey, James H. Chesebro, Mrinal K. Dewanjee, Heinz W. Wahner, Larry H. Hollier, Peter C. Pairolero, and Valentin Fuster

802 **Cardiovascular Effects of a Newly Synthesized Cardiotonic Agent (TA-064) on Normal and Diseased Hearts.** Masaya Kino, Yuzo Hirota, Shoji Yamamoto, Kenichi Sawada, Masatomo Moriguchi, Masahiro Kotaka, Shinichiro Kubo, and Keishiro Kawamura

CARDIOMYOPATHY

811 **Vulnerability of Patients With Obstructive Hypertrophic Cardiomyopathy to Ventricular Arrhythmia Induction in the Operating Room. Analysis of 17 Patients.** Kelley P. Anderson, Edward B. Stinson, Geraldine C. Derby, Philip E. Oyer, and Jay W. Mason

817 **Myocardial Texture Characterization by Two-Dimensional Echocardiography.** Anil K. Bhandari and Navin C. Nanda

826 **Sensitivity of Technetium-99m–Pyrophosphate Scintigraphy in Diagnosing Cardiac Amyloidosis.** Rodney H. Falk, Victor W. Lee, Alan Rubinow, William B. Hood, Jr., and Alan S. Cohen

831 **Survival in Men With Severe Chronic Left Ventricular Failure Due to Either Coronary Heart Disease or Idiopathic Dilated Cardiomyopathy.** Joseph A. Franciosa, Mary Wilen, Susan Ziesche, and Jay N. Cohn

METHODS

837 **Evaluation of Left Ventricular Performance Using Digital Subtraction Angiography.** Marvin W. Kronenberg, Ronald R. Price, Clyde W. Smith, Rose Marie Robertson, James M. Perry, David R. Pickens, Michael J. Domanski, C. Leon Partain, and Gottlieb C. Friesinger

843 **Evaluation of Intracardiac Thrombus With Computed Tomography.** Haruo Tomoda, Mitsumoto Hoshiai, Hideo Furuya, Sachio Kuribayashi, Makoto Ootaki, Seiya Matsuyama, Shirosaku Koide, Shiaki Kawada, and Akira Shotsu

853 **Absolute Left Ventricular Volume From Gated Blood Pool Imaging With Use of Esophageal Transmission Measurement.** Alan H. Maurer, Jeffry A. Siegel, Barry S. Denenberg, Blase A. Carabello, Arnold K. Gash, James F. Spann, and Leon S. Malmud

859 **Effect of Exercise Protocol on the Left Ventricular Response to Exercise.** Carl Foster, Duncan S. Dymond, James D. Anholm, Michael L. Pollock, and Donald H. Schmidt, *With the technical assistance of* John G. Carpenter

EXPERIMENTAL STUDIES

865 **Influence of Aortic Stenosis on the Hemodynamic Importance of Coronary Artery Narrowing in Dogs Without Left Ventricular Hypertrophy.** Robert L. Feldman, Wilmer W. Nichols, James R. Edgerton, C. Richard Conti, and Carl J. Pepine

872 **Topographic Changes in the Left Ventricle After Experimentally Induced Myocardial Infarction in the Rat.** Charles S. Roberts, Derek Maclean, Eugene Braunwald, Peter R. Maroko, and Robert A. Kloner

877 **Scar Thinning Due to Ibuprofen Administration After Experimental Myocardial Infarction.** Edward J. Brown, Jr., Robert A. Kloner, Frederick J. Schoen, Haim Hammerman, Sharon Hale, and Eugene Braunwald

884 **Effects of Flurbiprofen in Altering the Size of Myocardial Infarcts in Dogs: Reduction or Delay?** David E. Chambers, Derek M. Yellon, David J. Hearse, and James M. Downey

891 **Effects of Reduced Coronary Flow on Thallium-201 Accumulation and Release in an In Vitro Rat Heart Preparation.** Samuel Z. Goldhaber, John B. Newell, Joanne S. Ingwall, Gerald M. Pohost, Nathaniel M. Alpert, and Eric T. Fossel

BRIEF REPORTS

897 **Supraventricular Nonreentrant Tachycardia Due to Simultaneous Conduction Through Dual Atrioventricular Nodal Pathways.** Frederick J. Sutton and Yu-Chen Lee

900 **Survival After Sudden Obstruction of the Left Main Coronary Artery.** Moshe Y. Flugelman, Meir Shalit, Arie Shefer, Yonathan Hasin, and Mervyn S. Gotsman

901 **Hyperkalemia and Cardiac Arrest from Fluoride Exposure During Hemodialysis.** Michael McIvor, Romulo F. Baltazar, Juan Beltran, Morton M. Mower, Robert Wenk, Jack Lustgarten, and Joseph Salomon

902 **Coronary Arterial Rupture During Coronary Angioplasty.** Jeffrey E. Saffitz, Thomas E. Rose, John B. Oaks, and William C. Roberts

904 **Q-T Prolongation and Torsades de Pointes Ventricular Tachycardia Produced by the Tetracyclic Antidepressant Agent Maprotiline.** Howard C. Herrmann, Lee M. Kaplan, and Barbara E. Bierer

906 **Angiographic Evidence of Hemorrhagic Myocardial Infarction After Intracoronary Thrombolysis With Streptokinase.** William C. Little and Edwin W. Rogers

908 **Real-Time 2-Dimensional Echocardiographic Visualization of Thrombus on a Björk-Shiley Mitral Valve Prosthesis. Emergency Cesarean Section and Mitral Valve Replacement in Late Pregnancy.** Basil S. Lewis, Nearchos E. Agathangelou, Luis A. Dos Santos, and Manuel J. Antunes

909 **Cardiac Rhabdomyosarcoma Presenting as Hypereosinophilic Syndrome.** Martin J. Sullivan, Gregory P. Wanger, Steven A. Schonfeld, and Thomas M. Bashore

POINT OF VIEW

911 **How Should We Describe Hearts in Which the Aorta Is Connected to the Right Ventricle and the Pulmonary Trunk to the Left Ventricle? A Matter for Reason and Logic.** Anton E. Becker and Robert H. Anderson

CONTENTS IN BRIEF

CORONARY HEART DISEASE

1243 **Effects of Discontinuing Maintenance Digoxin Therapy in Patients With Ischemic Heart Disease and Congestive Heart Failure in Sinus Rhythm.** Mihai Gheorghiade and George A. Beller

1251 **Efficacy and Safety of Verapamil in Patients With Angina Pectoris After 1 Year of Continuous, High-Dose Therapy.** Donald A. Weiner, Carolyn H. McCabe, Sally S. Cutler, Mark A. Creager, Thomas J. Ryan, and Michael D. Klein

1256 **Enhanced Detection of Proximal Right Coronary Artery Stenosis With the Additional Analysis of Right Ventricular Thallium-201 Uptake in Stress Scintigrams.** Jack Gutman, Michael Brachman, Alan Rozanski, Jamshid Maddahi, Alan Waxman, and Daniel S. Berman

1261 **Prognostic and Predictive Value of Exertional Hypotension in Suspected Coronary Heart Disease.** K. E. Hammermeister, Timothy A. DeRouen, Harold T. Dodge, and May Zia

1267 **Effects of a Cardioselective Beta$_1$ Partial Agonist (Corwin) on Left Ventricular Function and Myocardial Metabolism in Patients With Previous Myocardial Infarction.** Michel F. Rousseau, Hubert Pouleur, and Marie-Françoise Vincent

1275 **Relation of Segmental Wall Motion to Global Left Ventricular Function in Acute Myocardial Infarction.** Fumitaka Ohsuzu, Charles A. Boucher, John B. Newell, Tsunehiro Yasuda, Herman K. Gold, Robert C. Leinbach, Kenneth A. McKusick, Robert D. Okada, Simon Rosenthal, Gerald M. Pohost, and H. William Strauss

1282 **Effect of Metoprolol on Indirect Signs of the Size and Severity of Acute Myocardial Infarction.** Johan Herlitz, Dag Elmfeldt, Åke Hjalmarson, Stig Holmberg, Ivan Malek, Gunnar Nyberg, Lars Rydén, Karl Swedberg, Anders Vedin, Finn Waagstein, Anders Waldenström, Johan Waldenström, Hans Wedel, Lars Wilhelmsen, and Claes Wilhelmsson

1289 **Role of Myocardial Ischemia in the Genesis of Stress-Induced S-T Segment Elevation in Previous Anterior Myocardial Infarction.** Henry Gewirtz, Michael Sullivan, George O'Reilly, Steven Winter, and Albert A. Most

1294 **Enzymatic Estimation of Myocardial Infarct Size When Early Creatine Kinase Values Are Not Available.** Janet L. Smith, Dieter Ambos, Herman K. Gold, James E. Muller, W. Kenneth Poole, Daniel S. Raabe, Robert E. Rude, Eugene Passamani, Eugene Braunwald, Burton E. Sobel, Robert Roberts, and the MILIS Group

1301 **Serial Exercise Testing Up to 6 Years After Coronary Bypass Surgery: Behavior of Exercise Parameters in Groups With Different Degrees of Revascularization Determined by Postoperative Angiography.** Helmut Gohlke, Christa Gohlke-Bärwolf, Ladislaus Samek, Peter Stürzenofecker, Martin Schmuziger, and Helmut Roskamm

1307 **Cardiokymography During Exercise Testing: A New Device For the Detection of Coronary Artery Disease and Left Ventricular Wall Motion Abnormalities.** Donald A. Weiner, Carolyn H. McCabe, Gina Dagostino, Sally S. Cutler, and Thomas J. Ryan

1312 **Rest and Redistribution Thallium-201 Myocardial Scintigraphy to Predict Improvement in Left Ventricular Function After Coronary Arterial Bypass Grafting.** Abdulmassih S. Iskandrian, A-Hamid Hakki, Sally A. Kane, Inder P. Goel, Eldred D. Mundth, A-Hadi Hakki, and Bernard L. Segal, *With the technical assistance of* Angelo Amenta

SYSTEMIC HYPERTENSION

1317 **Long-Term Converting-Enzyme Inhibition as a Guide to Surgical Curability of Hypertension Associated With Renovascular Disease.** Jan Staessen, Christopher Bulpitt, Robert Fagard, Paul Lijnen, and Antoon Amery

1323 **Nifedipine Tablets for Systemic Hypertension: A Study Using Continuous Ambulatory Intraarterial Recording.** Robert S. Hornung, Brian A. Gould, Roderick I. Jones, Tansukh N. Sonecha, and Edward B. Raftery

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

1329 **Relation Between Site of Origin of Ventricular Tachycardia and Relative Left Ventricular Myocardial Perfusion and Wall Motion.** Thomas M. McFarland, David M. McCarthy, P. Todd Makler, Jr., and Mark E. Josephson

1334 **Ultrarapid Single-Capture Train Stimulation for Termination of Ventricular Tachycardia.** John D. Fisher, Eliot Ostrow, Soo Gyum Kim, and Jeffrey A. Matos

CONGESTIVE HEART FAILURE

1339 **Hemodynamic and Myocardial Performance Characteristics After Verapamil Use in Congestive Heart Failure.** Jack Ferlinz and P. Dennis Citron

1346 **Efficacy of Prazosin in the Management of Chronic Congestive Heart Failure: A 6-Month Randomized, Double-Blind, Placebo-Controlled Study.** Roy V. Markham, James R. Corbett, Alyce Gilmore, William A. Pettinger, and Brian G. Firth

1353 **Acute Hemodynamic Effects of Endralazine: A New Vasodilator for Chronic Refractory Congestive Heart Failure.** Arshed A. Quyyumi, Donald Wagstaff, and Thomas R. Evans

1358 **Exercise Intolerance in Patients With Chronic Left Heart Failure: Relation to Oxygen Transport and Ventilatory Abnormalities.** John R. Wilson and Nancy Ferraro

1364 **Hemodynamic Effects of Dibutyryl Cyclic AMP in Congestive Heart Failure.** Shinobu Matsui, Eiji Murakami, Noboru Takekoshi, Jiro Emoto, and Munetoshi Matoba

THERAPY

1369 **Pharmacokinetic and Pharmacodynamic Effects of Diltiazem.** Mark S. Smith, Chacko P, Verghese, David G. Shand, and Edward L. C. Pritchett

VALVULAR HEART DISEASE

1375 **Prevalence of Submitral (Anular) Calcium and Its Correlates in a General Population-Based Sample (The Framingham Study).** Daniel Savage, Robert J. Garrison, William P. Castelli, Patricia M. McNamara, Sandra J. Anderson, William B. Kannel, and Manning Feinleib

1379 **Left Ventricular Volume and Ejection Fraction Response to Exercise in Aortic Regurgitation.** Lynne L. Johnson, Eric R. Powers, Wesley R. Tzall, Janet Feder, Robert R. Sciacca, and Paul J. Cannon

CARDIOMYOPATHY

1386 **Atrial Systole and Left Ventricular Filling in Hypertrophic Cardiomyopathy: Effect of Verapamil.** Robert O. Bonow, Terri M. Frederick, Stephen L. Bacharach, Michael V. Green, Pamela W. Goose, Barry J. Maron, and Douglas R. Rosing

1392 **Regression of Myocardial Cellular Hypertrophy With Vasodilator Therapy in Chronic Congestive Heart Failure Associated With Idiopathic Dilated Cardiomyopathy.** Donald V. Unverferth, John P. Mehegan, Raymond D. Magorien, Barbara J. Unverferth, and Carl V. Leier

METHODS

1399 **Comparison of Digital Intravenous Ventriculography With Direct Left Ventriculography for Quantitation of Left Ventricular Volumes and Ejection Fractions.** Sharon L. Norris, Robert A. Slutsky, G. B. John Mancini, William L. Ashburn, Gabriel Gregoratos, Kirk L. Peterson, and Charles B. Higgins, *With the technical assistance of* Ellen Einsidler and Wesley Dillon

1404 **Regional Distribution of Pulmonary Blood Volume: An Index of Pulmonary Capillary Wedge Pressure Determined From Blood Pool Scintigraphy.** Timothy M. Bateman, Richard J. Gray, Lawrence S. C. Czer, Ronald L. Levy, Morgan E. Stewart, Michele A. DeRobertis, David E. Brown, Jack M. Matloff, H. J. C. Swan, and Daniel S. Berman

EXPERIMENTAL STUDIES

1409 **Sustained Limitation of Myocardial Necrosis 24 Hours After Coronary Artery Occlusion: Verapamil Infusion in Dogs With Small Myocardial Infarcts.** Derek M. Yellon, David J. Hearse, Miles P. Maxwell, David E. Chambers, and James M. Downey

1414 **Diastolic Synchronized Retroperfusion Versus Reperfusion: Effects on Regional Left Ventricular Function and Myocardial Blood Flow During Acute Coronary Occlusion in Dogs.** Jean C. Farcot, Alain Berdeaux, Jean F. Giudicelli, Jean P. Vilaine, and Jean P. Bourdarias

1422 **Effects of Ortho-Iodo Sodium Benzoate on Acute Myocardial Ischemia, Hemodynamic Function, and Infarct Size After Coronary Occlusion in Dogs.** Robert E. Rude, John Tumas, Marcel Gunst, Robert A. Kloner, Laurence W. V. DeBoer, and Peter R. Maroko

1428 **Relation of Immediate and Delayed Thallium-201 Distribution to Localization of Iodine-125 Antimyosin Antibody in Acute Experimental Myocardial Infarction.** Ban An Khaw, William Strauss, Gerald M. Pohost, John T. Fallon, Hugo A. Katus, and Edgar Haber

1433 **Nature of "Residual Fast Channel" Dependent Action Potentials and Slow Conduction in Guinea Pig Ventricular Muscle and Its Modification by Isoproterenol.** Makoto Arita, Tatsuto Kiyosue, Masahiro Aomine, and Sunao Imanishi

1441 **Vessel Wall Arachidonate Metabolism After Angioplasty: Possible Mediators of Postangioplasty Vasospasm.** Andrew Cragg, Stanley Einzig, Wilfrido Castaneda-Zuniga, Kurt Amplatz, James G. White, and Gundu H. R. Rao

1446 **Cryosurgery of the Fetal Ductus Artieriosus.** Page A. W. Anderson, Frederic B. Askin, and Marcos J. Pupkin

1451 **Coronary Constriction by Leukotriene C_4, D_4, and E_4 in the Intact Pig Heart.** David Ezra, Lillie Boyd, Giora Feuerstein, and Robert E. Goldstein

CardioCare.

Providing answers to the complex issues of dual-chamber follow-up.

Dual-chamber pacemakers have contributed to the restoration of more normal lifestyles for thousands of cardiac patients. But, they are inherently complicated devices. Each manufacturer offers different design, programming, method and logic. So completing proper follow-up analysis requires an understanding of each brand's unique characteristics. If you're like most physicians, dual-chamber pacemaker therapy represents only a small fraction of your overall practice. Yet, accurate, timely and reliable follow-up is an important priority. What's the answer? **CardioCare.**

Experience you can depend on.
With over half a million telephone follow-up tests completed and another 200,000 scheduled this year, CardioCare understands pacemaker follow-up. Over 3,000 physicians rely on us to be their silent partner for dependable telephone follow-up. The reason? We do it full-time, on all makes and models of pacemakers—and it's the only thing we do. **CardioCare.**

Personal service you control...24 hours a day.
CardioCare respects the personal relationship you've developed with your patient. The follow-up service and frequency are prescribed by you. Our job is to maintain the personal touch with the patients you prescribe for telephone testing and provide as much information as possible to assist you in follow-up. We do it with 24-hour, 365-day-a-year service. And when unexpected complications occur, you're alerted immediately. Thus, you'll be able to respond quickly to the personal needs of your follow-up patients. **CardioCare.**

Service that meets your expectations.
There can be no compromises in dual-chamber follow-up. Not only do we *schedule and call* the patient for testing, we review every ECG thoroughly, chart the data and immediately

send you the results for analysis. Or, we'll provide full ECG interpretation by our certified cardiologists. You make the decision regarding the level of CardioCare™ service you want for your practice or clinic.

CardioCare.

Decide for yourself at our expense.

Making the decision to use a professional telephone monitoring service, like CardioCare, to supplement your pacemaker follow-up is an important consideration. It requires careful analysis of your specific needs. We would like to offer you our consulting service at no charge to help you analyze your practice. We'll send one of our service specialists to thoroughly analyze your telephone follow-up clinic costs and procedures. Then we'll offer a comparative evaluation, with specific recommendations—all in a written report. Why not call CardioCare at 1-800-223-0500 and ask for Maureen Cullen and arrange a no-cost clinic analysis?

CardioCare just may be the answer to dual-chamber pacemaker follow-up for you. It's a question of whether you should devote your valuable time to telephone follow-up issues, or to areas where your attention and expertise simply can't be matched.

CardioCare™

Service you can trust.

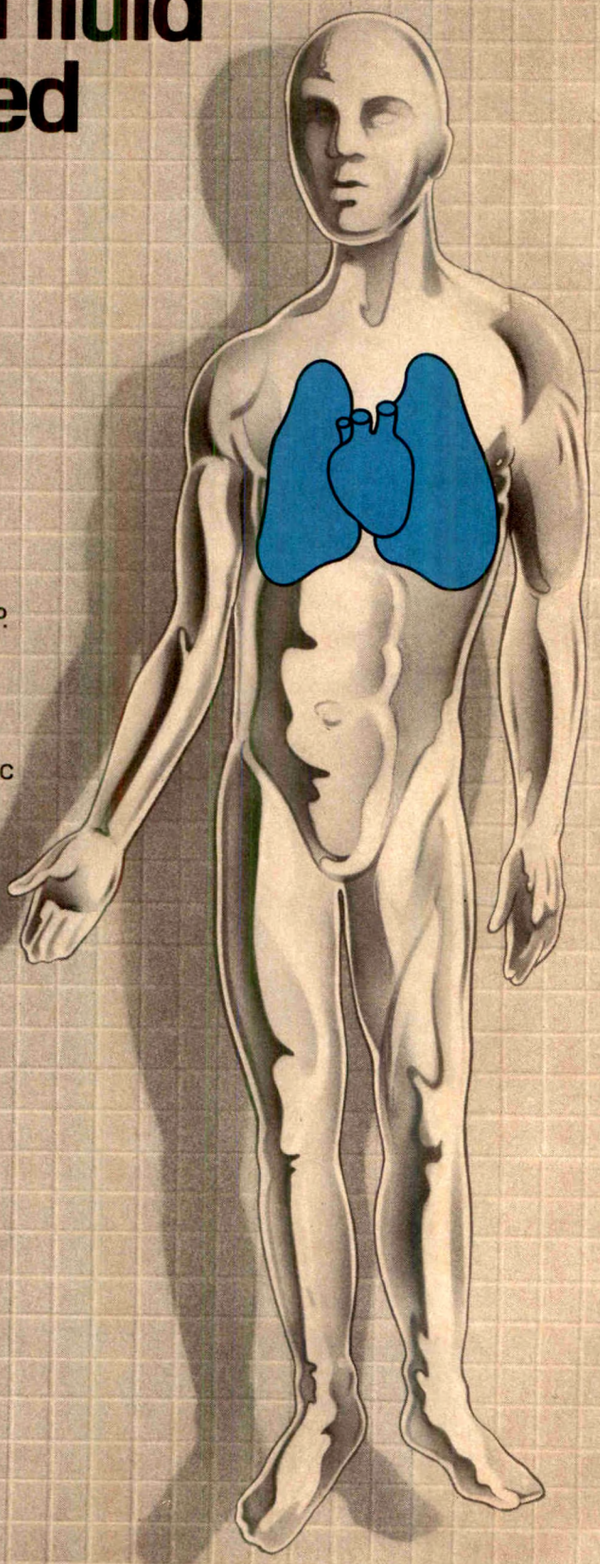
Therapeutic challenge:

Redistribution of fluid in CHF associated with acute MI



In Early CHF[1]

Pulmonary congestion with increased preload.

Findings: Elevated preload, elevated blood pressure, normal or slightly decreased cardiac output, PCWP greater than or equal to 18 mm Hg.

Therapeutic goal:
Reduce pulmonary congestion, lower PCWP to 15 to 18 mm Hg.

In Late CHF[1]

Pulmonary congestion with increased preload and afterload.

Findings: Low cardiac output, depressed blood pressure, and high PCWP.

Therapeutic goal:
Reduce pulmonary congestion, preload, and afterload, increase cardiac output, and lower PCWP to 15 to 18 mm Hg.

Why wait for the patient to become unresponsive to traditional diuretic/digitalis therapy?

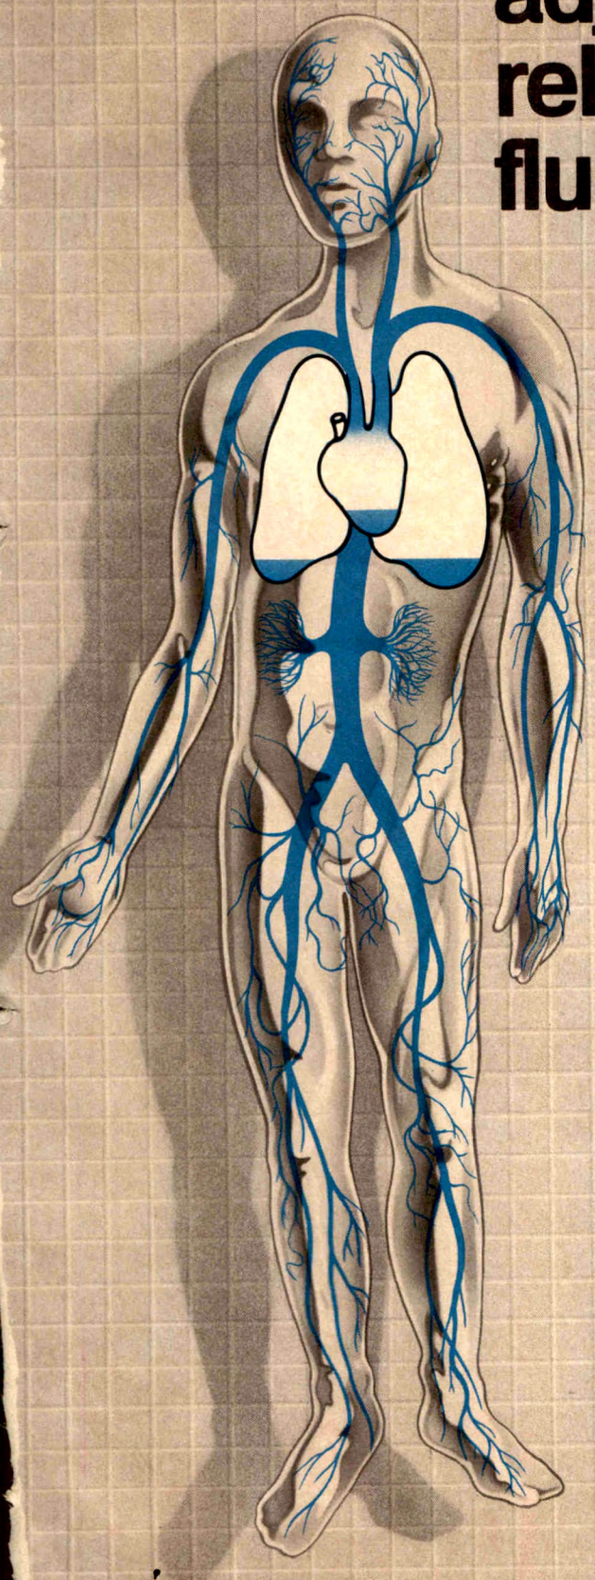
Division of American Hospital Supply Corporation

Give Tridil® (nitroglycerin) adjunctively to help relieve the fluid-burdened heart



In a dose-related manner, Tridil produces dilation of both arterial and venous beds—for a therapeutic redistribution of fluid.

Suggested therapy in early CHF

If blood pressure is normal:
Tridil to reduce preload and PCWP. Diuretics to decrease fluid volume.

If blood pressure is elevated:
Tridil should be initiated immediately to decrease preload, PCWP, and blood pressure, while maintaining coronary perfusion.

Suggested therapy in late CHF

If blood pressure is normal or only moderately depressed:
Vasopressors and Tridil adjunctively, with continuous hemodynamic monitoring.

If blood pressure is significantly depressed:
Vasopressors and Tridil adjunctively to reduce preload, afterload, and PCWP. Dopamine to increase the contractility of the myocardium. PCWP should be monitored.

Use of nonabsorbing Tridilset®

Sorptive loss of Tridil may range up to 80% when infused through a conventional PVC administration set[2] To overcome this problem, administer Tridil through Tridilset administration set or Tridilset V.I.P.™ volumetric pump connector set.

The most frequent adverse reaction in patients treated with Tridil is headache. Please see the following page for a brief summary of prescribing information. Note: Tridil is a potent drug and must be diluted before infusion.

For additional information, contact the Medical Services Department, American Critical Care, division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 312/473-3000.

2. Baaske DM, et al: Administration set suitable for use with intravenous nitroglycerin. *Am J Hosp Pharm* 1982;39:121-122.

TRIDIL® (nitroglycerin) SYSTEM

American Critical Care

TRIDIL® (nitroglycerin)

Brief Summary of Full Prescribing Information

NOT FOR DIRECT INTRAVENOUS INJECTION. TRIDIL® MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION OF FULL PRESCRIBING INFORMATION). THE ADMINISTRATION SET USED FOR INFUSION WILL AFFECT THE AMOUNT OF TRIDIL DELIVERED TO THE PATIENT. (SEE WARNINGS, AND DOSAGE AND ADMINISTRATION SECTIONS.)

CAUTION

SEVERAL PREPARATIONS OF NITROGLYCERIN FOR INJECTION ARE AVAILABLE. THEY DIFFER IN CONCENTRATION AND/OR VOLUME PER VIAL. WHEN SWITCHING FROM ONE PRODUCT TO ANOTHER ATTENTION MUST BE PAID TO THE DILUTION AND DOSAGE AND ADMINISTRATION INSTRUCTIONS.

CONTRAINDICATIONS

TRIDIL should not be administered to individuals with:

1. A known hypersensitivity to nitroglycerin or a known idiosyncratic reaction to organic nitrates.
2. Hypotension or uncorrected hypovolemia, as the use of TRIDIL in such states could produce severe hypotension or shock.
3. Increased intracranial pressure (e.g., head trauma or cerebral hemorrhage).
4. Constrictive pericarditis and pericardial tamponade.

WARNINGS

1. Nitroglycerin readily migrates into many plastics. To avoid absorption of nitroglycerin into plastic parenteral solution containers, the dilution and storage of TRIDIL for intravenous infusion should be made only in *glass* parenteral solution bottles.
2. Some filters absorb nitroglycerin; they should be avoided.
3. Forty to 80% of the total amount of nitroglycerin in the final diluted solution for infusion is absorbed by the polyvinyl chloride (PVC) tubing of the intravenous administration sets currently in general use. The higher rates of absorption occur when flow rates are low, nitroglycerin concentrations are high, and the administration set is long. Although the rate of loss is highest during the early phase of infusion (when flow rates are lowest) the loss is neither constant nor self-limiting; consequently no simple calculation or correction can be performed to convert the theoretical infusion rate (based on the concentration of the infusion solution) to the actual delivery rate.

Because of this problem, American Critical Care has developed TRIDILSET® an administration set in which loss of TRIDIL is minimal (less than 1%). TRIDILSET (or a similar administration set) is recommended for infusions of TRIDIL.

DOSING INSTRUCTIONS MUST BE FOLLOWED WITH CARE. IT SHOULD BE NOTED THAT WHEN TRIDILSET IS USED, THE CALCULATED DOSE WILL BE DELIVERED TO THE PATIENT BECAUSE THE LOSS OF TRIDIL DUE TO ABSORPTION IN STANDARD PVC TUBING WILL BE KEPT TO A MINIMUM. NOTE THAT THE DOSAGES COMMONLY USED IN PUBLISHED STUDIES UTILIZED GENERAL-USE PVC ADMINISTRATION SETS AND RECOMMENDED DOSES BASED ON THIS EXPERIENCE ARE TOO HIGH WHEN TRIDILSET IS USED.

PRECAUTIONS

TRIDIL (nitroglycerin) should be used with caution in patients with severe liver or renal disease.

Excessive hypotension, especially for prolonged periods of time, must be avoided because of possible deleterious effects on the brain, heart, liver, and kidney from poor perfusion and the attendant risk of ischemia, thrombosis, and altered function of these organs. Paradoxical bradycardia and increased angina pectoris may accompany nitroglycerin-induced hypotension. Patients with normal or low pulmonary capillary wedge pressure are especially sensitive to the hypotensive effects of TRIDIL. If pulmonary capillary wedge pressure is being monitored, it will be noted that a fall in wedge pressure precedes the onset of arterial hypotension, and the pulmonary capillary wedge pressure is thus a useful guide to safe titration of the drug.

Carcinogenesis, mutagenesis, impairment of fertility

No long-term studies in animals were performed to evaluate carcinogenic potential of TRIDIL.

Pregnancy

Category C. Animal reproduction studies have not been conducted with TRIDIL. It is also not known whether TRIDIL can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. TRIDIL should be given to a pregnant woman only if clearly needed.

Nursing Mothers

It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TRIDIL is administered to a nursing woman.

Pediatric Use

The safety and effectiveness of TRIDIL in children have not been established.

ADVERSE REACTIONS

The most frequent adverse reaction in patients treated with TRIDIL is headache, which occurs in approximately 2% of patients. Other adverse reactions occurring in less than 1% of patients are the following: tachycardia, nausea, vomiting, apprehension, restlessness, muscle twitching, retrosternal discomfort, palpitations, dizziness and abdominal pain.

The following additional adverse reactions have been reported with the oral and/or topical use of nitroglycerin: cutaneous flushing, weakness, and occasionally drug rash or exfoliative dermatitis.

OVERDOSAGE

Accidental overdosage of TRIDIL may result in severe hypotension and reflex tachycardia which can be treated by elevating the legs and decreasing or temporarily terminating the infusion until the patient's condition stabilizes. Since the duration of the hemodynamic effects following TRIDIL administration is quite short, additional corrective measures are usually not required. However, if further therapy is indicated, administration of an intravenous alpha adrenergic agonist (e.g., methoxamine or phenylephrine) should be considered.

DOSAGE AND ADMINISTRATION

(For complete information, please see Full Prescribing Information)

NOT FOR DIRECT INTRAVENOUS INJECTION

TRIDIL IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION. TRIDIL SHOULD NOT BE ADMIXED WITH OTHER DRUGS.

Some patients with normal or low left ventricular filling pressures or pulmonary capillary wedge pressure (e.g., angina patients without other complications) may be hypersensitive to the effects of TRIDIL and may respond fully to doses as small as 5 mcg/min. These patients require especially careful titration and monitoring.

There is no fixed optimum dose of TRIDIL. Due to variations in the responsiveness of individual patients to the drug, each patient must be titrated to the desired level of hemodynamic function. Therefore, continuous monitoring of physiologic parameters (e.g., blood pressure and heart rate in all patients, other measurements such as pulmonary capillary wedge pressure, as appropriate), MUST BE PERFORMED to achieve the correct dose. Adequate systemic blood pressure and coronary perfusion pressure must be maintained.

HOW SUPPLIED

NDC 0094-0090-05, 25 mg-5 ml ampul. NDC 0094-0090-10, 50 mg-10 ml ampul. Each ml contains 5 mg nitroglycerin. Protect from freezing.

The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

Rheumatology

A Primary Care Approach

Written by:

Bruce M. Rothschild, MD

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8 $39.50
430 pp., illus., November 1982,

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation o the latest techniques in diagnosis and therapeutic intervention of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but commo disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and store away on a library shelf
- the primary care physicians' answer to the huge, weighty tome on Rheumatology which offer too little on diagnosis and treat ment and too much on etiology and mechanisms of disease

Table of contents

Section 1 - Investigative Techniques, Chapter 1 - Th Rheumatologic History and Physical Examination, Chapter 2 - Ar throcentesis and Joint Fluid Evaluation, Chapter 3 - Laborator Studies, Chapter 4 - Radiology of Joint Disease, **Section 2 - Pattern of Disease,** Chapter 5 - Infectious Agent Arthritis, Chapter 6 - Ar thritis of Mechanical Derivation, Chapter 7 - Crystalline Arthritis Chapter 8 - Rheumatoid Arthritis, Chapter 9 - Juvenile Rheumatoi Arthritis, Chapter 10 - Ankylosing Spondylitis, Chapter 11 Reiter's Syndrome and Psoriatic Arthritis, Chapter 12 - Arthriti Associated with Gastrointestinal Disease, Chapter 13 - Endocrine Metabolic, and Deposition Disease, Chapter 14 - Arthriti Associated with Hematologic Disease, Chapter 15 - Miscellaneou Causes of Arthritis, Chapter 16 - Nonarticular Rheumatism Chapter 17 - Systemic Lupus Erythematosus, Polymyositis, an Sjogren's Syndrome, Chapter 18 - Scleroderma, Chapter 19 - Vas culitis/Vasculopathy, **Section 3 - Management,** Chapter 20 - Ap proach to Diagnosis, Chapter 21 - Compliance and Quackery Chapter 22 - Salicylate Pharmacodynamics, Chapter 23 - Medica tion Therapy, Chapter 24 - Rehabilitation Therapy, Chapter 25 Surgical Intervention

To order your copy of this important new book, please use the order form below.

ORDER FORM

AJCF3

Please send me **Rheumatology: A Primary Care Approach** -$39.50, on 30 day approval.

☐ Enclosed is my check for $39.50 plus $1.50 for handling. Yorke pays postage (same return privilege). (New York residents add appropriate sales tax. Add $5.00 per book for orders outside the U.S. and Canada.)

☐ Please bill my ☐ VISA ☐ MasterCard
Card No. _____ MC Interbank No. _____
Exp. Date _____ Signature _____

☐ Please bill me plus postage and handling (U.S. and Canadian orders only.)

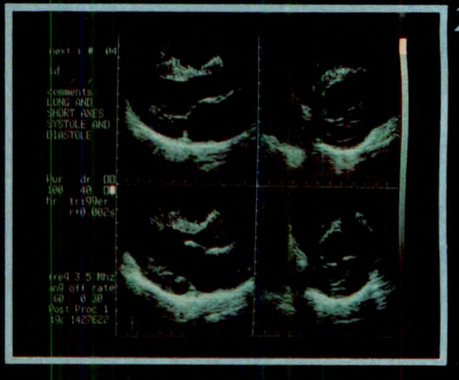
1. Dynex/C Probes: Out in Front

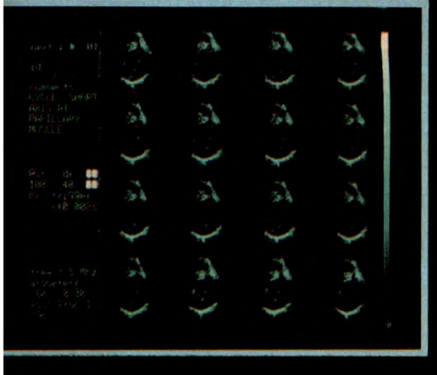
Dynex/C 3.5 and 5 MHz mechanical sector probes, feature four unique characteristics which put them far ahead of the field:

- □ Inherently fine spatial resolution due to computer controlled automatic line density optimization.
- □ An extremely wide, continuously variable 15-105° sector angle.
- □ Exceptionally fast frame rates: more than 70 frames per second, continuously variable.
- □ A continuously adjustable offset angle ranging from 0-45°.



2. Multiformatting: Comparison at a Glance

Dynex/C's ability to display four images simultaneously gives the cardiologist an incomparable diagnostic tool. He may compare four identical views taken over a period of time, or study four different images acquired during the same examination — for example, tomographic sections along the long and short axes, at end systole and end diastole.



3. CCRM™ — Cardiac Cycle Review Mode

The CCRM is an exclusive Dynex/C feature for viewing fast sequential 2-D cardiac events, or a complete heart cycle.

Cardiac scanning at an extremely fast frame rate stops at a pre-selected ECG point. The last 16 frames acquired are stored in memory, and may be reviewed separately or in closed-loop cine mode at a user-selected speed.

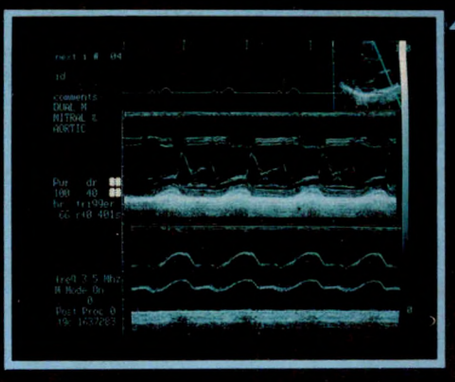
elscint

4. M-Mode Display Capabilities

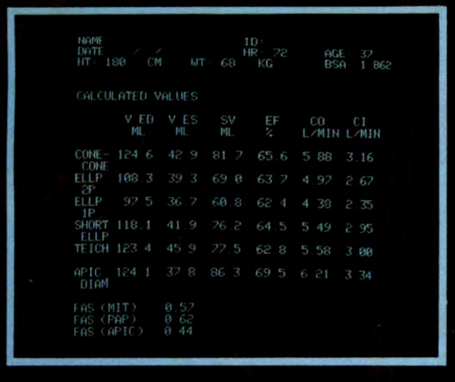
Dynex/C's M-mode has two features of truly exceptional value to the cardiologist:

1. Simultaneously with normal M-mode, Dynex/C displays a two-dimensional image with M-mode position precisely defined by a cursor.
2. *Dual M-mode:* simultaneous display of two M-modes from different cardiac regions, both synchronized with a user-selected ECG or PCG point.

4



5



5. Advanced Cardiac Data Calculations

Dynex/C's comprehensive software and powerful computer enable precise measurements and on-line calculations of many vital cardiac parameters. Frozen M-mode displays give aortic and mitral valve stroke volume and flow, pre-ejection/ejection time ratio, fractional IVS shortening, and over 30 other values.

Left ventricular volume is determined from 2-D images using *six* advanced calculation methods. Stroke volume, cardiac output, ejection fraction, cardiac index and more, are computed and displayed.

Dynex C: we speak from a position of strength.

The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decre excretion of quinidine
With coumarin anticoagulants	Reduction of clotting factor concentration
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
With digoxin	Increased plasma concentrations of dig (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases wh the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: T drug should be used with caution due to excretion of the quinidine in breast milk. AD REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headach disturbed vision) may appear in sensitive patients after a single dose of the drug. GAST TINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Wide complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (inclu tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypote TOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpu cytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, de syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision blurred vision, disturbed color perception, reduced vision field, photophobia, dig blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthm vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Information.
